Only one of the 22 hybrids, B6, produced an antibody which reacted with islets of Bouin's fixed pancreas. As shown in Fig. 1*b*, antibody B6, similarly to the anti-islet antibodies of patients with type I diabetes mellitus (Fig. 1*a*), reacts preferentially with islet cells of Bouin's fixed human type 0 pancreas. Preincubation of antibody B6 with insulin does not block its binding (Fig. 1*c*). Figure 1*d* is a fluorescein photomicrograph of a pancreas section incubated with antibody GM607, a negative control monoclonal IgM antibody (Fig. 2), as contrasted with the parental myeloma (IgG)[10]. We have subcloned the B6 hybrid cells by limiting dilution without feeder layers into microwells of 96-well Linbro plates. All six hybrid clones produced and secreted IgM ($\sim 0.4\ \mu g\ ml^{-1}$ of antibodies in spent culture supernatant) that reacted with islet cells in the same way as the parental B6 hybrid (Fig. 3). As all hybrid clones derived from B6 expressed anti-islet IgM, it is likely that hybrid B6 was itself a clone. The fact that all B6 clones were producing anti-islet IgM to the same extent (Fig. 3) and that B6 hybrids and its clones have maintained the production of the same amounts of anti-islet IgM after approximately 1 yr in tissue culture strongly suggest that such human–human hybridomas are quite stable. Fig. 1 Indirect immunofluorescence with Bouin's fixed human pancreas. Lymphocytes from 20 ml of heparinized blood from a child with type I diabetes were fused with the GM1500 6TG-2 human myeloma cell line using polyethylene glycol by methods previously described[10]. Supernatants from cultures were screened for antibodies reacting with the cell surface of a cloned rat insulinoma cell line using a ^{51}Cr-release assay[3], an ^{125}I-protein A radioassay[13] and fluorescein-coupled anti-antibodies in an indirect immunofluorescence assay. In addition, supernatants were incubated with 4-μm thick sections of Bouin's fixed human pancreas (type 0), and anti-islet antibodies were detected using fluorescein-coupled anti-human antibody (Miles). Supernatants from the GM607 (IgM) and the GM1500 (IgG) human myelomas were used as negative controls. Culture B6, which produces an anti-islet antibody, has been cloned by limiting dilution, and has stably produced antibody in culture for >1 yr. Antibody B6 is produced by cells grown in RPMI medium supplemented with 10% newborn calf serum, hypoxanthine (10^{-4} M) and thymidine (1.6×10^{-5} M). Antibody is collected from culture supernatants by adding an equal volume of saturated $(NH_4)_2SO_4$. The precipitate is resuspended in 1/20th its original volume of Dulbecco's phosphate-buffered saline (PBS) and then dialysed against PBS. Antibody B6 is then affinity-purified using rabbit anti-human antibody coupled to Sepharose. The antibody is eluted from this affinity column in 1-ml fractions with a glycine-HCl buffer (*p*H 2.28, 0.05 M glycine HCl, 0.15 M NaCl) neutralized with 20 μl of 1 M Tris and dialysed against PBS. *a*, Serum from a patient with type I diabetes; *b*, antibody B6; *c*, antibody B6 after incubation with insulin; *d*, control negative antibody GM607. ×188.

confirm that the cells producing antibody B6 are hybrid cells, the cell line B6 and the B6-derived positive clone 10-13, the patient's lymphocytes and the GM1500 parental cell line were HLA-typed by Dr Frances Ward (Duke University). As shown in Table 1, B6 and clone 10-13 cells contain the HLA antigens of both the myeloma-derived parent and the patient.

Anti-islet antibodies reacting with sectioned human pancreas are traditionally assayed using frozen sections of human pancreas[1] and only recently have Bouin's fixed sections been used to detect anti-islet antibodies[11]. We therefore studied the reaction of antibody B6 with frozen sections of human pancreas, both with and without acetone fixation (Fig. 4). Antibody B6 on frozen sections reacted only with cells that also stained with antibody to glucagon (A cells), whereas with Bouin's fixed sections, all islet cells reacted. Similar to results using anti-insulin antibody, double immunofluorescence with anti-somatostatin and anti-human pancreatic polypeptide antibodies showed no overlap of the cells reacting with antibody B6 (not shown).

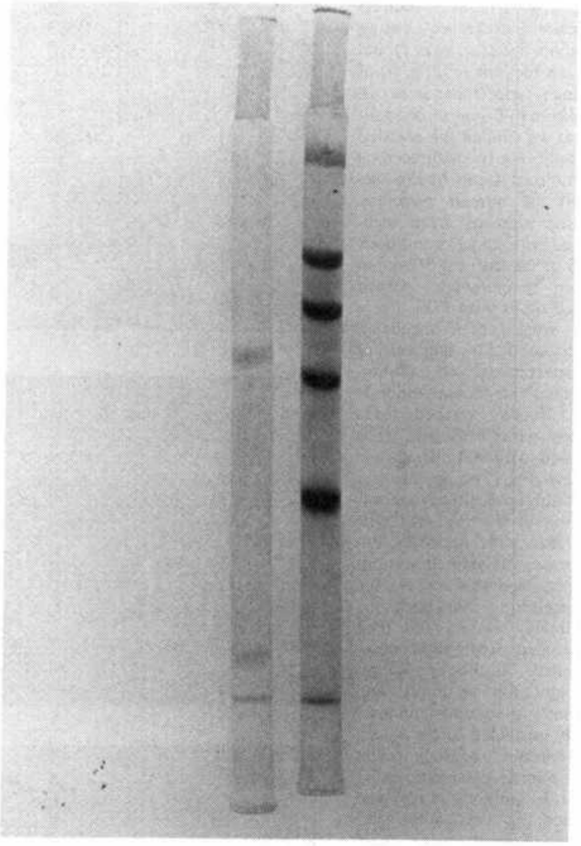

Fig. 2 10% Polyacrylamide gel run in reducing conditions with 10% SDS and stained with Coomassie blue (R250). Left gel, affinity-purified antibody B6; right gel, molecular weight standards (200,000; 116,250; 92,500; 66,200; 45,000). Heavy chain of antibody B6 has the molecular weight of an IgM heavy chain.

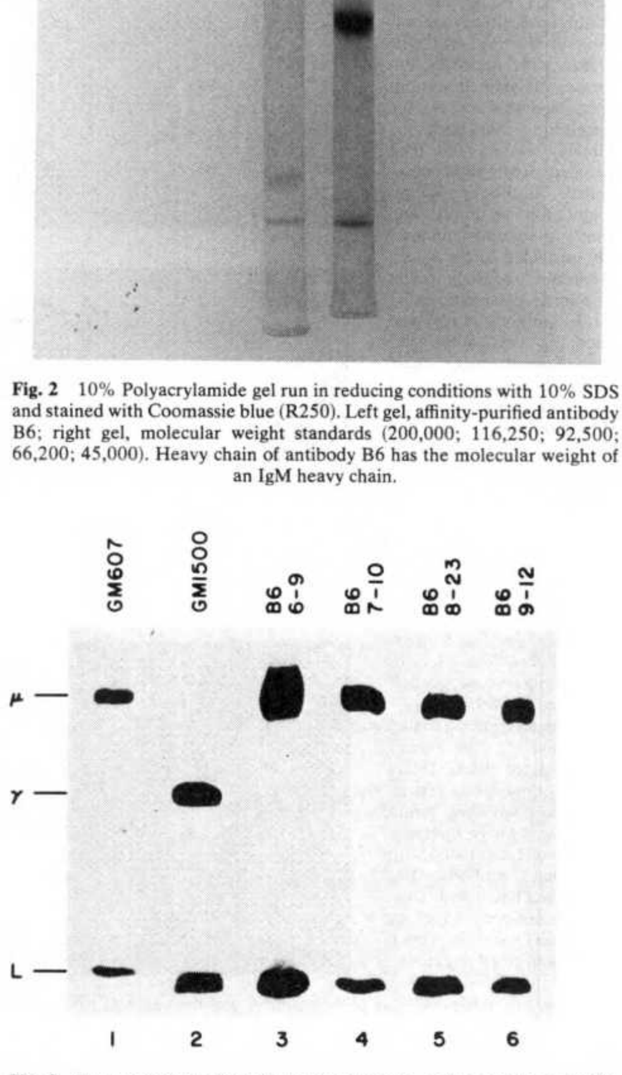

Fig. 3 Immunoprecipitation of immunoglobulin chains produced by B6 clones. The immunoprecipitation of the human immunoglobulin chains was carried out as described previously by using anti-human immunoglobulin rabbit antisera[10]. The human chains were separated by SDS-polyacrylamide gel electrophoresis[10]. Lane 1, human immunoglobulin chains secreted by GM607 human lymphoblastoid cells[10]; lane 2, human immunoglobulin chains secreted by the GM1500 human myeloma-derived parent; lanes 3–6, human immunoglobulin chains secreted by four clones of the B6 hybrid. Identical results were obtained with two additional clones and the parental B6 hybrid.

The technology for the production of murine and rat monoclonal antibodies is well developed, and such techniques have

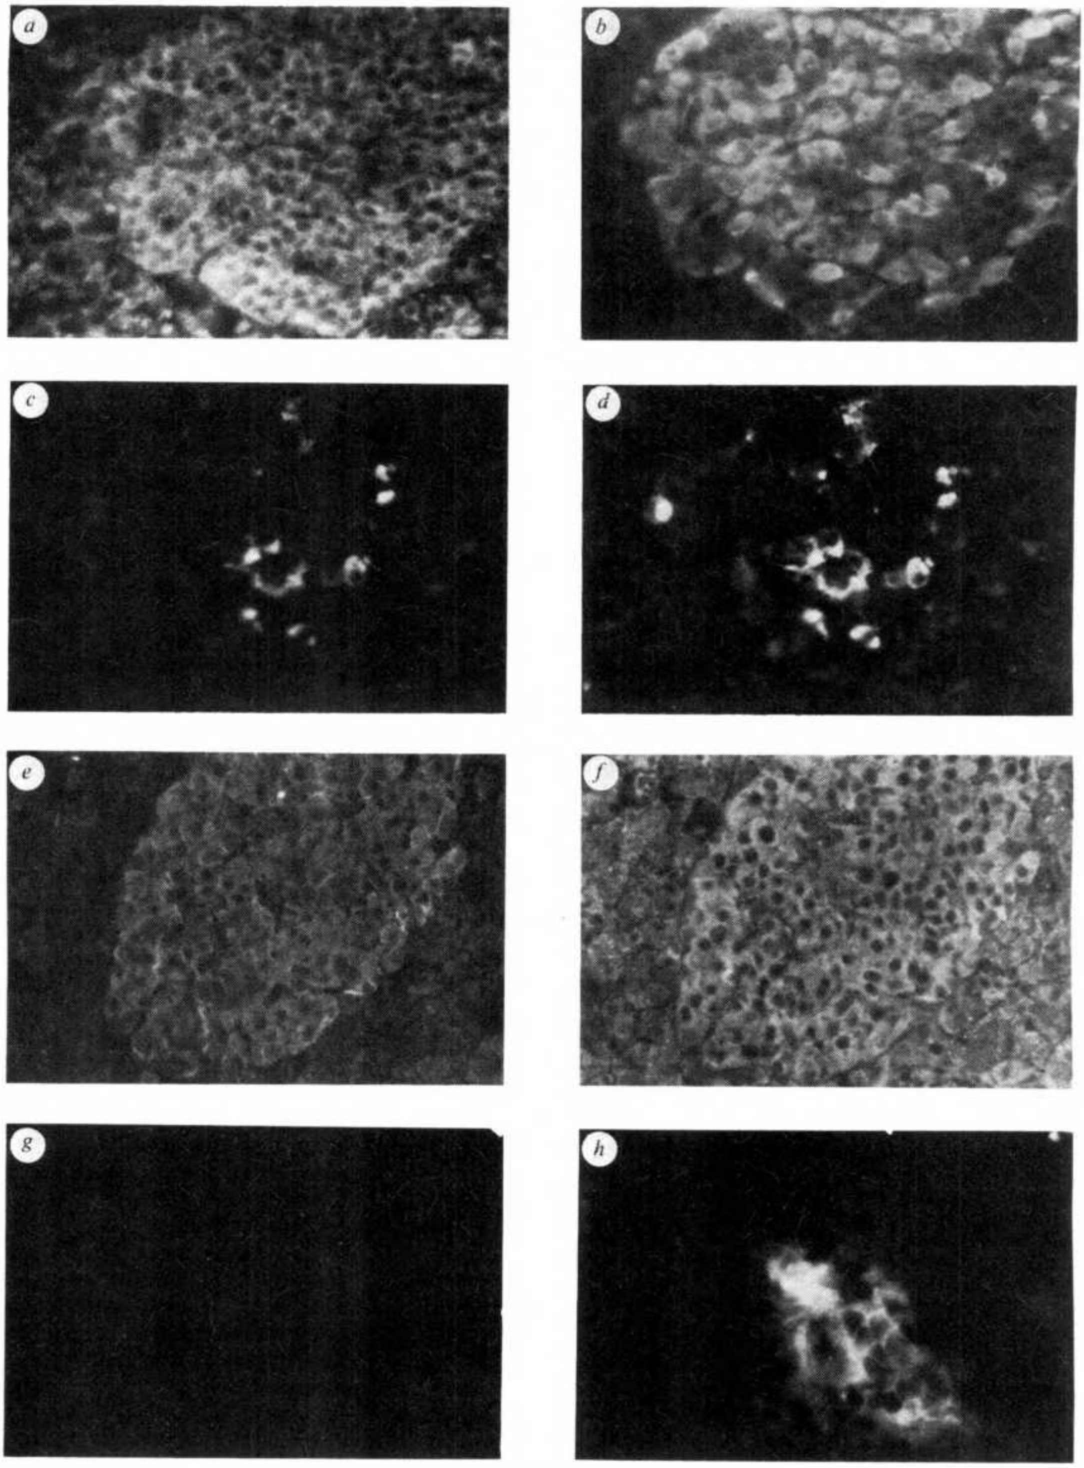

Fig. 4 Double indirect immunofluorescence using Bouin's fixed (*a*, *b*, *e*, *f*) and frozen sections (*c*, *d*, *g*, *h*) of human type 0 pancreas. In addition to Bouin's fixed pancreas we studied the reaction of antibody B6 with acetone or unfixed 4-μm frozen sections of human pancreas. Tissue sections were incubated with 25 μl of antibody (B6 or control) for 30 min at room temperature, washed three times with PBS (5 min per wash), then incubated with a 1:50 dilution of fluorescein-coupled affinity-purified anti-human antibody for 30 min, washed three times with PBS and then viewed with a Leitz diavert microscope equipped for epifluorescence. For determination of the islet cell type reacting with antibody B6, fluorescently stained sections were incubated with the appropriate anti-hormonal antibody, washed and then incubated with rhodamine-coupled antibody. Rabbit antiglucagon antibody and rabbit anti-somatostatin antibody (provided by M. Appel, Worchester, Mass.), rabbit anti-human pancreatic polypeptide antibody (Lilly) and guinea pig anti-insulin antibody (Cappel) were used. After a 30-min incubation at room temperature with the anti-hormonal antibody diluted 1:50 in PBS, 1% albumin, the sections were washed with PBS and incubated for an additional 30 min with a 1:50 dilution of appropriate anti-rabbit or anti-guinea pig rhodamine-labelled antisera. By sequentially viewing the section with the 'rhodamine' and 'fluorescein' fluorescent filters of our Leitz microscope, the cell type reacting with antibody B6 was determined. Human monoclonal antibodies [GM607 (IgM) and GM1500 (IgG)], normal rabbit serum, or normal guinea pig serum served as negative controls. Sections were incubated with monoclonal antibody B6, washed, incubated with antiglucagon antibody (*a*–*d*) or anti-insulin antibody (*e*–*h*), washed and then incubated with rhodamine-coupled anti-rabbit (*a*–*d*) or anti-guinea pig (*e*–*h*) antibody and then viewed with a Leitz microscope equipped for epifluorescence with either the fluorescein (*a*, *c*, *e*, *g* to detect B6 binding) or rhodamine filter (*b*, *d*, *f*, *h* to detect hormonal content). ×143.

been widely applied[12]. The production of human monoclonal antibodies by human–human 'hybridomas' has been more difficult. Ours is the first report of a human hybridoma producing a monoclonal autoantibody reacting with islet cells.

The pattern of reaction of antibody B6 with Bouin's fixed pancreas and frozen sections of pancreas is dramatically different. Bouin's fixation involves incubation of the pancreas with picric acid whereas frozen sections are simply air-dried or dipped in acetone before incubation with antibody B6. The qualitative difference in reaction pattern indicates that the method of pancreatic fixation can dramatically alter the interpretation of binding of even a single antibody. Such differences in reactivity indicate that the two techniques are not equivalent and may contribute to differences in clinical assays using the two methods.

Drs Bottazo and co-workers have described IgM antibodies in patients with type I diabetes and other individuals which bind to A cells on frozen sections[5]. Antibody B6 is an IgM monoclonal antibody which, on frozen sections, binds to A cells. As patients with type I diabetes express a series of anti-islet antibodies, the production of monoclonal antibodies with these specificities should now be feasible using the techniques which resulted in the generation of hybridoma B6. The ability to produce human monoclonal autoantibodies by simply fusing circulating lymphocytes provides a powerful tool for studying the autoimmune phenomenon of type I diabetes mellitus.

A monoclonal antibody that appears to recognize the receptor for human T-cell growth factor; partial characterization of the receptor

Warren J. Leonard, Joel M. Depper, Takashi Uchiyama, Kendall A. Smith*, Thomas A. Waldmann & Warner C. Greene

The Metabolism Branch, National Cancer Institute, NIH, Bethesda, Maryland 20205, USA and *Dartmouth Medical School, Hanover, New Hampshire 03226, USA

T-cell growth factor (TCGF or interleukin-2) is an inducible glycoprotein hormone of molecular weight 15,000 (ref. 1) synthesized and secreted by T lymphocytes following activation with antigen or mitogen[2,3]. TCGF is required for proliferation and expansion of T cells following antigen encounter[4,5] and to maintain them in long-term culture *in vitro*[6–9]. Full expression of the human immune response requires both the induction of TCGF synthesis and the formation of specific TCGF membrane receptors[10,11]. Monoclonal antibodies binding TCGF have been prepared[12,13]. In contrast, antibodies specific for the TCGF membrane receptor have not been identified, nor has the receptor been characterized. We have prepared a monoclonal antibody, termed anti-Tac[14,15], which appears to bind to the human membrane receptor for TCGF. In support of this, we now demonstrate that anti-Tac suppresses TCGF induced proliferation of T cells and blocks binding of radiolabelled TCGF to cells from a cloned human continuous T-cell line. Also we have partially purified and characterized the putative TCGF receptor. This receptor is a glycoprotein with a molecular weight (M_r) of 47,000–53,000.

Monoclonal anti-Tac was used in both ascites and Protein A–Sepharose purified[16] forms. Two human continuous T-cell (CTC) lines, CTC-2 and HUT–102B2, were used in these studies. CTC-2 is TCGF dependent and derived from the peripheral blood of a patient with a nonleukaemic cutaneous T-cell lymphoma. CTC-2 is a subclone of CTC-1 and has been in culture for more than 2 yrs. HUT–102B2 is a cloned CTC line established from a lymph node of the same patient[17]. In contrast to CTC-2, HUT–102B2 constitutively produces sufficient endogenous TCGF so that exogenous TCGF is not required. Cells from this clone express membrane TCGF receptors[18]. As recently reported by Poiesz and co-workers[19], HUT–102B2 cells contain and shed type C retrovirus. Cells from both CTC lines formed rosettes with sheep erythrocytes, reacted with OKT3 monoclonal antibody (a pan-T-cell-specific reagent)[20], and did not exhibit detectable surface immunoglobulin or Epstein–Barr nuclear antigen.

We initially looked at the effect of anti-Tac on TCGF-induced proliferation of CTC-2 cells. As shown in Fig. 1*a*, anti-Tac ascites markedly inhibited TCGF-induced ^{3}H-thymidine incorporation at final dilutions of 10^{-2}–10^{-4}, whereas equivalent concentrations of control ascites had no significant effect. Purified anti–Tac antibody also inhibited proliferation of CTC-2 cells, but purified monoclonal anti-Ia, though binding to these cells, had no effect (Fig. 1*b*). In agreement with these data, G. Bonnard and co-workers have independently demonstrated anti-Tac inhibition of TCGF induced proliferation of other human CTC lines (personal communication). In contrast, anti-Tac did not inhibit the growth of TCGF independent T-cell lines (CEM, HUT–78) or Epstein–Barr virus-transformed B-cell lines including a B-cell line derived from the same patient as the CTC lines.

All these experiments were performed in the absence of complement and anti-Tac did not produce cell death measured by short-term (4 h) ^{51}Cr -release assays or long-term (24–48 h) supravital dye exclusion[21] studies. In addition, the inhibitory effect of anti-Tac on proliferation of CTC-2 cells was reversible. CTC-2 cells precultured for 18 h with inhibitory concentrations of anti-Tac (10^{-3} dilution of ascites) incorporated thymidine in amounts equivalent to untreated cells following removal of cell-associated antibody by thorough washing and stimulation with TCGF.

We next investigated whether anti-Tac inhibited TCGF-induced proliferation by blocking the interaction of TCGF with its membrane receptor. ^{3}H-TCGF was prepared by phytohaemagglutinin induction of TCGF synthesis in a cloned human T leukaemia cell line (JURKAT)[22] in the presence of ^{3}H-lysine and ^{3}H-leucine. Radiolabelled TCGF produced in the absence of serum was purified by ultrafiltration and molecular sieve chromatography as previously described[10], and produced a single spot when evaluated by two-dimensional gel electrophoresis. As shown in Fig. 2, preincubation of HUT–102B2 cells with anti-Tac at concentrations greater than 3 μg ml^{-1} produced nearly complete blockade of purified ^{3}H-TCGF binding in experiments performed at 37 °C. In contrast, while binding to these cells, similar amounts of monoclonal anti-Ia did not alter ^{3}H-TCGF binding. The dose–response relationship

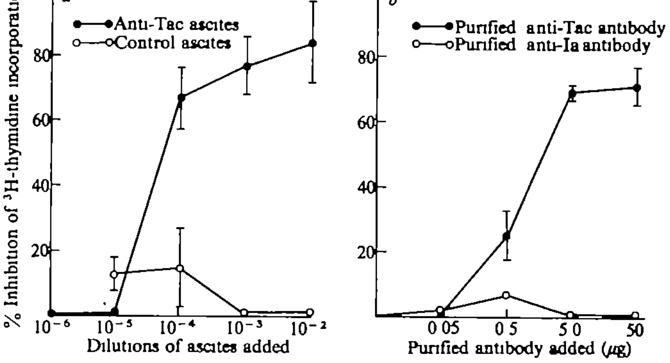

Fig. 1 Anti-Tac blocks TCGF induced proliferation of T cells from a human CTC line. CTC-2 cells were washed four times in a balanced salt solution and suspended at 0.5×10^6 cells per ml in RPMI 1640–10% heat-inactivated fetal calf serum. Aliquots (0.2 ml) of this cell suspension were distributed into wells of flat-bottom 96 well microtitre plates and preincubated with varying concentrations of antibodies for 30 min at room temperature. *a*, Data obtained with dilutions of heat-inactivated anti-Tac and control ascites (SPQC 11, from Dr M. Potter); *b*, data obtained with Protein A-Sepharose-purified anti-Tac and DEAE-purified monoclonal anti-Ia antibodies. Crude TCGF was subsequently added at a final concentration of 10% v/v. Triplicate cultures were incubated for 48 h at 37 °C in a humidified atmosphere containing 5% CO_2. Four hours before the end of culture, 1.0 μCi of ^{3}H-methyl-thymidine was added to each well followed by transfer of cells onto fibreglass filters with a multiple channel automated cell collector. Cell-associated radioactivity was measured by liquid scintillation. Data are expressed as % inhibition of the response obtained in cultures receiving TCGF alone (28,288±784 c.p.m.).

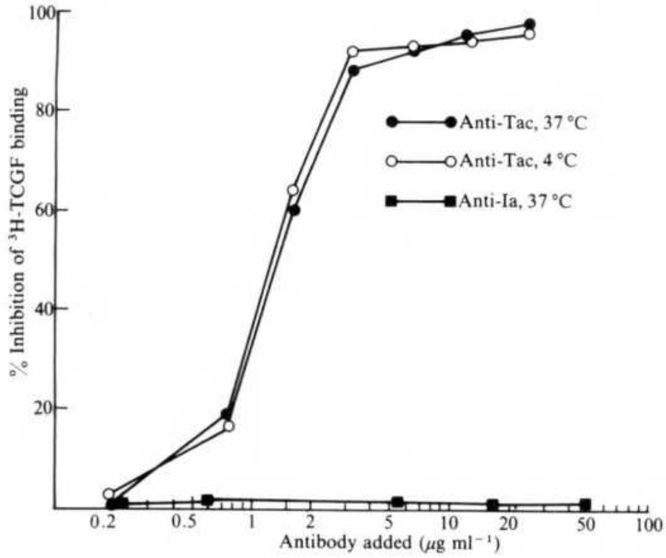

Fig. 2 Anti-Tac blocks the binding of ^{3}H-TCGF to HUT–102B2 cells. HUT–102B2 cells were washed three times in RPMI 1640 and resuspended at 1.1×10^7 cells per ml in RPMI 1640 containing 25 mM HEPES and 2 mg per ml bovine serum albumin. Cells and varying amounts of purified anti-Tac or anti-Ia antibodies were incubated together for 90 min at 37 or 4 °C in a rotating water bath. Following this preincubation, 50 pmol of purified ^{3}H-Leu, ^{3}H-Lys TCGF were added and the reaction was continued for an additional 20 min at 37 °C or 60 min at 4 °C. Cells were then pelleted, resuspended in 100 μl of RPMI 1640, and centrifuged (9,000*g* for 90 s) through cushions of 84% silicone and 16% paraffin oil to remove unbound ^{3}H-TCGF. Microfuge tube tips were excised, placed in liquid scintillation vials, and the cells solubilized by addition of 100 μl 1% SDS and 3 ml of liquid scintillation mixture followed by measurement of cell-associated radioactivity. Each experiment was performed in duplicate. Data shown are from two different experiments. A third experiment performed at 37 °C produced similar results.

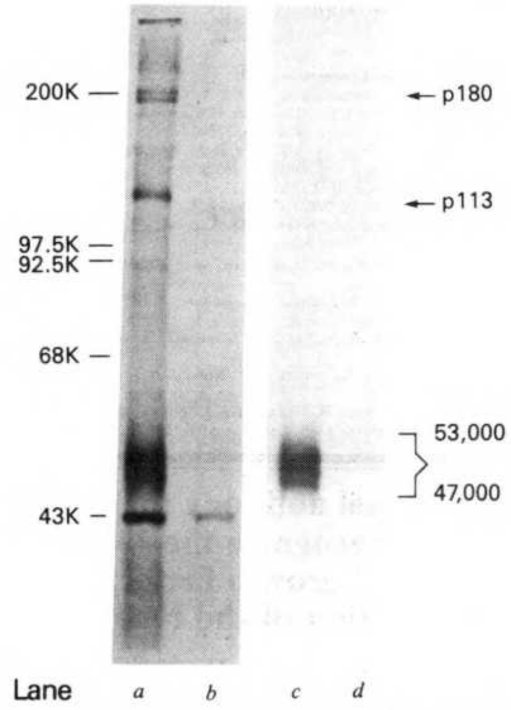

Fig. 3 Purification of the anti-Tac membrane receptor. Five million HUT–102B2 cells were washed twice in a balanced salt solution and suspended in 5 ml of methionine-free Selectamine medium (Gibco) containing 5% dialysed fetal calf serum. 0.3 mCi of NEN translation grade ^{35}S-methionine (>800 Ci mmol^{-1}) was added and the cells were cultured overnight at 37 °C. Cells were washed once and extracted in 0.14 M NaCl, 10 mM Tris *p*H 7.5, 1% Triton X-100, and 100 μg ml^{-1} phenylmethylsulphonyl fluoride (PMSF) for 30 min at 4 °C. The supernatant of a 60-min spin at maximum speed was then immunoprecipitated as follows. The supernatant was cleared once with 5 μl of control ascites (NS1, a non-secreting ascites provided by Dr Jay Berzofsky, NIH), 5 μl of RPC5 (a control IgG2a-k antibody, Litton Bionetics), and 50 μl of 10% w/v formaldehyde fixed Cowan I strain staphylococci and then once with 50 μl of the staphylococcal organisms alone. The supernatant was immunoprecipitated with 2–3 μg of protein A sepharose purified anti-Tac or UPC10 (a second control IgG2a-k antibody, Litton Bionetics) for 20 min at room temperature followed by a 20 min incubation with 20 μl of Cowan I strain staphylococci at room temperature. The immunoprecipitate was resuspended in a buffer containing 0.1% SDS, 0.5% NP40, 0.2% deoxycholate, 100 μg ml^{-1} PMSF and washed twice through the same buffer containing 1M sucrose. Final pellets were boiled in 1% SDS in the presence or absence of 0.1M dithiothreitol and analysed on 7.5% discontinuous SDS-polyacrylamide gels. Gels were intensified and fluorographed for 24 to 48 h at −195 °C. Analysis under reducing conditions is shown. *a* and *b* show the electrophoretic patterns obtained following immunoprecipitation of ^{35}S-methionine incorporated cells with anti-Tac and UPC10, respectively. The bands at 200,000 (200K) and 43,000 (43K) co-migrate with myosin and actin, respectively. Migration of molecular weight standards is shown on the left. The locations of p180, p113, and p50 are indicated on the right. *c* and *d* represent electrophoretic patterns obtained after immunoprecipitating surface-labelled cells with anti-Tac and UPC10, respectively. Approximately 5–10×10^6 cells were washed and suspended in 100 μl of a balanced salt solution and 1 mCi carrier-free ^{125}I was added. 4 μl lactoperoxidase solution (1U per 10 μl) and 7.5 μl H_2O_2 solution (0.03%) were then added and cells incubated for 4 min at room temperature. An additional 2 μl of lactoperoxidase solution and 7.5 μl H_2O_2 were added and cells incubated for an additional 4 min. Cells were then washed in a balanced salt solution and immunoprecipitated as described above.

for anti-Tac inhibition of TCGF-induced CTC proliferation and blockade of TCGF binding were similar in several experiments. As shown in Fig. 2, anti-Tac also inhibited ^{3}H-TCGF binding at 4 °C. These data argue that anti-Tac inhibition of TCGF binding is not simply secondary to receptor capping or co-capping with subsequent receptor endocytosis or shedding, because these rearrangements are largely inhibited at 4 °C (ref. 23).

Studies of ^{125}I-anti-Tac binding to HUT–102B2 cells at 20 °C revealed half saturation of available receptor sites within 3.75 min of anti-Tac addition. Next, ^{125}I-anti-Tac was incubated with HUT–102B2 cells at 4 °C in the presence of 0.1% sodium azide to block cap formation and energy-dependent endocytosis. After 1 h, steady-state binding was achieved. Excess unlabelled antibody was then added and reversible binding was demonstrated as 90% of the bound radiolabelled anti-Tac molecules were shown to dissociate. Glutaraldehyde fixed HUT–102B2 cells bound ^{125}I-anti-Tac in amounts slightly less than non-fixed cells. Preliminary Scatchard analysis[24] of anti-Tac binding with HUT–102B2 cells indicates ~100,000 high-affinity receptors per cell. This receptor number is 7- to 8-fold higher than the number of TCGF receptors reported by Robb *et al.*[10]. This difference may in part be accounted for by different experimental binding conditions and slightly different cell lines (our HUT–102B2 line is not 6-thioguanine resistant in contrast to that of Robb and co-workers). Anti-Tac had a K_d of $\sim 10^{-9}$ mol l^{-1} suggesting a much lower affinity than that reported for TCGF ($K_d \sim 10^{-12}$ mol l^{-1})[10]. Thus, the preincubation with anti-Tac before addition of ^{3}H-TCGF may have been critical to our ability to perform the successsful competitive binding experiment (Fig. 2).

Finally, we have partially purified and characterized the membrane receptor recognized by anti-Tac. SDS-polyacrylamide gel electrophoretic analysis of this receptor from HUT–102B2 cells is shown in Fig. 3. In both reducing (shown) and nonreducing (not shown) conditions, two major proteins with molecular weights of approximately 113,000 and 47,000–53,000 were precipitated by anti-Tac antibodies from cells internally labelled with ^{35}S-methionine (*a*). A third minor band with an M_r of approximately 180,000 was also identified. For convenience, we will denote these bands p113, p50, and p180, respectively. None of these bands was identified in immunoprecipitations using control UPC10 IgG2a-k antibodies (*b*). Further, similar bands have been found in immunoprecipitations performed on phytohaemagglutinin stimulated peripheral blood lymphocytes from a normal individual (data not shown), thereby providing evidence that none are related solely to viral products. To determine whether any of these proteins are located on the outer cell membrane, similar anti-Tac and UPC10 immunoprecipitations were performed using cells that were surface iodinated with the lactoperoxidase method (*c* and *d*). Only p50 was immunoprecipitated with anti-Tac. We therefore hypothesize that this protein represents the actual binding site for anti-Tac. This protein can be identified in immunoprecipitations from cells incorporated with ^{3}H-D-glucosamine (Fig. 4), thus demonstrating that it is a glycoprotein, as is usually the case for membrane receptors. The roles of p113 and p180 are unknown. One or both may be part of a theoretical receptor complex, and therefore coimmunoprecipitated because of strong hydrophobic interactions with p50. It is also possible that neither has any functional relation to the receptor identified by anti-Tac, but rather that they contain antigenic determinants that result in their recognition by anti-Tac.

In summary, we have prepared a monoclonal antibody which blocks the binding of purified ^{3}H-TCGF to human CTC cells and inhibits TCGF induced proliferation of CTC cells, and which we hypothesize binds to the TCGF receptor. The receptor recognized by the antibody is a glycoprotein of molecular weight ~47,000–53,000. In recent studies with human peripheral blood T cells, we have also found that anti-Tac inhibits (>80%) soluble or alloantigen induced T-cell proliferation as well as the generation of cytotoxic T cells in allogeneic cell cocultures. Further, anti-Tac suppresses immunoglobulin production in cultures of peripheral blood lymphocytes stimulated with pokeweed mitogen, a T-cell dependent polyclonal activator. Thus, anti-Tac may permit not only further characterization of the human TCGF receptor but in addition may allow analysis of the site(s) and mechanism of TCGF action in both the cellular and humoral phases of the human immune response.

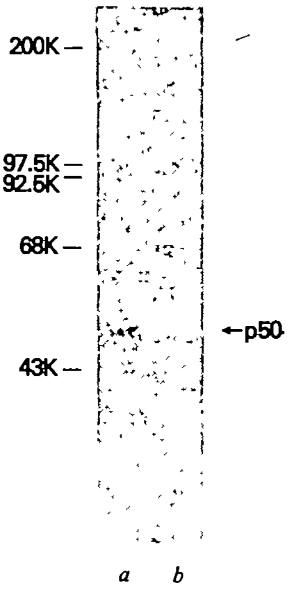

Fig. 4 The anti-Tac membrane receptor is a glycoprotein. 5×10^6 HUT-102B2 cells were washed once in a balanced salt solution and resuspended in RPMI media containing 5% fetal calf serum. Two hundred microcuries of D-[1,6-^{3}H(*N*)]-glucosamine HCl (NEN, 32.5 Ci mmol^{-1}) were then added and cells incubated for 4 h at 37 °C. Cells were washed once in balanced salt solution and then extracted with 0.14 M NaCl, 10 mM Tris-HCl *p*H 7.5, 1% Triton X-100, and 100 μg ml^{-1} PMSF for 30 min on ice. The extracts were then immunoprecipitated with anti-Tac (*a*) or UPC10 (lane *b*) as described in Fig. 3 legend, and then electrophoresed on 7.5% SDS gels and autoradiographed. Molecular weight markers are indicated on the left.

We thank Dr P. Knudson for the anti-Ia antibody and Ms Jeri Roth for technical assistance. J.M.D. is a recipient of a National Arthritis Foundation postdoctoral fellowship.

Luteinizing hormone release from dissociated pituitary cells by dimerization of occupied LHRH receptors

H. Gregory & C. L. Taylor

Studies of luteinizing hormone-releasing hormone (LHRH) have revealed several structural requirements for its biological activity[1]. Shortening of the decapeptide leads to loss of activity; positions 1, 6 and 10 are regarded as important in that they have a high affinity for the hormone receptor, and positions 2 and 3 (His-Trp) are thought to comprise the active centre of the molecule (replacement of His or Trp produces the most effective antagonists). Using a potent agonist analogue of the decapeptide, <Glu-His-Trp-Ser-Tyr-D-Lys-Leu-Arg-Pro-NHEt, coupled to ferritin, we have demonstrated previously the binding, aggregation and internalization of bound hormone using dissociated pituitary cells[2]. Similar processes occur for other biologically active peptides, for example, insulin[3] and epidermal growth factor (EGF)[4]. Using a pure antagonist in the simpler LHRH system we now show that the N-terminal portion of the molecule is important for receptor aggregation and that dimerization of occupied LHRH receptors is a necessary early stage in the release of luteinizing hormone.

The octapeptide, Z-Gln-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-NHEt, is an effective inhibitor of LHRH both *in vitro* and *in vivo*[5]. We prepared the 6-D-Lys analogue of this peptide to allow easy substitution at a central position in the molecule;

Table 1 Secretion of luteinizing hormone from porcine pituitary cells in culture

Peptide	Antiserum	LH released
LHRH (10^{-9} M)		185±24
LHRH (10^{-8} M)		300±34
Inhibitor (10^{-9} M)		29±5
Inhibitor (10^{-6} M)		49±5
LHRH (10^{-9} M) + inhibitor (10^{-6} M)		35±12
Inhibitor (10^{-8} M)	Rabbit anti-inhibitor (1:1,000 dilution)	215±36
Inhibitor (10^{-6} M)	Rabbit anti-inhibitor (1:1,000 dilution)	112±16
Inhibitor (10^{-8} M)	Rabbit anti-D-Lys agonist (1:1,000 dilution)	29±8
LHRH (10^{-8} M)	Rabbit anti-inhibitor (1:1,000 dilution)	361±51

Cells were incubated at 37 °C for 24 h after dissociation at 4×10^6 cells per 2.5-cm diameter Petri dish; before each experimental incubation they were washed three times in serum-free medium. The cells were then incubated in 1 ml medium for 30 min with additions as shown. Values are ng $\mathrm{ml^{-1}}$ ± s.e.m. luteinizing hormone.

this in turn would allow the formation of active macromolecular conjugates with the agonist[2]. The peptide was prepared from the protected heptapeptide described previously[2] (H-Trp-Ser-Tyr($\mathrm{Bu^t}$)-D-Lys(BOC)-Leu-Arg-Pro-NHEt). This was coupled, in dimethylformamide, with the activated derivative Z-Gln-OCP, and the product purified by chromatography on Sephadex LH-20 in methanol. The side chain protecting groups were removed with trifluoroacetic acid/water (9:1) and the peptide was isolated by chromatography on Sephadex G-50 in acetic acid/water (1:4). Analysis of an acid hydrolysate showed good amino acid ratios and the peptide was revealed as a single spot by high voltage electrophoresis at *p*H 2.1, 6.5 and 8.9 using ninhydrin, Ehrlich's and Sakaguchi visualization reagents and by TLC on silica gel plates in *n*-butanol/acetic acid/water (4:1:5).

The pure peptide was then coupled through the side chain of the central Lys residue to bovine serum albumin (BSA) using 1-ethyl-3(3-dimethylaminopropyl)carbodiimide. Antisera to the peptide were raised in rabbits by injection of conjugate (1.0 mg) in Freund's complete adjuvant subcutaneously (s.c.), followed by two booster injections of conjugate in saline at intervals of 4 weeks. The antisera were able to bind iodine-labelled LHRH, indicating that there were features common to the hormone and antagonist.

Dissociated porcine pituitary cells were prepared as described previously[6] and luteinizing hormone (LH) release measured by radioimmunoassay for the various treatments (Table 1). Clearly, the 6-D-Lys analogue of the antagonist[5] retained similar activity *in vitro* as gonadotropin release by the native hormone was suppressed completely at concentrations 100 times that of the agonist. The analogue alone gave no gonadotropin release at concentrations up to 10^{-6} M, indicating that the occupied receptor complex lacked the structure required for a biological response. However, the presence of antibodies converted this antagonist complex into a functional agonist by aggregating occupied receptors as a first stage. Lower levels of gonadotropin were secreted at higher concentrations of peptide, presumably because of extensive binding of antibody by free peptide in solution. The specificity of the effect was demonstrated by the fact that the antiserum raised against the peptide having <Glu-His instead of Z-Gln was unable to evoke a response. Although this indicated that antibody binding occurred through the N-terminal region, the anti-inhibitor antiserum may have multiple specificity and could also contain different immunoglobulin isotypes. Thus, although aggregation is involved, its scale and specificity is unclear.

From the rabbit antiserum to the inhibitory peptide, we prepared pure IgG having specificity for the N-terminus of the peptide (for experimental details see Table 2). The purified specific IgG and Fab proteins were then used to study LH release from pituitary cells (Table 2).

For this particular cell preparation, LHRH at 10^{-7} M stimulated LH release 3–4-fold. The inhibitor alone was ineffective at 10^{-9} M but in conjunction with purified specific IgG at $\sim10^{-11}$ M, LH release occurred. That this required divalency was apparent from the inability of similar amounts of Fab fragment to evoke similar effects and by the ability of goat anti-rabbit anti-serum to induce the Fab–antagonist complex to stimulate LH release. The effect of all agents together (Table 2) indicated that LH release was only mediated via the LHRH receptor.

Previously, we have observed aggregation and internalization of bound LHRH[2] and it has been shown that receptor aggregation is essential for the action of some polypeptide hormones. Thus, antibodies to the insulin receptor produced insulin-like responses directly[7,8] and a degraded EGF analogue became

Table 2 Sequential experiments with porcine pituitary cells in culture showing LH release for each treatment period.

Control period	Period 1		Period 2	
25.0±2.4	LHRH (10^{-7} M)	94.4±4.7		
30.3±4.2	Inhibitor (10^{-9} M)	28.2±1.8		
30.5±1.8	Inhibitor (10^{-9} M) + 1.3 ng $\mathrm{ml^{-1}}$ IgG	78.4±4.3		
20.0±4.7	Inhibitor (10^{-9} M) + 0.13 ng $\mathrm{ml^{-1}}$ IgG	26.4±2.6		
30.5±3.73	Inhibitor (10^{-9} M) + 0.8 ng $\mathrm{ml^{-1}}$ Fab	37.6±8.3	Inhibitor (10^{-9} M) + 0.8 ng $\mathrm{ml^{-1}}$ Fab + GaRS (1:20)	150±20.3
23.6±2.8	Inhibitor (10^{-9} M) + 0.8 ng $\mathrm{ml^{-1}}$ Fab + LHRH (10^{-7} M)	120.5±6.2	Inhibitor (10^{-9} M) + 0.8 ng $\mathrm{ml^{-1}}$ Fab + LHRH (10^{-7} M) + GaRS (1:20)	126.4±16.2

Pituitary cells were prepared and plated out as described in Table 1. Between each 30-min incubation period, the cells were rinsed with serum-free medium for three 1-min periods. Values are ng $\mathrm{ml^{-1}}$ ± s.e.m. luteinizing hormone. The goat anti-rabbit serum (GaRS) had no significant effect on LH release when used alone at 1:20 dilution. The purified specific IgG and Fab proteins used in the study were prepared as follows.

Rabbit antiserum (1 ml) to the inhibitory peptide, diluted with phosphate-buffered saline (PBS), was recycled through an affinity column comprising 2 ml Sepharose coupled to 20 mg of the C-terminal peptide-sequence (Leu-Arg-Pro-NHEt) at 4 °C for 48 h. The non-retarded serum solution was recycled through a 5 ml column of Sepharose–Protein A (Pharmacia) for 24 h. The column was washed with 5 vol PBS, eluted with 5 ml 0.1 M citrate buffer, *p*H 3.5 and the eluate neutralized immediately with 0.5 ml M Tris-HCl buffer, *p*H 8.0. The lyophilized eluate was taken up into water and applied to a column of Ultrogel ACA 34 (60×0.9 cm) in 0.05 M ammonium bicarbonate. The fractions from the single peak in the precalibrated IgG position (2.6 mg) were combined and lyophilized. Half the sample was taken up into 200 µl buffer (0.1 M phosphate *p*H 7.0, 0.01 M cysteine, 0.002 M EDTA) and treated with 15 µg papain at 37 °C for 16 h. In the subsequent Ultrogel chromatography designed to obtain Fab fragments, we observed no intact IgG.

mitogenic when aggregated by antibody[9]. However, for these larger molecules, it is possible that the antisera have multiple specificity; the simpler octapeptide used here allows clearer definition of the effects.

Since our initial report of the conversion of a pure antagonist to agonist[10], we have shown that a different antagonist when converted to a dimer, could be activated using anti-serum[11], thus confirming the phenomenon. Here, use of purified immunoglobulin and peptide monomer allows firm conclusions to be made concerning the nature of the hormone-receptor interactions.

The high specificity of the hormone for the receptor presumably involves several amino acids, and the antigenic determinants of proteins and polypeptides have also been shown to encompass several amino acids[12]. Thus, it is unlikely that residues contained in the antigen-binding site are available for receptor binding at the same time and vice versa; the logical conclusion is that the octapeptide cannot bind more than one antibody molecule concurrent with the receptor site being occupied by this inhibitor. The IgG preparation, which is a divalent protein specific to the peptide N-terminus, can produce a biological response from an inactive hormone complex. This indicates that formation of an occupied receptor dimer (and no greater aggregation is required) by lateral movement through the membrane is a necessary step in the response pathway after binding of hormone to the receptor. Accepting that the octapeptide is only large enough to bind to the receptor and to one antibody molecule, it follows that the C-terminal region must have a dominant role in binding to the receptor, and this is common to both agonist and antagonist. That the anti-antagonist antibody recognizes the N-terminal region is supported by the fact that the anti-agonist antibody (Table 1) was unable to induce LH release, thus it is proposed that the ⌊Glu-His-Trp-Ser sequence is important in the dimerization of occupied receptors. We conclude, therefore, that this small peptide hormone is able to exert an effect on a normal cell population by having a sequence allowing specific binding, followed by a second sequence that causes dimerisation of the receptors, thus leading to biological expression by an as yet undefined series of stages.

Tumour promotion by TCDD in skin of HRS/J hairless mice

Alan Poland, David Palen & Edward Glover

McArdle Laboratory for Cancer Research, University of Wisconsin, Madison, Wisconsin 53706, USA

2,3,7,8-Tetrachlorodibenzo-*p*-dioxin (TCDD) serves as the prototype for a group of environmental toxicants, the halogenated aromatic hydrocarbons[1–3], which evoke a characteristic pattern of acute toxic and biochemical responses, and which produce these effects by stereospecific and reversible binding to a soluble protein receptor[2,4,5]. The chronic administration of TCDD[6–9] (and several other halogenated aromatic hydrocarbons)[10–13] to rats and mice has produced an increased incidence of hepatocellular carcinomas as well as tumours in other tissues. However, because TCDD is not a mutagen[14,15] and does not bind appreciably to DNA *in vivo*[16], it has been suggested that this compound is not a complete carcinogen, but rather acts as a tumour promoter, enhancing neoplastic expression in already initiated cells[17,18]. TCDD has been shown to be a potent tumour promoter in a two-stage model of carcinogenesis in rat liver[19], but has proven ineffective in the classical model in mouse skin (using CD-1 and Swiss-Webster mice)[20,21]. We have recently shown that TCDD produces epidermal hyperplasia and hyperkeratosis, and squamous metaplasia of the sebaceous glands in mice bearing the recessive trait, *hairless* (*hr*), but causes no changes in the skin of mice which are wild type or heterozygous at this locus[22]. Here we examine the capacity of TCDD to promote tumour formation in the skin of HRS/J hairless (*hr/hr*) mice and their congenic, haired (*hr*/+) littermates. Following the application of an initiating dose of a carcinogen, repeated skin application of TCDD produced papillomas in *hr/hr* mice but not *hr*/+ mice. In HRS/J hairless mice, tumour promotion by TCDD elicits the same incidence and multiplicity of skin papillomas as does the classical tumour promoter, 12-*O*-tetradecanoylphorbol-13-acetate (TPA), but at 1/100th the dose.

HRS/J is an inbred strain of mice segregating for the *hr* locus[23]; haired mice (*hr*/+) and hairless mice (*hr/hr*) are genetically identical except at the *hr* locus and closely linked loci on chromosome 14. Initiation of the skin of HRS/J (*hr*/+) haired mice with dimethylbenz(*a*)anthracene (DMBA 0.2 μmol) and subsequent twice-weekly topical application of the classical tumour promoter TPA, 2 μg per mouse, produced skin papillomas (Fig. 1*a*). Administration of DMBA alone or repeated application of TPA without prior initiation produced no tumours. Compared with other mouse strains[24], HRS/J haired mice are relatively sensitive to this regimen of DMBA/TPA: by 11 weeks of promotion, 100% of the mice developed papillomas, and by 14 weeks the tumour multiplicity (number of papillomas/number of surviving mice) was 9.2 papillomas per mouse. Following initiation with DMBA, repeated topical administration of TCDD (20 ng per mouse twice weekly for 8 weeks, then 50 ng per mouse twice weekly) failed to produce any papillomas over the 25-week course of the experiment.

Table 1 Comparison of TCDD and TPA as tumour promoters in HRS/J hairless mice

			At 20 weeks		
Initiation	Promotion		Tumour incidence (surviving mice with tumours/surviving mice)		Tumour multiplicity (average no. of papillomas/surviving mice)
MNNG	Acetone		1/19	5%	0.05
MNNG	TCDD	3.75 ng*	11/20	55%	0.7
MNNG	TCDD	7.5 ng	13/17	77%	1.5
MNNG	TCDD	15 ng	10/10	100%	4.0
MNNG	TCDD	30 ng	15/19	79%	1.6
Acetone	TCDD	30 ng	0/19	0%	0
MNNG	TPA	1 μg	5/19	26%	0.4
MNNG	TPA	3 μg	13/18	72%	1.6

HRS/J hairless female mice, 7 weeks old, were administered a single dose of MNNG (5 μmol in 50 μl of acetone) or the solvent alone applied to the dorsal skin, and then treated twice weekly with various doses of TCDD or TPA (in 50 μl of acetone) for 20 weeks. There were initially 20 mice per group and the survival was 85% or more in all groups except group 4 (TCDD 15 ng). Ten animals died in this group after 15 weeks of promotion, from dehydration coincident with being changed to a new type of cage. These deaths did not alter the tumour incidence or tumour multiplicity, that is, at 15 compared with 16 weeks.

* Dose of compound per mouse, given twice weekly.

In contrast, HRS/J (*hr/hr*) hairless mice, initiated with DMBA and treated with the same regimen of TCDD, did develop papillomas (Fig. 1*b*). After 25 weeks of TCDD

0028-0836/82/460271—03$01.00

promotion, 15 of 19 surviving mice (79%) had one or more skin tumours, with an average multiplicity of 1.4 tumours per mouse. Administration of DMBA alone produced a single papilloma, and in the absence of initiation, TCDD produced no papillomas. The time course of tumour incidence and tumour multiplicity produced by promotion with TCDD (20 ng per mouse, twice weekly) and TPA (2 μg per mouse, twice weekly) were very similar (Fig. 1*c*). Thus, TPA promotes tumour formation in the skin of both HRS/J haired and hairless mice, while TCDD is effective only in *hr*/*hr* mice.

A further comparison of TPA and TCDD is shown in Table 1. HRS/J hairless mice were initiated with *N*-methyl-*N*′-nitro-*N*-nitrosoguanidine (MNNG) and treated twice weekly with various doses of TCDD or TPA. TCDD produced a dose-related increase in the incidence and multiplicity of skin papillomas at doses of 3.75, 7.5 and 15 ng per mouse. At the highest dose tested, 30 ng per mouse, TCDD produced greater toxicity and was less effective as a tumour promoter. Comparable tumour promotion was produced by twice-weekly administration of TCDD at 7.5–15 ng per mouse ($2.3\text{–}4.6 \times 10^{-11}$ mol) and TPA at 3 μg per mouse (4.8×10^{-9} mol); thus, TCDD seems to be ~100 times more potent than TPA on a molar basis. However, one cannot formally compare the relative potencies of these compounds unless they act by a similar mechanism and produce the same maximum response with parallel log dose–response curves.

We examined the capacity of several halogenated aromatic hydrocarbon congeners and commercial mixtures of halobiphenyl isomers to promote tumour formation in the skin of HRS/J hairless mice (Table 2). 2,3,7,8-Tetrachlorodibenzofuran (TCDBF) and 3,4,5,3′,4′,5′-hexabromobiphenyl, both approximate isostereomers of TCDD which bind to the cytosol receptor and evoke a number of receptor-mediated responses including induction of microsomal monooxygenase activity[5,25], terminal differentiation of XB cells in culture[26] and hyperplasia and hyperkeratosis in the skin of hairless mice[22], are effective tumour promoters. TCDBF (1 μg per mouse, twice weekly) produced a greater tumour multiplicity than a near-optimally effective regimen of TCDD, and the TCDBF-treated mice showed less toxicity and better weight gain. The relatively rapid metabolism of TCDBF in the mouse[27] may permit attainment of a high local skin concentration of the compound without systemic accumulation and toxicity. 2,7-Dichlorodibenzo-*p*-dioxin and 2,4,5,2′,4′,5′-hexabromobiphenyl, congeners which neither bind to the cytosol receptor nor produce the characteristic biochemical and toxic effects of TCDD[22,25], were inactive as tumour promoters at the doses tested. Aroclor 1254 (1 mg per mouse twice weekly), a commercial mixture of chlorinated biphenyl isomers which has been widely used in industry in capacitors and transformers, as a lubricant and heat transfer fluid, slightly enhanced the incidence of skin tumours in MNNG-initiated mice, but this effect was not statistically significant. In contrast, Firemaster FF-1, a commercial mixture of brominated biphenyl isomers used as a flame retardant[28], was an effective tumour promoter, but the dose regimen used was toxic and produced severe hepatomegaly and hepatic porphyria.

Several aspects of these experiments require further comment. First, the epidermal and systemic effects produced by repeated skin painting with TPA and TCDD are in sharp contrast. In HRS/J haired and hairless mice, TPA produces an acute inflammation and hyperplasia of the epidermis, with little systemic toxicity. TCDD produces no gross or histological changes in the skin of *hr*/+ mice[22]. Hairless mice, repeatedly treated with TCDD, develop a scaly, shiny and taut appearance to their skin, and histologically one observes epidermal hyperplasia and hyperkeratosis, squamous metaplasia of the sebaceous glands, and accumulation of keratinaceous material in the dermal cysts which are normally found in *hr*/*hr* mice. In contrast to TPA, TCDD produces no acute inflammatory response in the skin, neither oedema nor leukocyte infiltration[22]. TCDD and other halogenated aromatic hydrocarbons produce several dose-related systemic lesions in both *hr*/*hr* and *hr*/+ mice: reduced weight gain or, at high doses, weight loss, loss of cutaneous and abdominal fat, thymic atrophy and liver enlargement and parenchymal cell changes[29]. Hairless mice repeatedly administered high doses of TCDD have skin which is easily damaged and may develop abscesses about the face and in the preputial and rectal glands. The animals assume a humped stature, with the back arched above the shoulders, and they move about poorly.

Second, the incidence and multiplicity of tumours produced by initiation and TPA promotion are less in HRS/J hairless mice than in haired mice, as noted previously by Giovanella *et al.*[30] and seen in Fig. 1*b*, *c*. Thus, the relatively low tumour multiplicity produced by TCDD and congeners in HRS/J *hr*/*hr* mice is a constraint of the animal model, and not a reflection of a poor promoting efficacy of these compounds.

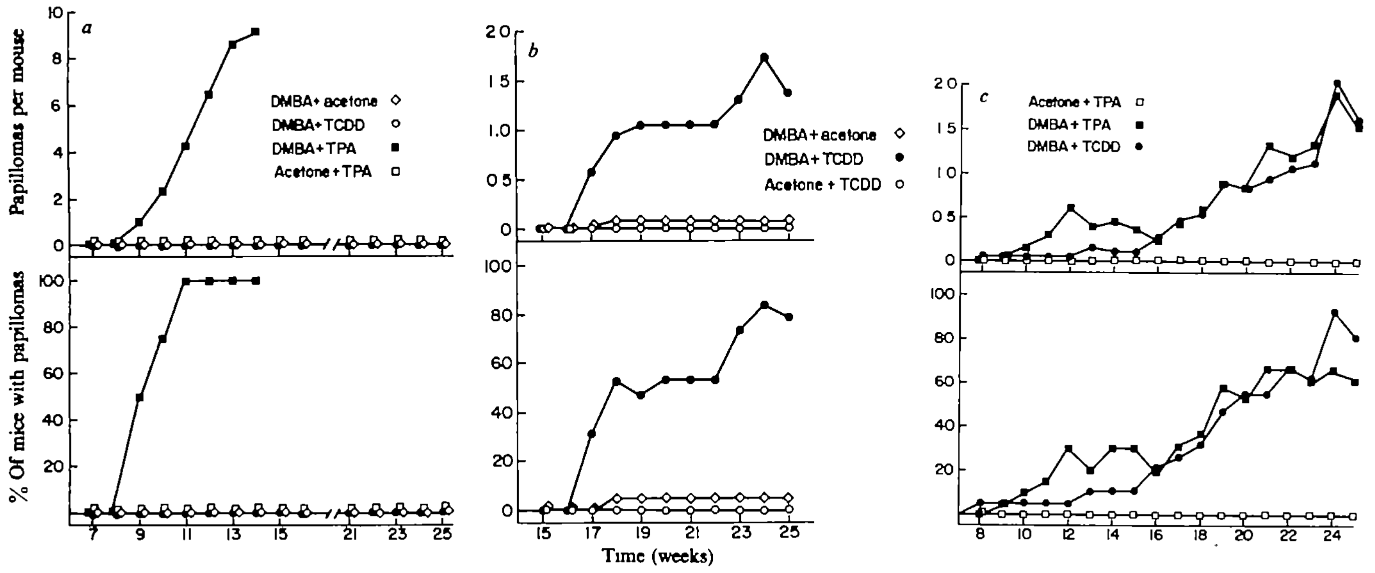

Fig. 1 Tumour promotion by TPA and TCDD in the skin of HRS/J *hr*/+ and *hr*/*hr* mice. *a*, Haired (*hr*/+) mice were shaven, initiated with a single dose of DMBA (0.2 μmol) applied to the skin, or with solvent (acetone), and then painted twice weekly with TPA (2 μg per mouse), TCDD (50 ng per mouse for 8 weeks, then 20 ng per mouse) or acetone. *b*, Hairless (*hr*/*hr*) mice: treatment regimens same as in *a*. *c*, Hairless (*hr*/*hr*) mice were administered DMBA (0.2 μmol) twice, 1 week apart, or the solvent, and then topically treated twice weekly with TPA (2 μg per mouse) or TCDD (20 ng per mouse). For experiments in *a*–*c*, each treatment group consisted of 20 female mice, and had 16 or more survivors at the end of the experiment. All compounds were dissolved in acetone. for initiation 100 μl of the acetone solution of DMBA was applied to *hr*/+ and *hr*/*hr* mice, and for promotion 50 μl of acetone or acetone solutions were applied to *hr*/*hr* mice, and 100 μl of these solutions to *hr*/+ mice.

Table 2 Tumour promotion by halogenated aromatic hydrocarbons in HRS/J hairless mice

Group	Initiation	Promotion	Dose (dose per mouse, twice weekly)	*n*	20 weeks Tumour incidence (surviving mice with tumours/surviving mice)		20 weeks Tumour multiplicity (average no. of papillomas/surviving mice)
1	MNNG	Acetone		26	0/23	0%	0
2	Acetone	TCDD	50 ng, 5 weeks, then 20 ng	26	0/18	0%	0
3	MNNG	TCDD	50 ng, 5 weeks, then 20 ng	26	16/19	84%	1.6
4	MNNG	2,3,7,8-Tetrachlorodibenzofuran	1.0 μg	20	19/19	100%	4.9
5	Acetone	2,3,7,8-Tetrachlorodibenzofuran	1.0 μg	20	1/20	5%	0.05
6	MNNG	3,4,5,3′,4′,5′-Hexabromobiphenyl	20 μg	20	12/20	60%	1.5
7	Acetone	3,4,5,3′,4′,5′-Hexabromobiphenyl	20 μg	20	0/20	0%	0
8	MNNG	2,4,5,2′,4′,5′-Hexabromobiphenyl	20 μg	20	0/20	0%	0
9	Acetone	2,4,5,2′,4′,5′-Hexabromobiphenyl	20 μg	26	0/22	0%	0
10	MNNG	2,7-Dichlorodibenzo-*p*-dioxin	20 μg	20	0/19	0%	0
11	Acetone	2,7-Dichlorodibenzo-*p*-dioxin		20	0/20	0%	0
12	MNNG	Aroclor 1254	1 mg	20	4/19	21%	0 3
13	Acetone	Aroclor 1254	1 mg	20	0/19	0%	0
14	MNNG	Firemaster FF-1	2 mg, 5 weeks, then 1 mg	26	9/15	60%	2.0
15	Acetone	Firemaster FF-1	2 mg, 5 weeks, then 1 mg	20	1/16	6%	0.13

HRS/J hairless female mice, 8 weeks old, received a single administration of MNNG (5 μmol in 50 μl of acetone) or solvent alone applied to the skin, and were then treated topically twice weekly with test compound dissolved in 50 μl of acetone for 20 weeks Treatment with Firemaster FF-1 produced a significant mortality and the dose was reduced after 5 weeks The appreciable mortality in other groups (2, 3 and 6) occurred largely in the first 6 weeks of the experiment, resulted primarily from dehydration and did not seem to be a result of the treatment regimen. Additional animals were added to these groups, so all groups consisted of 20 or 26 mice.

Third, skin tumours elicited by promotion with TCDD (and congeners) were often smaller (1–3 mm) and progressed more slowly than those elicited by promotion with TPA. Virtually all the tumours were keratinizing squamous cell papillomas, regardless of the promoter used. Finally, in all treatment groups (Fig. 1*a–c*), the survival rate was >80%. HRS/J mice harbour a murine leukaemia virus, and the expression of the recombinant polytropic virus and the incidence of lymphatic leukaemia are greater in *hr/hr* mice than *hr/+* mice[31–33]. By 10 months of age, leukaemia develops in 45% of *hr/hr* mice and only 1% of the heterozygote *hr/+* mice[31]. In all experiments with *hr/hr* mice (Fig. 1*b*, *c*, Tables 1, 2), 0–15% of the animals developed leukaemia (as evidenced by enlarged spleen, thymus, lymph nodes and/or liver) which either resulted in their premature death or was detected at autopsy at the termination of the experiment. The incidence of leukaemia was not significantly different in any of the treatment groups, and seemed to be independent of exposure of the animals to a carcinogen or halogenated aromatic hydrocarbons.

TCDD and related halogenated aromatic hydrocarbons comprise a class of potent tumour promoters which seem to act by a mechanism that is distinct from that of TPA and its congeners. The epidermal hyperplasia[22] and most probably the tumour promotion (as suggested by the structure–activity relationship in Table 2) produced in hairless mice by these halogenated aromatic hydrocarbons are mediated through the cytosol receptor. In contrast, the promoting activities of TPA, other phorbol and diterpene esters, and structurally unrelated compounds such as teleociden and debromoaplysiatoxin[34–37], apparently act through another mechanisms.

Two aspects of this model of tumour promotion in the skin of hairless mice may prove especially useful. First, comparison of the pleiotropic responses produced by TCDD in the skin of congeneic HRS/J *hr/hr* and *hr/+* mice may permit identification of the additional battery of genes expressed in *hr/hr* skin which are in some manner associated with promotion. Second, it may be determined if any of the biochemical effects produced by TPA and congeners and implicated in their mechanism of action[18] are also common to the response produced by halogenated aromatic hydrocarbons.

Our model of tumour promotion by TCDD and congeners may be relevant to humans because the hyperplastic/metaplastic response produced in the skin of the mutant hairless mouse is similar to that evoked by these compounds in human skin.

This study was supported in parts by grants from the National Institute of Environmental Health Sciences ES 01884 and NCI grant CA-07175. A.P. is a Burroughs Wellcome Scholar in Toxicology. Surface sialic acid reduces attachment of metastatic tumour cells to collagen type IV and fibronectin

Attachment of cells to substrate containing fibronectin, laminin and collagens has been shown to influence cell proliferation[1], differentiation[2,3] and migration[4], aspects of cellular behaviour known to be altered by malignant transformation. Recent studies on mutant cell lines displaying altered attachment to substrate and changes in cell-surface carbohydrate composition have provided evidence for the involvement of glycoconjugates in cell attachment[5–7]. Using this approach, we have now found that a non-metastatic wheat germ agglutinin-resistant (WGA^R) mutant of the highly metastatic murine tumour MDAY-D2 has a three- to fourfold reduction in neuraminidase-accessible cell-surface sialic acid which seems to allow enhanced attachment to basement membrane collagen type IV and fibronectin, but not to laminin. Furthermore, neuraminidase treatment of the WGA-sensitive metastatic tumour cells enhanced their attachment to collagen type IV and fibronectin, but not to laminin. Neuraminidase treatment had no effect on attachment of the WGA^R mutant cells to any of the substrates.

Yogeeswaran and Salk[8] have recently shown that the metastatic capacity of a range of murine tumour cell lines is positively correlated with the degree of sialation of available galactose and *N*-acetylgalactosamine residues on cell-surface glycoconjugates. This correlation is supported by the finding that some WGA^R mutants of the B16 melanoma are non-metastatic[9] and deficient in cell-surface sialic acid[10]. WGA binds preferentially to the oligosaccharide portions of glycoconjugates containing *N*-acetylglucosamine and sialic acid[11]. The lectin must bind to the cell surface to exert its toxic effects and, as might be expected, some genotypic classes of WGA^R cells have less surface sialic acid and hence show decreased WGA binding[12]. MDW40, the non-metastatic WGA^R mutant of MDAY-D2, also binds less WGA[13,14] and shows a three- to fourfold reduction in neuraminidase-accessible sialic acid compared with the parental tumour cells and two WGA-sensitive (WGA^S) revertants designated W40M1 and W40M4 (Table 1). The highly metastatic WGA^S revertants are lines established from metastatic nodules found in the organs of mice injected with the WGA^R mutant. MDW40 cells have previously been shown to grow only at the subcutaneous site of injection where over time, one or a few cells become WGA sensitive and highly metastatic. The revertant tumour cells progressively dominate the primary tumour cell population and metastasize to distant organs[14,15] (for example, W40M1 and W40M4). The origin and phenotypes of the tumour cell lines are summarized in Table 1. These observations are similar to those of Bramwell and Harris who have shown that some WGA^R tumour cell variants which are poorly tumorigenic revert at the site of inoculation to the WGA-sensitive and more malignant phenotype[16].

Two WGA^R mutants of MDAY-D2 have previously been shown to be highly immunogenic and for this reason, poorly tumourogenic in the syngeneic host. In contrast MDW40 is highly tumourogenic, poorly immunogenic and completely non-metastatic, differing from the parental tumour line in only the latter phenotype[17]. Interaction between tumour cells and the host which do not involve immune stimulation are known to influence metastatic capacity. In particular, metastatic tumour cells must invade local tissues, move into and out of the circulation and grow at secondary sites, processes which by definition require contact between the tumour cell and host extracellular matrix proteins.

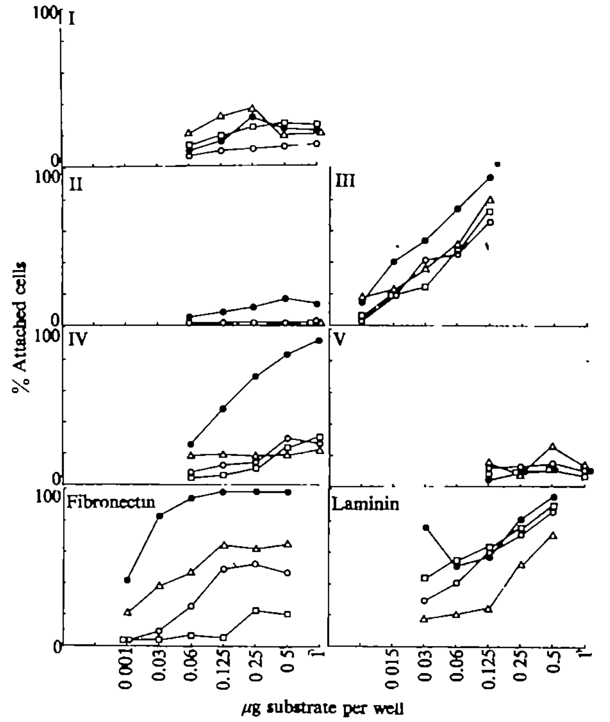

Fig. 1 Adhesion of untreated tumour cells to purified collagens, laminin and fibronectin. Replicate wells in Terasaki Microtest plates (Falcon Plastics) were coated with the following substrates; collagen types I (lathyritic rat skin), II (bovine articular cartilage), III (fetal bovine skin), IV (mouse EHS tumour) and V (human placenta), laminin (mouse EHS sarcoma) and fibronectin (human plasma). The purification of these proteins followed standard procedures[23–27] Each well of the Microtest plates was coated with 5 μg bovine serum albumin (BSA) and concentrations of substrate ranging from 0.001 to 1 μg. The BSA and substrates were allowed to dry for 2 h Tumour cells from tissue culture in log growth phase were washed three times in PBS at 4 °C, adjusted to 5×10^4 per ml in Dulbecco's minimal essential medium (DMEM)/F12 nutrient mixture (3/1, v/v), 15 mM HEPES, *p*H 7, and 10-μl aliquots of the cell suspensions were added to triplicate wells, incubated at 37 °C for 30 min then turned upside-down and incubated for a further 30 min. Cells adhering to the substrate, and those falling to the base of the droplet were counted and the mean per cent adhering calculated from triplicate counts. Background adhesion to wells coated with BSA alone ranged from 0 to 10%. The data represent the mean of three experiments. ●, MDW40; △, MDAY-D2; ○, MDW40M1; □, MDW40M4.

The non-metastatic WGA^R mutant, the parental tumour line and two metastatic revertant lines were compared for their ability to attach to laminin, fibronectin and collagen types I–V using a modification of a sensitive drop assay[18]. Compared with the metastatic lines, attachment of MDW40 to collagen type IV and fibronectin was increased (Fig. 1). A small increase in MDW40 attachment to collagen type III was also apparent. Tumour cell attachment to collagens I, II and V was minimal and no differences between the various lines were observed. The four tumour cell lines readily attached to laminin but there were no consistent differences between attachment of the mutant and wild-type cells to this substrate.

The tumour cells were grown in suspension cultures and showed a rounded morphology and negligible attachment to the Falcon tissue culture plastic. With one exception the cells displayed the same rounded morphology following attachment to each of the substrates. MDW40 cells spread only on fibronectin at concentrations >0.03 μg per well and required 2–3 h for optimal flattening. Although MDW40 cells attached to fibronectin at concentrations of <0.03 μg per well they did not flatten, which is consistent with the interpretation that cells require a minimal number of attachment points to spread[19]. The weak attachment of the metastatic cell lines to fibronectin

0028–0836/82/460274—03$01.00

may therefore preclude spreading. MDW40 attached firmly to plastic coated with extracellular matrix produced by endothelial cells in tissue culture. After 3 days of growth on this substrate a tightly packed layer of polygonal shaped cells was formed. The metastatic cell lines remained rounded and loosely attached to plastic coated with endothelial cell extracellular matrix (data not shown). It is known that growth of some tumour cell lines on endothelial cell extracellular matrix results in a more differentiated cell morphology, reflected by firm attachment, cell spreading and formation of non-overlapping cell monolayers[3].

In an attempt to mimic the attachment phenotype of the mutant, tumour cells were pretreated with neuraminidase and compared with sham-treated cells for their ability to adhere to laminin, fibronectin and collagen types III and IV (Fig. 2). Neuraminidase treatment had no effect on adhesion of MDW40 cells but greatly enhanced that of MDAY-D2, W40M1 and W40M4 cells to collagen type IV and fibronectin. Similar though less marked effects were observed with collagen type III as substrate, and no differences were observed with laminin. The results indicate that decreased cell-surface sialic acid can increase cell attachment to fibronectin and collagen type IV while not affecting attachment to laminin. Therefore, cell attachment to fibronectin and collagens may be mediated by cell-surface receptors different from those which mediate attachment to laminin. Selective inhibition of hepatocyte attachment to laminin or fibronectin by the same respective proteins in soluble form has led to identical conclusions[20].

Our results indicate that a mutation leading to increased cell-surface sialic acid may produce a less adhesive cell. Furthermore, some ricin-resistant mutants of baby hamster kidney cells have been shown to bind less ricin due to masking of the ricin receptors by sialic acid and to be less adhesive to fibronectin-coated plastic than the parental cell line[6,7]. These results and our own are consistent with the proposal that cell attachment to certain substrates such as fibronectin and collagen type IV requires carbohydrate chains which are potential acceptors of terminal sialic acid residues.

Table 1 Comparison of neuraminidase-accessible sialic acid on WGA^{R} mutant and wild-type cells

Tumour cell lines	Phenotype*	Release of counts from ^{3}H-N-acetyl mannosamine-labelled cells (%)†	Thiobarbituric acid assay (nM sialic acid per mg cell protein)‡
MDAY-D2	Met, WGA^{S}, Oua^{S}	16.7 ± 5.1	$1\ 91 \pm 0.35$ (5)
MDW40	Non Met, WGA^{R}, Oua^{R}	$4\ 1 \pm 1.8$	0.59 ± 0.13 (4)
W40M1	Met, WGA^{S}, Oua^{R}	22.2 ± 9.5	1.89 ± 0.06 (2)
W40M4	Met, WGA^{S}, Oua^{R}	$16\ 0 \pm 5\ 7$	1.69 ± 0.12 (3)

* The origin of the highly metastatic (Met) DBA/2 tumour MDAY-D2 has been described in detail previously[24]. WGA (2–5 $\mu g\ ml^{-1}$) and ouabain (0.1 mM) added to MDAY-D2 in tissue culture reduced cell growth by 90% (D_{10}) (WGA^{S}, Oua^{S}). MDW40 is a ouabain-resistant (Oua^{R}) mutant ($D_{10} = 3$ mM) of MDW4, a non-metastatic WGA^{R} mutant ($D_{10} = 50\ \mu g\ ml^{-1}$) of MDAY-D2[14]. MDW40 cells have been shown to grow only locally at the site of a subcutaneous inoculation and when 10^{5} cells are injected intravenously less than 5% of the mice die of tumour takes. Recent experiments have demonstrated that 28–35 days after intravenous injection of MDW40 cells, one or a few tumour cells form hybrids with a host cell *in situ*, acquiring the WGA-sensitive phenotype[15]. The WGA-sensitive tumour cells selectively dominate the subcutaneous tumour cell population and metastasize to distant organs, resulting in death 60–90 days after tumour cell inoculation. W40M1 and W40M4 are WGA^{S}, Oua^{R} resistant tumour cell lines isolated from the liver and spleen respectively of two DBA/2 mice injected subcutaneously with 10^{5} MDW40 cells 90 days earlier.

† Tumour cells, 5×10^{5} per ml, were cultured in RPMI plus 10% fetal calf serum and 2 $\mu Ci\ ml^{-1}$ [6-^{3}H]*N*-acetylmannosamine. After 48 h, the cells were washed three times in Dulbecco's phosphate-buffered saline (PBS) and samples of 10^{6} cells in 100 µl of PBS, 5 mM $CaCl_2$, *p*H 6.1, were incubated alone (*C*) or with 0.02 U of neuraminidase (Behringwerke) (*N*) for 60 min. at 37°C. The cells were washed twice in PBS, solubilized and radioactivity was measured The formula $(C - N/C) \times 100$ was used to calculate the percentage of neuraminidase-accessible sialic acid[10] The results are the mean ± s.e. of three experiments.

‡ Tumour cells were washed three times and 20×10^{6} cells in 0 5 ml PBS, 5 mM $CaCl_2$, *p*H 6.1, were incubated with 2 U of neuraminidase (Sigma, type V) for 60 min at 37°C. The cells were pelleted and sialic acid in the supernatant was measured using the thiobarbituric acid assay Protein was measured using the Bio-Rad reagent and ovalbumin as the standard. The results represent the mean ± s.e. of the number of experiments indicated in parentheses.

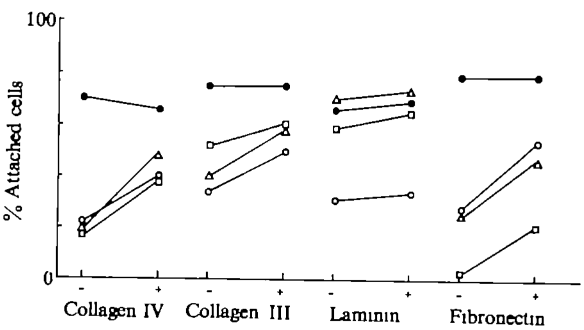

Fig. 2 The effect of neuraminidase treatment on adhesion to collagens, laminin and fibronectin Cells were washed three times in PBS, and two samples of 10^{6} cells in 200 µl of Dulbecco's PBS, *p*H 6.9, were incubated with and without 0.02 U of neuraminidase from *Arthrobacter woafociens* (Behringwerke) at 37 °C for 30 min. 2 ml of PBS was then added, the cells were centrifuged, the supernatant was removed and a further treatment with 0.02 U neuraminidase carried out The cells were then washed three times in cold PBS, resuspended at 5×10^{4} ml in DMEM/F12 nutrient mixture (3/1, v/v), 15 mM HEPES, *p*H 7, and kept on ice The adhesion of treated and untreated cells to fibronectin (0 03 µg per well), laminin (0 25 µg per well) collagen III (0.06 µg per well) and collagen IV (0.25 µg per well) was measured. The data represent the mean of three experiments. Neuraminidase treatment enhanced binding of the metastatic cell lines to collagen IV ($P < 0.05$), fibronectin ($P < 0.05$) and collagen III ($P < 0.1$), but not to laminin ($P < 0\ 95$) as determined by a paired *t*-test. ●, MDW40; △, MDAY-D2; ○, MDW40M1; □, MDW40M4.

The specific glycoconjugates involved in cell attachment have not been clearly defined. Glycolipids terminating in galactose have been shown to mediate homotypic adhesion[21] and polysialylated gangliosides seem to inhibit fibronectin-mediated cell attachment in a nonspecific manner[22]. These findings are consistent with our results and with the hypothesis that specific glycoconjugates terminating in galactose (that is, non-sialylated *N*-linked complex or *O*-linked mucin type as well as glycolipids) may be receptors for a lectin-like interaction with fibronectin.

In a manner analogous to ricin binding, sialation of the oligosaccharide may reduce fibronectin binding. These results do not preclude the earlier suggestion that sialic acid increases the net negative charge of the cell and effects a charge repulsion of the cell and substratum[23]. However, this is less likely since changes in sialation did not effect cell attachment to laminin.

The avidity of attachment to substrate may change cellular behaviour. Compared with their normal counterpart, transformed cells are known to be less adhesive and less dependent on substratum for growth, properties which may allow the cells to escape from the primary tumour. Firm attachment of cells can induce differentiation[2] and contact inhibition of growth[1]. Our results suggest that the increase in sialation of the metastatic tumour cell surface[8] can result in decreased attachment to basement membrane proteins collagen type IV and fibronectin, predisposing the tumour cells to increased mobility and decreased growth control by substratum contact.

We thank Dr I. Vlodavsky for the gift of extracellular matrix coated dishes, and Ms U. Rohmann and Mrs E. Sum for typing assistance.

Characterization of a growth hormone-releasing factor from a human pancreatic islet tumour

Jean Rivier, Joachim Spiess, Michael Thorner* & Wylie Vale

Peptide Biology Laboratory, The Salk Institute, PO Box 85800, San Diego, California 92138, USA
* Department of Internal Medicine, University of Virginia School of Medicine, Charlottesville, Virginia 22908, USA

The neuroregulation of growth hormone (GH) secretion is mediated in part by a stimulatory, GH-releasing factor (GRF) and an inhibitory peptide, somatostatin[1], both of which reach the adenohypophysis by the hypothalamic-hypophysial portal system[2]. Somatostatin has been shown to be a tetradecapeptide[3,4], a large form of which was later also sequenced[5]. The existence of a GRF is supported by physiological evidence[6–9] and by reports of GH-releasing activity in hypothalamic extracts[10–17]. Although several agents with GH-releasing activity have been identified[14–16], none is of high potency and fulfils the criteria expected of a physiological GRF[18,19]. GH-releasing activity observed in extracts of carcinoid and pancreatic islet tumours removed from patients with GH hypersecretion, acromegaly and pituitary adenoma or hyperplasia has been partially characterized[20–23]. We report here the sequence of a 40 residue GH-releasing peptide purified from a pancreatic islet tumour described earlier by Thorner *et al.*[23]. A synthetic replicate of this peptide, termed human pancreatic tumour GRF [hpGRF(1–40)]-OH, co-elutes on HPLC with the native peptide and is highly potent in stimulating GH secretion *in vitro* and *in vivo*. A close structural homology with the peptides of the glucagon–secretin family, and more particularly with PHI[24], is recognized. Structure–activity studies show that hpGRF(1–29)-NH$_2$ has full intrinsic activity and potency *in vitro*.

hpGRF was purified from a pancreatic tumour removed from a subject who presented symptoms and signs of acromegaly and increased GH levels that rapidly abated after surgical removal of the tumour[23]. Throughout the purification, we used an *in vitro* method for assaying the ability of a putative GRF to stimulate the secretion of GH by primary cultures of rat pituitary cells (see ref. 25 and Fig. 3 legend).

The tumour was processed in two batches (I and II) of 2.5 and 5 g respectively. Batch I allowed us to optimize extraction and chromatographic conditions that led to the final two-step purification of hpGRF from batch II (see Fig. 1 legend for details). Approximately 6 nmol of >80% pure GRF were obtained, corresponding to an overall recovery of >50%.

Both purification steps yielded one major zone of GRF-like activity. The independent processing of side cuts from the gel permeation or generated during reverse-phase HPLC purification indicated that very closely related molecules having GRF activity may be present in the extracts. Their relative amounts, however, could not be more than 5% of the total on the basis of absorbance readings. Furthermore, it is not excluded that these distinct active entities may have been the result of molecular alterations (oxidation of methionine or partial hydrolysis) that occurred during processing of the fractions.

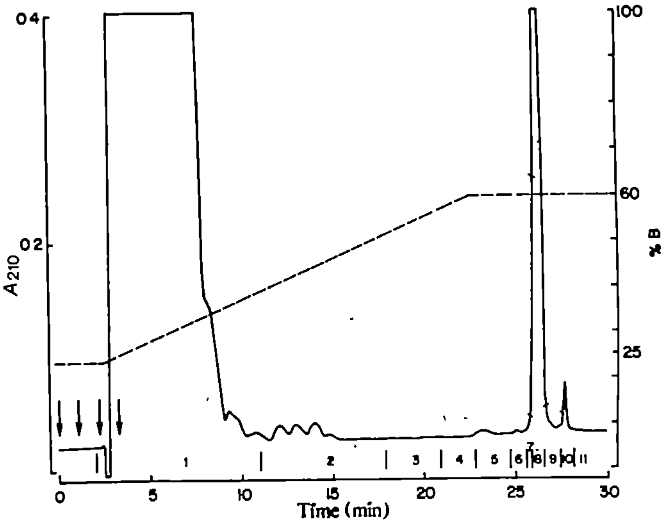

Fig. 1 Extraction and gel permeation chromatography of hpGRF· batch II was lyophilized, polytroned in 10 vols acetone, maintained at −20 °C for 2 days and centrifuged. The acetone precipitate was extracted in hot (>90 °C) acid (1 M acetic acid + 0.1 M HCl) containing 10 mM EDTA and 0.5% β-mercaptoethanol (β-ME) and 5 µg ml^{-1} pepstatin, heated for 2 min, polytroned, chilled and centrifuged. The supernatant was defatted by 3×4 vols ether/petroleum ether (1·2) and applied to a 3.5×120 cm column containing Sephadex G-50 fine and eluted with 3 M acetic acid/0.5% β-ME at a flow rate of 20 ml h^{-1} Fractions (9.4 ml) were collected, aliquots were lyophilized and assayed in pools. GH-releasing activity was detected in fractions 55–76 corresponding to K_{av} 0.20–0.38. HPLC purification of hpGRF: the zone containing most of the GRF activity (K_{av} 0.24–0.33) was applied through multiple injections (4×1 ml) to a Vydac diphenyl end-capped (5 µm, 300 Å pore size, 4.5×250 mm) column (three equivalent runs were performed with the following loads 1/5 and twice 2/5 of total), which was then eluted with an acetonitrile gradient (3→30% in 25 min) in TEAP buffer[37]. The activity was associated with several absorbance peaks eluting 22–25 min after the start of the gradient (flow rate 1 2 ml min^{-1}). A second HPLC step was performed on the pool of the active fractions from the previous run after partial evaporation of the acetonitrile in a spin vacuum concentrator. A Vydac C$_{18}$ (5 µm, 300 Å, 4.5×250 mm) column was eluted with an acetonitrile gradient (21→36% in 20 min) at a flow rate of 1.2 ml min^{-1} after multiple injections (2×1 ml) of the concentrated fractions at the relative loads described earlier. All the activity was associated with one symmetrical absorbance peak eluting 21 5 min after the start of the gradient. The total pool of the active fraction (injection volume of 3.5 ml loaded in three aliquots of 1 ml and one of 0.5 ml) was re-run on the same Vydac C$_{18}$ end-capped column at a flow rate of 1.2 ml min^{-1} and room temperature in the gradient conditions shown in the figure (A = 0.1% trifluoroacetic acid (TFA) in water, B = 0.1% TFA in 60% CH$_3$CN/40% water) to concentrate hpGRF and free it, before sequencing, from β-ME which had been added to each tube at each step in order to retain a high level of biological activity. Indeed, partial oxidation of methionine-27 to methione sulphoxide leads to a significant loss of activity (~2% of that of the parent compound) as was shown with synthetic analogues. Fraction 8 was subsequently submitted to composition and sequence analysis Native hpGRF and hpGRF(1–40)-OH co-elute on HPLC under conditions (Vydac C$_{18}$, 1.2 ml min^{-1}, 27→31% CH$_3$CN in 20 min) that would separate them from all other analogues described here including hpGRF(1–40)-NH$_2$.

The primary structure of purified hpGRF was determined by Edman degradation in a Beckman 890C spinning cup sequencer, modified according to Wittmann-Liebold[26], to be: Tyr-Ala-Asp-Ala-Ile-Phe-Thr-Asn-Ser-Tyr-Arg-Lys-Val-Leu-Gly-Gln-Leu-Ser-Ala-Arg-Lys-Leu-Leu-Gln-Asp-Ile-Met-Ser-Arg-Gln-Gln-Gly-Glu-Ser-Asn-Gln-Glu-Arg-Gly-Ala-. The sequencing strategy and results are described elsewhere[27] and summarized in Fig. 2 legend.

Fully protected hpGRF(1–40)-NH$_2$ was synthesized in a stepwise manner on a p-methylbenzhydrylamine resin and hpGRF(1–40)-OH was synthesized on a chloromethylated resin

0028-0836/82/460276—03$01.00

according to the general solid-phase approach of Merrifield[28] using experimental procedures described earlier[29,30]. After complete deprotection and cleavage by hydrofluoric acid, the crude preparations of hpGRF(1–40) and analogues were purified using preparative HPLC techniques developed in our laboratory (see Fig. 3 legend). The abilities of native hpGRF, synthetic hpGRF(1–40)-OH, hpGRF(1–40)-NH_2, and 8-bromo cyclic AMP to stimulate GH secretion by cultured rat pituitary cells are compared in Fig. 3. Both synthetic peptides and the native hpGRF exhibit similar potencies and intrinsic activities in this assay. In multiple culture assays, the minimally effective concentrations of synthetic hpGRF(1–40)-OH are 3–8 pM, the EC_{50} values 20–100 pM and the maximally effective concentrations are reached by 1 nM. Thus the *in vitro* potency of the synthetic peptide is either similar to or greater than the potencies of the hypophysiotropic peptides isolated from the hypothalamus (thyrotropin-releasing hormone, gonadotropin-releasing hormone, somatostatin[19] and corticotropin-releasing factor[31]).

We have synthesized several extended and shortened analogues of hpGRF(1–40) and tested them *in vitro*. The following peptides exhibited similar (within a factor of 2) potencies to hpGRF(1–40)-OH *in vitro*: hpGRF(1–29)-NH_2, hpGRF(1–32)-NH_2, hpGRF(1–39)-NH_2, hpGRF(1–40)-NH_2, hpGRF(1–40)-Phe-NH_2, hpGRF(1–40)-Phe-OH and hpGRF(1–40)-Phe-Gln-NH_2. These results demonstrate that the N-terminal 29 residues of hpGRF possess all the information required for full *in vitro* activity and suggest that the C-terminal region of hpGRF is not critical for receptor recognition. Full intrinsic activity is observed in hpGRF(1–27)-NH_2 which possesses 10–20% of the potency of hpGRF(1–40)-OH.

hpGRF shows striking structural homology with the peptides of the glucagon family, particularly its new member PHI[24] (Fig. 2). hpGRF(1–27) and PHI have 12 common residues in an equivalent position, while 12 additional residues could represent single base changes. We have not observed any GH-releasing activity of PHI, (Gln[24])-PHI, vasoactive intestinal peptide or glucagon on anterior pituitary cells. However, the activity of 27- and 29-residue hpGRF analogues suggests that hpGRF may be further processed biologically with maintenance of hypophysiotropic activity.

It is not known whether hpGRF is normally produced in pancreatic islets or if this is an ectopic source for the peptide, or what is the relationship between the putative hypothalamic GRF and hpGRF-(1–40). Natural hpGRF and partially purified rat hypothalamic GRF, which exhibit similar chromatographic behaviour on Sephadex G-50, can be separated by HPLC. However, other observations suggest that they are structurally similar. There is ample precedence for a close structural relationship between peptides produced ectopically by tumours and those produced normally[32]. Furthermore, partial sequence analysis of the N-terminal region of highly purified rat hypothalamic GRF showed sequence homology with hpGRF (J.S., J.R. and W.V. unpublished results).

Biologically, hpGRF(1–40) and closely related peptides exhibit many properties expected of a putative GH-releasing factor[33]. Thus, synthetic hpGRF and purified rat hypothalamic GRF fractions exhibit parallel dose–response curves and intrinsic activities *in vitro* (Fig. 4). In agreement with our studies[13] using purified rat hypothalamic GRF, and others[17,34] using purified hypothalamic or pancreatic tumour GRF, we find that somatostatin non-competitively blocks GH release due to synthetic hpGRF[33]. However, even at the highest somatostatin concentrations, hpGRF can still elicit some GH secretion. As with native tumour GRF[34], synthetic hpGRF-mediated GH secretion is calcium-dependent[33]. In agreement with Cronin *et al.*[35] who used native hpGRF, we find that synthetic hpGRF increases intracellular cyclic AMP and that somatostatin attenuates this rise (L. Bilezikjian and W.V., in preparation). The GH-releasing activity of synthetic and native hpGRF is strongly potentiated by pretreatment of cells with glucocorticoids and thyroid hormone[33]. hpGRF is also highly potent *in vivo*. A

Fig. 2 Comparison of the amino acid sequences of hpGRF and other members of the glucagon–secretin family. Residues of a given structure that are identical with the corresponding one of hpGRF are underlined. The primary structure of hpGRF was determined by Edman degradation. The phenylthiohydantoin derivatives of the amino acids were identified by reverse-phase HPLC[38] Several sequencing experiments, each using 0.7–1.2 nmol of peptide, were performed. The peptide was applied directly to the sequencer cup with or without previous treatment with 3-sulphophenylisothiocyanate or after incubation with trypsin, staphylococcal protease or BrCN that cleaved the peptide at different sites. The mixture of fragments was sequenced without purification The proposed primary structure hpGRF(1–40)-OH shown above satisfies sequence[27] and C-terminal (tritiation) analyses[40], and HPLC data. Amino acid analyses performed using previously reported methodology[39] gave the following composition as integers· 5 Asx, 2 Thr, 4 Ser, 7 Glx, 1 Pro, 3 Gly, 4 Ala, 2 Val, 1 Met, 2 Ile, 5 Leu, 2 Tyr, 2 Phe, 3 Lys, 4 Arg. Extra residues are likely to be associated with contaminating peptide(s). Gel filtration and finger printing data[27] exclude the possibility that hpGRF is significantly larger. VIP, vasoactive intestinal peptide; GIP, gastric inhibitory polypeptide

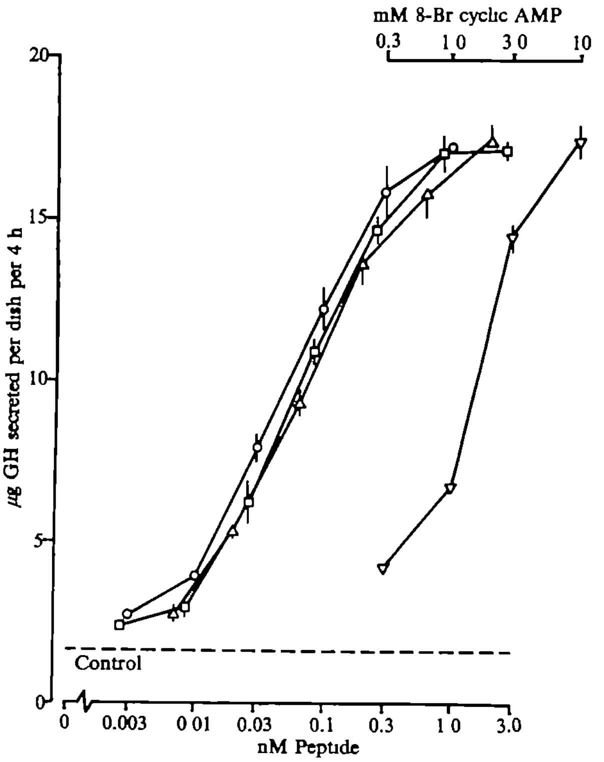

Fig. 3 Effects of native hpGRF (○), synthetic hpGRF(1–40)-NH_2 (□), synthetic hpGRF(1–40)-OH (△) and 8-bromo cyclic AMP (▽) on GH secretion over a 4 h period by rat pituitary cells in monolayer culture for 3–5 days. Cells were dissociated and cultured as described in refs 25, 33. Culture medium for this and other assays reported here include 5 nM dexamethasone and 30 pM triiodothyronine. GH levels are estimated by radioimmunoassay using NIADDK National Hormone and Pituitary Program kits prepared by Dr A. Parlow. For purification of the synthetic peptides, cartridges fitting Waters Associates prep LC-500 were packed with 17 μm C_{18} silica (300 Å; Vydac). A gradient of CH_3CN in TEAP[37] was generated by a low-pressure Eldex gradient maker. Desalting of the purified fractions independently checked for purity was achieved using a gradient of CH_3CN in 0.1% TFA. The centre cut was then lyophilized to yield the desired 40-residue peptide, the purity of which can be >98% (J.R., in preparation).

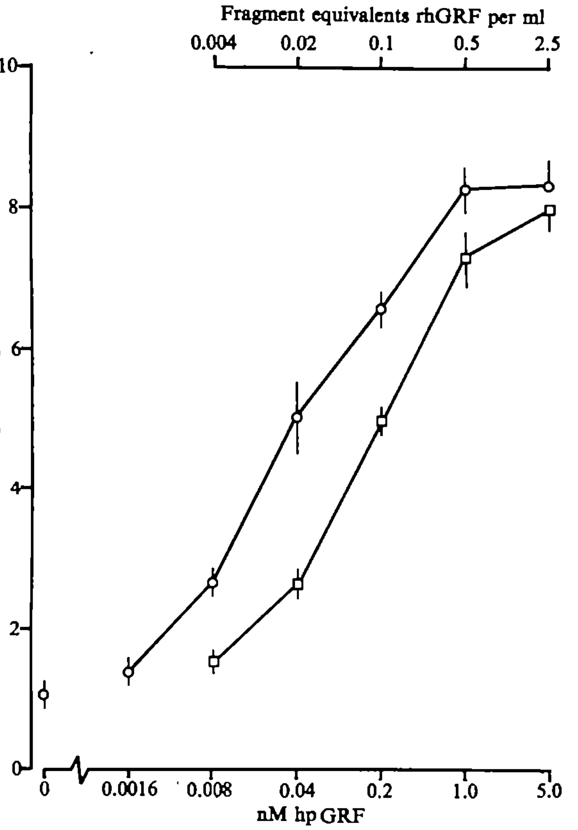

Fig. 4 Effects of synthetic hpGRF (○) and purified rat hypothalamic GRF (rhGRF; □) on secretion of GH by cultured rat pituitary cells. rhGRF was purified as described in ref. 33.

dose-related increase in GH plasma levels was observed (C. Rivier, J.R., J.S. and W.V., in preparation) after administration of from 40 ng per kg to 25 μg per kg of synthetic hpGRF to freely running catheterized rats pretreated with FLA-63, a dopamine β-hydroxylase inhibitor that suppresses spontaneous GH secretion[36].

The association of elevated GH levels in the patient with an hpGRF-containing tumour suggests that synthetic hpGRF and its analogues may be powerful GH secretagogues in humans and be of use in the diagnosis and treatment of human disorders.

Identification of plasmid (pKM101)-coded proteins involved in mutagenesis and UV resistance

Karen L. Perry & Graham C. Walker

Biology Department, Massachusetts Institute of Technology,
Cambridge, Massachusetts 02139, USA

Mutagenesis of *Escherichia coli* by UV and many chemicals is not a passive process and requires the intervention of host functions. The isolation of chromosomal *umuC* mutants, which are nonmutable by many DNA-damaging agents and are slightly sensitive to them, has led to the model that the *umuC* gene product(s) functions in a pathway of 'error-prone repair'[1-3]. *UmuC* mutants are suppressed by the introduction of the plasmid pKM101[4]; pKM101 was derived from the clinically isolated plasmid R46 by *in vivo* manipulations[5]. The *muc* (*m*utagenesis, *U*V and *c*hemical) region of pKM101 is required for this suppression and we have suggested that it is an analogue of the chromosomal *umuC* gene(s)[6]. We have now subcloned the *muc* region onto the high-copy number vector pKB354 and identified two protein products by gel electrophoresis of maxicell preparations. Complementation analysis of *muc* insertion mutations has confirmed the existence of two genes, *mucA* and *mucB*, whose protein products are required for pKM101's effects on mutagenesis and resistance to killing. The molecular weights (MWs) of the *mucA* and *mucB* proteins are 16,000 and 45,000 respectively.

The plasmid pKM101 has played an important part in the Ames test for detecting carcinogens as mutagens[7,8]. pKM101 confers on its host enhanced capacities for survival and mutagenesis that are $recA^+lexA^+$ dependent[9] and apparently inseparable by Tn*5* insertion mutagenesis[6]. Such insertions identified an approximately 1.6 kilobase (kb) region of pKM101 necessary for these phenotypes which we termed *muc*.

To determine whether the *muc* region is also sufficient for the expression of these phenotypes, we have now subcloned it into the multiple-copy number vector pKB354 (Ap^R, Tc^R; K. Backman, unpublished). pKB354 is a derivative of pBR322 which has lost the *Sal*I/*Hin*cII site in the *tet* gene, yet remains tet^+. *Hpa*I fragments of the pKM101 derivative pGW270 (ref. 10) were subcloned into the *Hin*cII site in the *bla* gene of

0028–0836/82/460278—04$01.00

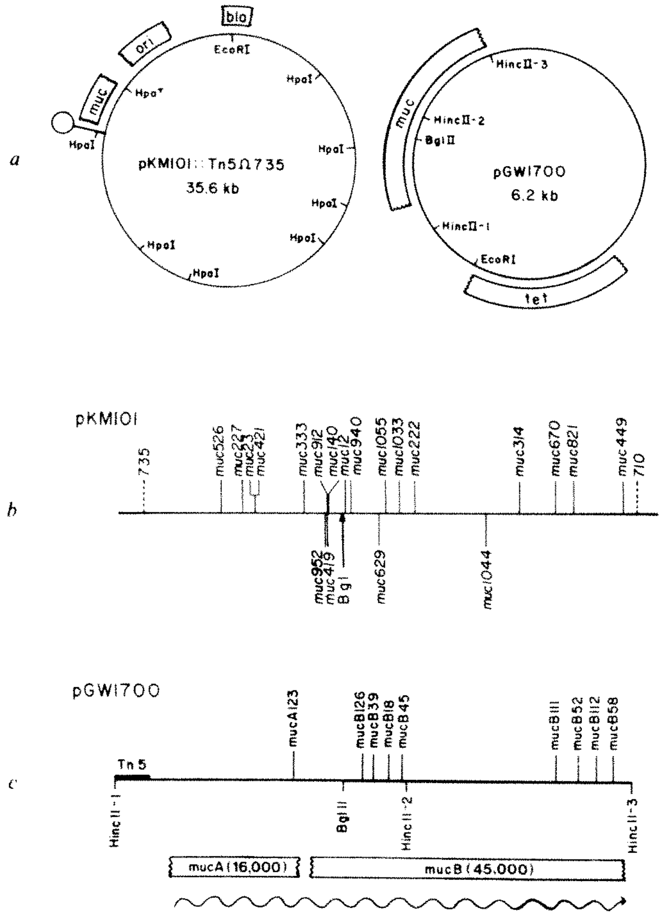

Fig. 1 *a*, Partial restriction map of pKM101::Tn*5Ω735* and pGW1700 showing the relative orientation of the *muc* region of the two plasmids. The construction of pGW1700 involved the insertion of a *Hpa*I fragment containing *mucA*, *mucB* and the end of Tn*5Ω735* into the *Hinc*II site of the high-copy number vector pKB354. *b*, Expanded map of the pKM101 *muc* region showing the location of Tn*5* insertions affecting mutagenesis. pKM101Ω710 and pKM101Ω735 are Tn*5* insertions which flank the *muc* region. *c*, Expanded map of the pGW1700 *muc* region showing the location of Tn*1000* insertions affecting mutagenesis and the position and direction of transcription of *mucA* and *mucB* (molecular weights in parentheses).

pKB354 and transformed into TK610 (*umuC36*, *uvrA6*[1]). Colonies were selected for tetracycline resistance and screened for ampicillin sensitivity and UV mutability. The screen for UV mutability made use of the revertible *his-4* marker of TK610. Tc^RAp^S colonies were spread as patches on minimal media containing a trace amount of histidine (0.02 mM) and irradiated with 2 J m^{-2} of UV from a germicidal lamp. Muc^+ patches were easily identified as they gave rise to as many as 100 His^+ revertants whereas the control patches rarely had more than one His^+ revertant.

In this manner, several Muc^+ derivatives were identified that contained hybrid plasmids in which the *muc* region was inserted into pKB354 in either of the two possible orientations. The expression of *muc* was qualitatively similar regardless of its orientation. One derivative, pGW1700, was selected for further studies. pGW1700 mediates the reactivation of UV-irradiated λ phage (Fig. 3*a*) and suppresses the nonmutability of *umuC36* strains by methyl methanesulphonate (MMS; Fig. 4) to a greater extent than does pKM101. These results indicate that the *muc* region is indeed sufficient for the expression of plasmid-mediated enhancement of survival and mutagenesis.

The proteins encoded by pGW1700 were examined on SDS-polyacrylamide gels using maxicell preparations[11] labelled with ^{35}S-methionine. The maxicell procedure takes advantage of the fact that, in *recA* cells, irradiation with appropriate doses of UV leads to the degradation of chromosomal but not plasmid DNA, thus allowing plasmid-coded proteins to be labelled specifically. pGW1700 encodes two proteins of MWs 16,000 and 45,000 respectively, which are not encoded by the vector (Fig. 2, tracks 1, 2). To determine whether these proteins are products of the *muc* gene(s), we isolated *muc* insertion mutants of pGW1700 generated by the transposable element Tn*1000* (ref. 12) and looked for truncated peptides. Initial attempts to obtain pGW1700 *muc*::Tn*1000* insertions used GW2100 (*umuC*::Tn*5*) as the recipient and proved difficult for reasons that are still unknown. Introduction of pGW2, a pkm101 *muc* mutant derived by *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine treatment[13], into GW2100 facilitated the isolation of such mutants. *Muc* insertions isolated in this manner map, by restriction endonuclease analysis, between the *Bgl*II and *Hinc*II-3 sites of pGW1700. Figure 1 compares the sites of the Tn*1000* insertions with those of the *muc*::Tn*5* insertions previously isolated in pKM101.

Maxicell preparations of the pGW1700 mutants *mucB58*::Tn*1000*, *mucB112*::Tn*1000* and *mucB126*::Tn*1000* lack the 45,000 MW protein, which we have identified as the product of the *mucB* gene (Fig. 2, tracks 3–5). Truncated peptides, resulting from translation termination occurring within Tn*1000* sequences[11], are present in the *mucB58*::Tn*1000* and *mucB112*::Tn*1000* extracts. Their sizes suggest that the direction of transcription of *mucB* is towards the *Hinc*II-3 site of pGW1700. (The ends of *mucB* are defined by the *mucB58*::Tn*1000* insertion and by a fusion of the 5' end of the gene to *lacZ* at the *Bgl*II site; S. J. Elledge and G. C. W., unpublished results.) None of the initial pGW1700 *muc*

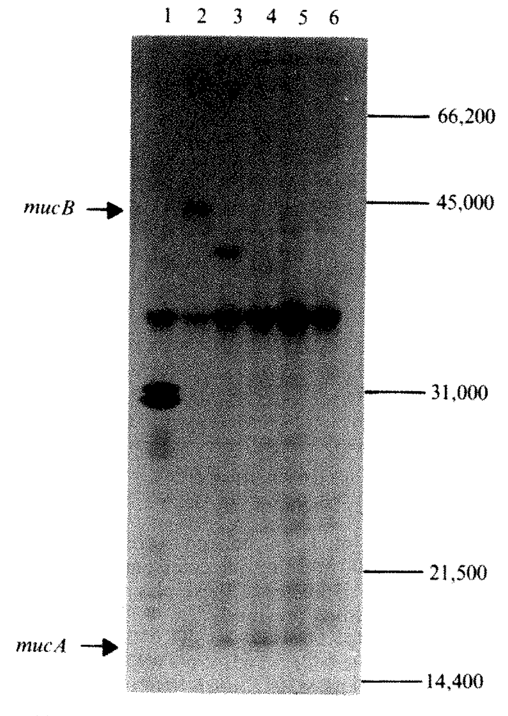

Fig. 2 ^{35}S-methionine-labelled proteins produced in maxicells by the plasmids pKB354 and pGW1700 (*mucA*$^+$, *mucB*$^+$) and by derivatives of pGW1700 in which Tn*1000* is inserted in either the *mucA* gene or the *mucB* gene. Maxicell extracts were prepared from plasmid-containing derivatives of RB901 (*spr*, *recA*) following UV irradiation to 35 J m^{-2}. Proteins were separated by electrophoresis on a 10–18% gradient polyacrylamide gel and visualized by fluorography. Arrows indicate the positions of the *mucA* and *mucB* proteins. Tracks 1, pKB354; 2, pGW1700; 3, pGW1700 *mucB58*::Tn*1000*; 4, pGW1700 *mucB112*::Tn*1000*; 5, pGW1700 *mucB126*::Tn*1000*; 6, pGW1700 *mucA123*::Tn*1000*. Molecular weights of the *mucA* and *mucB* proteins were determined by reference to unlabelled protein standards following staining with Coomassie blue. Molecular weights of the standards are indicated on the side.

insertion mutations affected the synthesis of the 16,000-MW protein. We suspected that such mutations were complemented by pGW2 in the GW2100 recipient and therefore went undetected. The use of GW2100(pKM101 *mucA421*::Tn*5*)[6] as a recipient permitted the isolation of pGW1700 *mucA123*::Tn*1000*. *mucA123*::Tn*1000* mutants fail to synthesize both the 45,000-MW *mucB* protein and the 16,000-MW *mucA* protein in maxicell preparations (Fig. 2, track 6). The apparent polarity of the *mucA123*::Tn*1000* mutation suggests that *mucA* and *mucB* constitute an operon, the *mucA123*::Tn*1000* insertion being in the promoter-proximal *mucA* gene.

The compatibility between pKM101 and pGW1700 derivatives has enabled us to carry out complementation analyses of several *muc* alleles which have revealed that both the *mucA* and *mucB* gene products are required for plasmid-mediated mutagenesis and repair. A deletion derivative of pKM101 *mucA421*::Tn*5* was constructed which lacks the internal *Xho*I fragments[14] of Tn*5*. Such deletions are reported to relieve polarity effects caused by insertion of the transposon[14]. *MucA421*::Tn*5*Δ*Xho*I and *mucB112*::Tn*1000* alleles complement to a moderate extent when tested for the capacity to reactivate UV-irradiated λ phage (Fig. 3*b*). The original insertion mutation, *mucA421*::Tn*5*, also complements *mucB112*::Tn*1000*, but to a lesser degree. Thus it seems that the *mucA421*::Tn*5* insertion is incompletely polar on *mucB*. Complementation of phage reactivation between *mucB1044*::Tn*5* and *mucA123*::Tn*1000* is also observed, but at a very low, yet reproducible, level (Fig. 3*a*).

Similar results were obtained in complementation analyses of MMS mutability, determined by reversion of the ochre *argE3* marker (Fig. 4). *mucA421*::Tn*5* and *mucB112*::Tn*1000* complement to mediate MMS mutagenesis to a level equivalent to that mediated by pKM101. Again, the *mucB1044*::Tn*5* and *mucA123*::Tn*1000* alleles complement to a lesser degree. We suspect that the differences in the extent of complementation reflect differences in the degree of polarity caused by the *mucA421*::Tn*5* and *mucA123*::Tn*1000* insertions. Alternatively, complementation may be affected by gene dosage effects caused by copy number differences between pKM101 and pGW1700 derivatives. No complementation of MMS mutability or phage reactivation was observed between *mucA421*::Tn*5* and *mucA123*::Tn*1000* or between *mucB1044*::Tn*5* and *mucB112*::Tn*1000*.

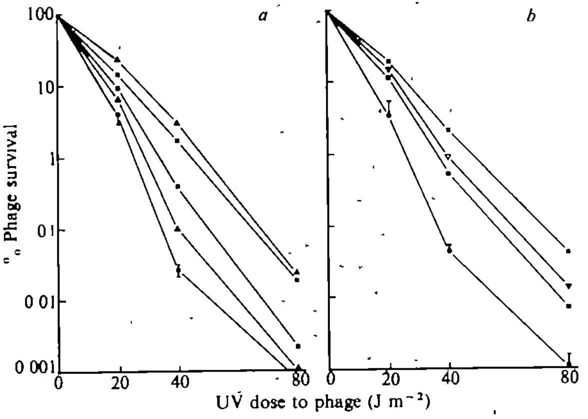

Fig. 3 Reactivation of UV-irradiated λcI857 mediated by pKM101 and pGW1700 and showing complementation between several *mucA* and *mucB* alleles of those plasmids. Reactivation was measured as described previously[6]. *a*, ●, TK610 (*umuC36*, *uvrA6*); ■, TK610(pKM101); ▲, TK610(pGW1700); □, TK610(pKM101 *mucA421*::Tn*5*, pGW1700 *mucB112*::Tn*1000*); △, TK610(pKM101 *mucB1044*::Tn*5*, pGW1700 *mucA123*::Tn*1000*). The following strains, also assayed for λcI857 reactivation, gave results similar to those of TK610: TK610(pKM101 Tn*5*), TK610(pGW1700 *mucA123*::Tn*1000*), TK610(pGW1700 *mucB112*::Tn*1000*), TK610-(pKM101 *mucA421*::Tn*5*, pGW1700 *mucA123*::Tn*1000*), TK610(pKM101 *mucB1044*::Tn*5*, pGW1700 *mucB112*::Tn*1000*). The range of values for these strains is indicated by the bars. *b*, ●, TK610(pKM101 *mucA421*::Tn*5*); ■, TK610(pKM101); ∇, TK610(pKM101 *mucA421*::Tn*5*Δ*Xho*I, pGW1700 *mucB112*::Tn*1000*); □, TK610 (pKM101 *mucA421*::Tn*5*, pGW1700 *mucB112*::Tn*1000*). The following strains, also assayed for λcI857 reactivation, gave results similar to those of TK610(pKM101 *mucA421*::Tn*5*): TK610(pKM101 *mucA421*::Tn*5*Δ*Xho*I) and TK610(pGW1700 *mucB112*::Tn*1000*). The range of values for these strains is indicated by the bars.

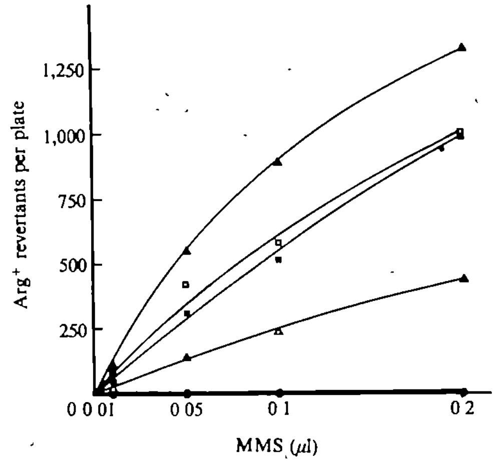

Fig. 4 MMS-induced reversion of the *argE3* mutation mediated by pKM101 and pGW1700 and showing complementation between several *mucA* and *mucB* alleles of those plasmids. To 2 ml of top agar supplemented with limiting (0.05 mM) arginine and nonlimiting concentrations of all other growth requirements were added 0.1 ml of a fresh stationary phase culture and the appropriate amount of a freshly prepared solution of MMS in dimethyl sulphoxide. The top agar was then poured on minimal-glucose plates which were then incubated at 37 °C for 4 days. Spontaneous revertants have been subtracted. ●, GW3201(TK610 *argE3*, *zii2*::Tn*5*); ■, GW3201(pKM101); ▲, GW3201(pGW1700); □, GW3201(pKM101 *mucA421*::Tn*5*, pGW1700 *mucB112*::Tn*1000*); △, GW3201(pKM101 *mucB1044*::Tn*5*, pGW1700 *mucA123*::Tn*1000*). The following strains, also included in the assay, were indistinguishable from GW3201: GW3201 (pKM101 *mucA421*::Tn*5*), GW3201(pKM101 *mucB1044*::Tn*5*), GW3201(pGW1700 *mucA123*::Tn*1000*), GW3201 (pGW1700 *mucB112*::Tn*1000*), GW3201(pKM101 *mucA421*::Tn*5*, pGW1700 *mucA123*::Tn*1000*) and GW3201(pKM101 *mucB1044*::Tn*5*, pGW1700 *mucB112*::Tn*1000*).

These results indicate that both *mucA* and *mucB* gene products are required for mutagenesis and repair, and that the phenotype of *mucA* insertions is not due simply to their polar effects on *mucB*. As we have yet to discern any phenotypic differences between *mucA* and *mucB* mutations, it seems likely that the two gene products act in concert to mediate mutagenesis and repair.

The chromosomal *umuC* locus of *E. coli* has recently been cloned and found to consist of two genes, *umuD* and *umuC*, that code for gene products of MWs 16,000 and 45,000 respectively[15]. The pKM101 *mucA* and *mucB* gene products are thus very similar in size to the chromosomally encoded *umuD* and *umuC* gene products, further supporting the hypothesis[4] that the proteins of the *muc* and *umuC* loci have analogous roles in the processing of damaged DNA that gives rise to mutations. We are now investigating the possibility of complementation between *muc* and *umu* alleles. As no *muc* alleles that we tested complemented the *umuC36* mutation carried by the host, either the individual *muc* gene products are insufficiently homologous to complement separately the corresponding *umu* gene products or the *umuC36* mutant is defective in both *umuD* and *umuC*. The identification of the *mucA* and *mucB* proteins should facilitate a systematic analysis of the biochemistry of error-prone repair.

We thank the members of our laboratory, particularly S. Elledge, C. Kenyon and S. Winans; L. Withers for help in preparing the manuscript; and K. Backman and R. Brent for providing plasmid vectors and bacterial strains. This work was supported by NCI grant R01-CA21615. K.L.P. was supported by NIH training grant GM07287. G.C.W. was a Rita Allen Scholar.

A transposon in *Streptococcus faecalis* with fertility properties

Certain strains of streptococci have been shown to be capable of conjugatively transferring drug resistance determinants in the apparent absence of plasmid DNA[1–6]. The transferrable tetracycline resistance (Tc^r) marker of *Streptococcus faecalis* DS16 has been located on a transposon, designated Tn *916*[2,4,7]. We show here that when chromosomal Tn *916* is conjugatively transferred it inserts into a number of different sites on the recipient chromosome. Our studies also imply that transfer and transposition share a common step, which may be excision of the transposon from the donor chromosome.

The ability of Tn*916* to transfer from plasmid-free donors (see Table 1 for description of bacterial strains) in overnight filter matings is shown in the data of Table 2. DS16C3 is able to transfer Tc^r at a frequency of about 10^{-8} to the plasmid-free recipient strain JH2-2. Transconjugants such as CG130 are capable of transferring Tc^r to the isogenic recipient JH2SS at a similar frequency. To investigate the nature of this transfer event, chromosomal DNA isolated from the donor and transconjugant strains listed in Table 2 was digested with *Hin*dIII restriction endonuclease, resolved by agarose gel electrophoresis, and transferred to nitrocellulose paper using the Southern technique[8]. The transferred DNA was probed with a ^{32}P-labelled *Eco*R1 restriction fragment (F') of pAM211 (a derivative of pAD1, a resident plasmid of DS16) that contains the entire transposon. There are no *Eco*R1 sites within Tn*916* and about 85% of the F' fragment consists of Tn*916* sequences. As Tn*916* contains a single *Hin*dIII site, two chromosome–transposon junction fragments should be resolvable after hybridization with the probe. The resulting autoradiogram (Fig. 1*a*) shows that three different transconjugants obtained from the DS16C3×JH2-2 mating, detailed in Table 2, display hybridization patterns (lanes 2–4) that differ from those seen in the donor (lane 1) as well as from each other. One such transconjugant, CG140, gave rise to two chromosome–transposon junction fragments (X and Y), whereas two other transconjugants, CG110 and CG130, gave rise to four or more bands. Figure 1*a* also shows the hybridization profiles of transconjugants derived from the secondary mating described in Table 2 that had used strain CG130 as the donor. Again the hybridization bands of the transconjugants (lanes (5–7) differed from those of the donor as well as from each other. Strain CG132 gave rise to a multiple band pattern, whereas two other transconjugant strains, CG131 and CG133, exhibited the simpler banding pattern.

The variation in hybridization profiles amongst different transconjugants implies that Tn*916* inserts at different sites on the recipient chromosome. These findings also argue against the possibility that Tn*916* existed on a plasmid which had escaped physical detection. If the latter had been the case, identical patterns should have been observed in the transconjugants.

The patterns of multiple bands observed with transconjugants CG110, CG130, and CG132 were reproducible, and do not represent incomplete digestion products. An autoradiogram of a Southern blot hybridization experiment involving *Eco*R1 digested chromosomal DNA and ^{32}P-labelled Tn*916* probe is shown in Fig. 1*b*. As expected, a single hybridizing fragment was detected in the *Eco*R1 digested chromosomal DNA from strains CG133, CG131, and DS16C3 (strains that gave rise to two hybridizing fragments in the *Hin*dIII digestion experiments—see Fig. 1*a*). By contrast, those transconjugants that gave rise to complex band patterns following *Hin*dIII digestion (CG132, CG130, and CG110) gave rise to more than one hybridizing fragment when digested with *Eco*R1. In every case, the hybridizing fragments following *Eco*R1 digestion of chromosomal DNA were larger than ~15 kilobase. These data strongly suggest the presence of non-tandem multiple copies of the entire transposon in strains CG110, CG130, and CG132; however, the possibility that major rearrangements of the transposon give rise to these data cannot be completely eliminated. We note that restriction enzyme analyses of several pAD1::Tn*916* plasmids formed by transposition from the CG110 chromosome revealed a typical ~15 kilobase insertion (data not shown).

Tc^r transconjugants of JH2-2 that exhibit altered transfer frequencies in secondary matings were readily obtainable, and usually represented about 20% of the original transconjugants. Strain CG110 was capable of donating Tn*916* at frequencies of about 10^{-6} (Table 2). To investigate the transposition of Tn*916* in such a strain the conjugative haemolysin plasmid pAD1 was introduced into strains CG110 and CG130, and the frequency of Tn*916* transposition from the chromosome to pAD1 was measured by determining the number of Tc^r, hyper-haemolytic transconjugants obtained after filter-mating of these

Table 2 Tn*916* transfer from plasmid-free donors

Donor strain	Recipient strain	Frequency of Tc^r transconjugants per recipients*	Representative transconjugants
DS16C3	JH2-2	1×10^{-8}	CG110 CG130 CG140
CG130	JH2SS	2×10^{-8}	CG131 CG132 CG133
CG110	JH2SS	4×10^{-6}	

* Filter matings were carried out as described in ref. 4, using Difco antibiotic medium no. 3 (AB3), and an initial ratio of one donor per ten recipients. Antibiotics were used in selective agar plates at the following concentrations: tetracycline, 10 μg ml^{-1}; rifampin, 25 μg ml^{-1}; fusidic acid, 25 μg ml^{-1}; and streptomycin, 1000 μg ml^{-1}. For reasons discussed in ref. 4, we generally express frequencies in terms of recipients (rather than donors) in cases where the values are very low. Frequency of spontaneous Tc^r mutations was less than 10^{-10}.

donor strains with JH2SS. The hyperhaemolytic phenotype results from an insertion within or near the haemolysin determinant of pAD1, and can be readily detected by an increased diameter of haemolysis zones on horse blood agar plates[4]. The frequency of hyperhaemolytic, Tc^r transconjugants was found to be more than 200 times higher when CG110 was the donor strain (4.9×10^{-6} per recipient) than when CG130 was the donor strain (1.8×10^{-8}). pAD1, *per se*, transferred equally well ($\sim10^{-2}$) from both hosts. Similar results were obtained with another independently isolated variant, CG100, which transferred Tn*916* at frequencies about 10 times higher than normal; transposition from the CG100 chromosome to pAD1 was similarly increased. These data indicate Tn*916* transfer and transposition may share a common step.

When located on a conjugative plasmid, Tn*916* was found to excise at relatively high frequency upon transfer to a recipient strain. pAM180 is a derivative of the ~26 kilobase erythromycin-resistance (Em^r) plasmid pAM81 with Tn*916* inserted into the *Eco*R1 fragment G. When donor strains containing pAM180 were filter-mated with JH2SS, a high degree of segregation of the Em^r and Tc^r determinants occurred, as can be seen in the data of Table 3. Although both the Em^r and Tc^r determinants transferred at similar frequencies, a significant proportion of erythromycin selected transconjugants (43–77%) were not resistant to tetracycline.

Of those transconjugants selected for tetracycline resistance, however, greater than 90% were also erythromycin resistant. Interestingly, in some of the erythromycin selected transconjugants that were tetracycline resistant Em^r and Tc^r were no longer linked, as implied by a great reduction in the transfer frequency of Tc^r, but not Em^r, in secondary matings. The loss of the Tc^r determinant from the plasmid possibly relates to a zygotic induction of one or more Tn*916*-related recombination enzymes.

To determine the structural integrity of pAM81 DNA sequences in the various types of transconjugant, DNA from representative plasmids was digested with *Hin*dIII and analysed by agarose gel electrophoresis (Fig. 2*a*). Plasmid DNA isolated from two Em^rTc^r transconjugants in which Em^r and Tc^r were no longer linked (CG184 and CG186) exhibit a restriction pattern identical to that seen for pAM81. (Note the two fragments of pAM180 that had contained Tn*916* sequences were lost, and pAM81 fragment G reappeared). It is presumed that Tn*916* transposed to the bacterial chromosome in these strains since they were tetracycline resistant and capable of transferring Tn*916* at very low frequency. Plasmid DNA from strain CG187 (Em^rTc^s) also gave rise to a restriction pattern identical to that of pAM81. In contrast, plasmid DNA from strain CG181 (Em^rTc^r), in which both resistance determinants remained linked, displayed a restriction pattern identical to that of the pAM180 donor. These data support the view that transposition involves an excision followed by insertion, but that insertion is not necessarily coupled to excision—in which case the excised element is lost.

Analogous results were obtained in matings that used as a donor strain CG190. This strain harbors a pAD1 derivative (pAM190) with two transposon insertions: Tn*917* (Em^r) and Tn*916* (see Table 1). The Tn*916* insertion gave rise to a nonhaemolytic phenotype, yet the strain displays a hyperhaemolytic phenotype on blood plates that contain tetracycline (10 μg ml^{-1}). This drug-influenced phenotype has been observed previously in certain pAD1::Tn*916* derivatives containing transposon insertions into or near the haemolysin determinant[9]. CG190 transferred Em^r at a frequency of $\sim2\times10^{-4}$ per donor to JH2-2 in overnight broth matings; and Tc^s derivatives (for example CG191) as well as Tc^r derivatives in which the Em^r and Tc^r determinants were no longer linked (CG194) were found among the transconjugants at a frequency of about 4%. Agarose gel electrophoresis of *Eco*R1 digested plasmid DNA from such transconjugants (Fig. 2*b*) revealed the presence of a fragment (*Eco*R1 D fragment) that had been missing in the original pAM190 DNA as a result of Tn*916* insertion. Most significant was the additional observation that transconjugants CG191, CG192, and CG194 all regained the haemolytic phenotype, implying that the excision of Tn*916* was precise.

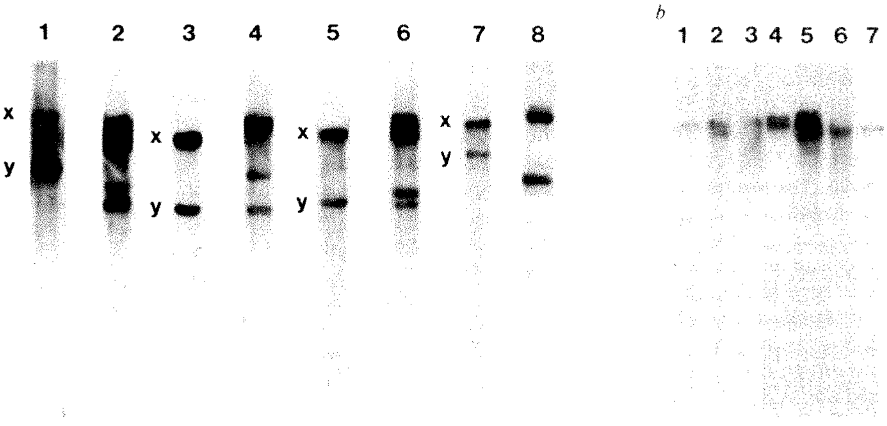

Fig. 1 Autoradiograms obtained from filter-blot hybridization analyses of chromosomal DNA from Tc^r transconjugants. *a*, *Hin*dIII digested DNA (1–2 μg) from transconjugants CG110, CG140, and CG130, (lanes 2–4 respectively) which were obtained using DS16C3 (lane 1) as donor. Lanes 5–7 contain *Hin*dIII digested DNA from transconjugants CG131, CG132, and CG133, respectively, which were obtained using CG130 as donor. Fragments marked x and y denote presumed chromosome–transposon junction fragments. Lane 8 contains *Hin*dIII digested pAM211 DNA and hybridizing bands are approximately 18.5 Kb and 7.5 kb. *b*, *Eco*R1-digested DNA (1–2 μg) from strains CG133, CG132, CG131, CG130, CG110, and DS16C3, (lanes 1–6 respectively). Lane 7 contains *Eco*R1 digested pAM211 DNA from which the probe had been made. Isolation of DNA by buoyant density gradient centrifugation and agarose gel electrophoresis was as described in ref. 4. DNA transfer and hybridization were essentially according to Southern[8] as modified by Wahl *et al.*[23], and used a BRL blot transfer system. The *Eco*R1 F′ fragment of pAM211 was purified by electroeluting the DNA from an agarose gel slice placed in a dialysis bag filled with electrophoresis buffer that had been embedded in 1% agarose. Following electrophoresis[4] the DNA was recovered by ethanol precipitation. Nick translation of pAM211 *Eco*RI F′ probe DNA with either ^{32}P-dCTP (670 Ci mmol^{-1}) or ^{32}P-dATP (410 Ci mmol^{-1}) was carried out using a nick-translation kit.

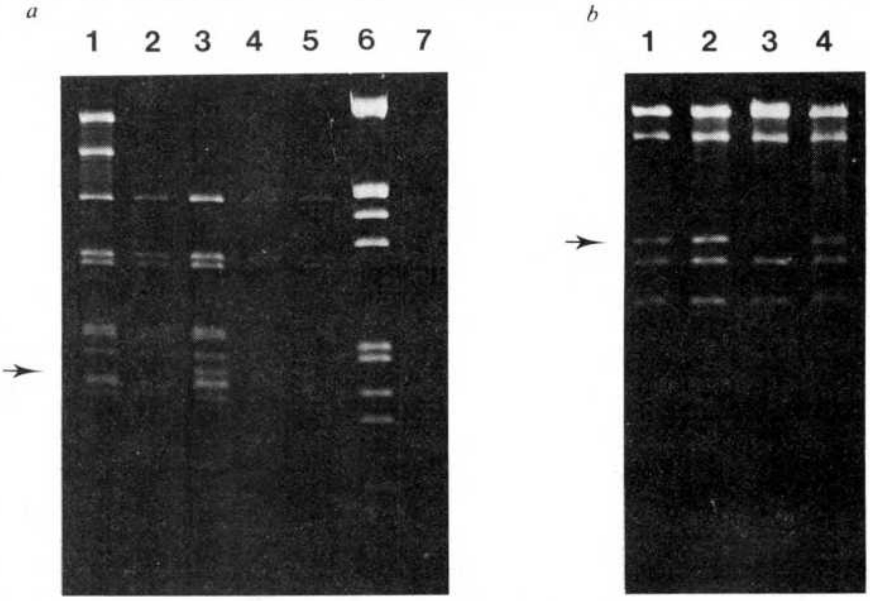

Fig. 2 Excision of Tn*916* from plasmid DNA after transfer to recipients. *a*, *Hin*dIII digests of transconjugant plasmid DNAs derived from the CG180 donor. Lanes 1 and 2 contain plasmid DNA from CG180 and CG130 (pAM81), respectively. The arrow marks fragment G, no longer present after Tn*916* insertion into pAM81. Lanes 3–5 contain plasmid DNA from the $Em^{r}Tc^{r}$ transconjugants CG184 and CG186, and the $Em^{r}Tc^{s}$ transconjugant CG187. Lane 7 contains plasmid DNA from the $Em^{r}Tc^{r}$ CG181 strain, and lane 6 contains λ DNA digested with *Eco*R1 and *Hin*dIII. *b*, *Eco*R1 digests of transconjugant plasmid DNAs derived from the CG190 donor. Lanes 1–4 contain plasmid DNA from the $Em^{r}Tc^{s}$ transconjugants CG191 and CG192, and the $Em^{r}Tc^{r}$ transconjugants CG193 and CG194. The restriction pattern obtained for pAM190 is identical to that of CG193 (data not shown). The arrow marks the *Eco*R1 fragment D of pAD1, lost as a result of Tn*916* insertion and regenerated after excision. The highest molecular weight band in lanes 1, 2 and 4 represents a doublet and includes the pAD1 *Eco*R1 A and B::Tn*917* fragments; whereas the highest molecular weight material in lane 3 represents a triplet which includes the *Eco*R1 D::Tn*916* fragment. (Broth matings were performed as in ref. 24.) Agarose gel electrophoresis utilized a 1% (Fig. 2*a*) or 0.7% (Fig. 2*b*) gel and Tris-borate buffer[25].

Transconjugants in which the Em^{r} and Tc^{r} markers remained linked, such as CG193, displayed an *Eco*R1 restriction pattern like the donor and were, as expected, nonhaemolytic.

On the basis of information known thus far we suggest the following model for Tn*916* behaviour. When located on the bacterial chromosome Tn*916* may spontaneously excise at low frequency. Although there is no direct evidence for the form the excised element might take, we think that it is most probably a circular molecule incapable of vegetative replication. Assuming that induction of key enzymes accompanies the excision step, the element now has the potential to: (1) insert back into the chromosome at a new, or perhaps the original site; (2) insert into a resident plasmid; (3) transfer into a recipient strain (if conditions warrant it); or (4) segregate. Conjugation could be viewed as occurring by a plasmid-like process, with zygotic induction of appropriate enzymes facilitating insertion into the recipient chromosome. The generation of multiple copies of Tn*916* in some transconjugants could arise by secondary transpositions (still via excision-insertion) from a replicated portion of the chromosome to an unreplicated region. Completion of replication thus results in one of the daughter chromosomes having two transposons. Conceivably when Tn*916* enters a new cell, a certain amount of time (a generation or so?) may be required to achieve levels of 'repressor' sufficient for stable maintenance of the element at one site. During this time there could be a tendency to move from one site to another.

Table 3 Segregation of Em^{r} and Tc^{r} in filter matings involving CG180 donors

	Em^{r} Tc^{r} transconjugants		
Experiment	Erythromycin selected*	Tetracycline selected	Erythromycin selected Em^{r} Tc^{r} transconjugants with unlinked markers
1	27/47 (57%)	41/43 (95%)	6/12
2	16/48 (33%)	46/48 (96%)	1/12
3	11/48 (23%)	44/48 (92%)	1/10

Tn*916* was inserted into pAM81 to generate pAM180 via overnight filter matings between CG110 (pAM81) and JH2SS followed by selection for tetracycline resistant transconjugants capable of transferring Tc^{r} linked to Em^{r} in secondary matings. (The plasmid pAM81, originally identified in *S. faecalis* DU81 is capable of conjugal transfer in filter matings at frequencies of about 10^{-4} per donor, Y. Yagi and L. Dempsey, personal communication.) Each donor was derived from a single colony isolate and was filter mated with JH2SS (JH2-2 in secondary matings) as described in Table 2. Frequency of Em^{r} and Tc^{r} transconjugants was 0.6–1.5×10^{-5} per donor.

* Although $Em^{r}Tc^{s}$ transconjugants appeared readily, random analyses of the CG180 donor failed to detect any Tc^{s} colonies (135/135 were $Em^{r}Tc^{r}$) implying dissociation of Tc^{r} occurred after, or during, transfer.

In view of the increasing reports of 'plasmid-free' transfer of resistance determinants, especially among the streptococci, Tn*916* may represent a prototype of a new class of genetic elements that could be referred to as 'conjugative transposons'. In this regard Smith and Guild[10] have recently obtained evidence suggesting that the conjugative multiple resistance element originating in *S. agalactiae* B109 may be located on a large transposon.

It is important to note that homology has recently been demonstrated between Tn*916* and the transferable Tc^{r} determinants (classified as *tetM*) of *S. pneumoniae* and *S. agalactiae*[11,12] as well as with a chromosomal Tc^{r} determinant (not yet shown to be transferable) in *S. mutans*[13]. Recent reports of transferable nonplasmid elements in *Clostridium difficile*[14] and *Bacteroides fragilis*[15–18] suggest that such elements may exist in a variety of prokaryotic genera (including Gram negative bacteria). Although certain R-plasmids in *Escherichia coli* (IncJ)[19] and *Haemophilis*[20] prefer to be integrated in the chromosome, their possession of replication functions and dependence on host recombination functions to integrate distinguishes these elements from Tn*916*.

We thank A. Franke, R. Craig, R. Hart, F. Macrina, M. Smith, J. Shaw and Y. Yagi for helpful discussions. This work was supported by NIH grants DE02731 and AI10318. C.G. is a recipient of a Public Health Service postdoctoral fellowship.

Regulatory sites for *his3* gene expression in yeast

Kevin Struhl*

MRC Laboratory of Molecular Biology, Hills Road,
Cambridge CB2 2QH, UK

The expression levels of many genes are regulated in response to particular environmental or developmental cues. A simple regulated gene can conceptually be divided into three elements: structural components that encode the gene product, promoter elements that are essential for gene expression, and regulatory elements responsible for changing the level of expression after a specific stimulus[1,2]. When cells of the yeast *Saccharomyces cerevisiae* are subjected to amino acid starvation, *his3* and many other amino acid biosynthetic genes are expressed threefold above the basal level[3,4]. Previously, I isolated mutations mapping outside the structural gene that severely reduce or eliminate *his3* expression[5,6]. These mutations define two distinct *his3* promoter elements located 115–155 and 32–52 base pairs (bp) from the site of transcriptional initiation. Here I describe 18 small deletion mutations, some of which express *his3* at the basal level but are unable to increase the level of expression in the appropriate physiological conditions. These define two regulatory sites located 32–41 and 80–100 bp upstream from the site of transcriptional initiation, and they strongly suggest that these regions are necessary for the positive regulation of *his3* expression. I consider the results in terms of models for the general control of amino acid biosynthesis.

his3 encodes imidazoleglycerol phosphate dehydratase (IGPD), an enzyme involved in histidine biosynthesis. Its expression is regulated coordinately with the genes involved in amino acid biosynthesis. When yeast cells are starved of histidine, methionine or tryptophan by adding appropriate inhibitors to the growth medium, the levels of IGPD increase about threefold (Table 1). In addition, *his3* expression is controlled in the expected manner by the *aas2* and *tra3* genes.

It is probable that *his3* is regulated solely as a function of general amino acid biosynthesis: first, IGPD levels do not depend on the presence or absence of histidine in the growth medium (Table 1). Second, growth conditions resulting in the selective induction of histidine biosynthetic enzymes have never been found. Third, mutations selected for defective regulation of histidine enzymes always affect other amino acid biosynthetic enzymes also[3]. These experiments, which fail to demonstrate histidine-specific regulation in yeast, are identical to those that clearly establish such control in *Salmonella typhimurium*.

The mapping positions of 18 mutations of the cloned *his3* gene are presented in Table 2. Each mutation deletes sequences (ranging between 9 and 66 bp) within the untranscribed region located 6–138 nucleotides upstream from the 5′ end of the gene. Using standard techniques, the mutant genes were introduced back into yeast cells so that the resulting strains contained one copy of the cloned DNA per cell at the normal *his3* chromosomal location (for experimental details see Fig. 1 legend). Strains harbouring these cloned mutant alleles were always grown in medium containing histidine so that *his3* expression was gratuitous for cell growth; inducing conditions were achieved by starving the cells of tryptophan. The IGPD levels are shown in Table 2. Two strains were examined for each *his3* allele. One strain contained all the original transforming DNA sequences; the other lacked the vector sequences and is equivalent to replacement of the original *his3*-532 mutation by the allele of interest (see Fig. 1 legend). The IGPD levels for both strains of any given mutant were always the same. Of the 18 mutations tested, 9 regulate *his3* expression properly. However, strains with any of the nine mutations produce IGP constitutively, that is, the enzyme levels are the same in normal conditions and during amino acid starvation. Thus, these nine mutations have the expected properties of *his3* regulatory mutations.

his3 regulatory sites are defined by comparing the DNA sequences of mutations that either regulate or fail to regulate *his3* expression. The simplest interpretation of the data assumes that: (1) a subset of the sequences deleted by a regulatory mutation is essential for normal regulation; and (2) sequences deleted by correctly regulated derivatives are unimportant. Such analysis, when applied to all the derivatives, leads to the simple and internally consistent description of *his3* regulatory elements illustrated in Fig. 2 and discussed below. It is difficult to disprove alternative explanations for the phenotype of any given mutation, and more complex models can be advanced to explain the data.

The extent of *his3*-Δ22 indicates a regulatory site that includes a sequence between 32 and 41 bp upstream from the start of transcription (nucleotides −32 to −41). Deletion of this region accounts for the regulatory defects of five other mutations (*his3*-Δ20, Δ21, Δ23, Δ24 and Δ25). As yet, the DNA sequences sufficient to constitute this regulatory site are not well mapped. However, sequences further upstream than −52

Table 1 Regulation of the *his3* gene

Strain	Genotype	Complete	−His	−Trp	+AT	+Eth
KY29	*trp1*-289 *his3*$^+$	1.0	1.0	3.0	3.0	3.2
KY137	*trp1*-289 *his3*-532	<0.1	NG	<0.1	NG	NT
KY107	*aas2*-5039 *his3*$^+$	1.0	1.1	NT	1.5	1.3
KY108	*tra3*-1 *his3*$^+$	3.0	3.0	NT	3.5	3.4

The yeast strains used were: KY29 (*mat-a ura3*-52 *trp1*-289) isolated by M. Thomas as strain M1-2B; KY137 (*mat-a ade2*-1 *ura3*-1 *ura3*-2 *trp1*-289 *his3*-532 *can1*$^-$) isolated by S. Scherer; KY107 (*mat-a aas2*-5039) and KY108 (*mat-a tra3*-1) both obtained from G. Fink[3]. Because *tra3*-1 renders strains temperature-sensitive for growth, all cultures were incubated at 27 °C with shaking. Complete medium contained 2% glucose, 0.67% yeast nitrogen base without amino acids (Difco), and 0.1 mg ml^{-1} each of histidine, tryptophan, uracil and adenine. In these conditions, the doubling time was 2 h for all strains except KY108, which doubled every 3 h. Strains incubated in complete medium lacking histidine (−His) grew at the same rate, except for KY137 which did not grow (NG). Cells grown in either of these non-starvation conditions were collected in the middle of exponential growth ($A_{600} = 2$ or $\sim 2\times 10^7$ cells ml^{-1}). To achieve amino acid starvation, cells were first grown in complete medium until A_{600} was ~1.0, concentrated by centrifugation, washed once with distilled water, and then resuspended in complete medium that either lacked tryptophan (−Trp), lacked histidine but contained 10 mM aminotriazole (+AT), or contained 20 μM ethionine (+Eth). The resuspended cells were incubated for a further 6–9 h; the cells undergo an average of one more cell division before their growth is arrested as a result of Trp, His or Met starvation. To determine the levels of IGPD activity, cells were collected, washed twice with water, permeabilized with 1.5% chloroform at 37 °C for 20 min, pelleted by centrifugation, and resuspended in 0.1 M triethanolamine, pH 7.7. The enzyme assay was performed as described previously[12] with minor modifications (to be published elsewhere). The enzyme levels are normalized to both the number of cells assayed and to the amount of absorbance at 290 nM released after chloroform treatment. The activity levels shown are relative to those of wild-type yeast grown in complete medium (defined as 1.0). For enzyme levels around 1.0, the error is ~10%.

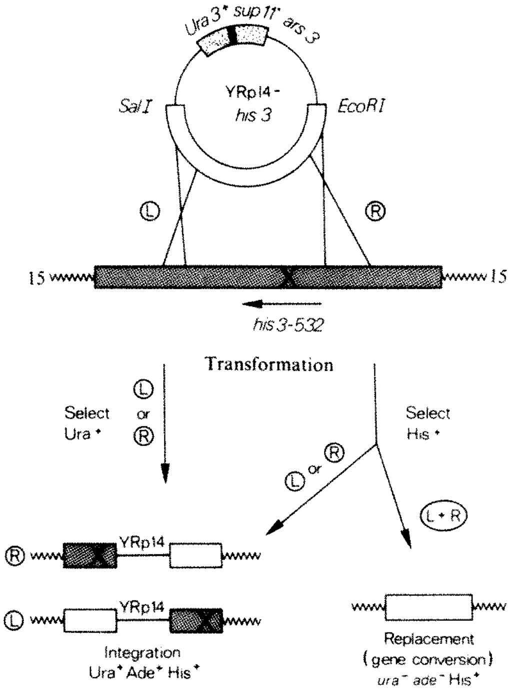

Fig. 1 Determining the phenotypes of cloned *his3* derivatives. The wild-type *his3* DNA used in these experiments (Sc2605) is a 6.1-kilobase pair (kb) fragment generated by *Eco*RI and *Sal*I cleavage[12]. In addition to the entire *his3* locus, it contains 2.9 kb flanking the 3′ end and 2.5 kb flanking the 5′ end. The isolation, haracterization and DNA sequence determination of the mutant derivatives of Sc2605 will be described elsewhere. The upper part of the figure shows the structure of *his3* hybrid molecules. All *his3*-containing DNA fragments (open boxes) were cloned into YRp14 (solid line with dotted boxes; see ref. 16), a vector containing the *ura3* gene, the ochre suppressing version of a tyrosine-inserting tRNA (*SUP11*), and *ars3*, a sequence that inefficiently causes hybrid molecules to replicate autonomously. YRp14 hybrid DNAs were introduced into KY137, a strain containing the ochre suppressible allele *ade2*-1, nonrevertible alleles *ura3*-1,2 and *his3*-532, and the revertible *trp1*-289 allele. Chromosome 15 of this strain is indicated by a wavy line below the YRp14-*his3* hybrid molecule. The shaded box indicates the 6.1-kb region homologous to the cloned *his3* derivatives; X marks the location of the *his3*-532 mutation[13]. Ura$^+$ or His$^+$ transformants were selected after 5 days of growth at 30 °C. All cloned *his3* fragments produced an equal number of His$^+$ and Ura$^+$ transformants for a given amount of DNA, except for Sc2884 (*his3*-Δ38) which produced no His$^+$ colonies. Essentially all such transformants were mitotically stable for the marker selected in the initial transformation event, indicating that the transforming sequences recombined with genomic DNA. Transformants containing autonomously replicating hybrid molecules were obtained only after ≥10 days. This is probably due to the inefficiency of *ars3*[16] and to lethality associated with multiple copies per cell of tyrosine-inserting suppressor tRNAs[14]. The figure shows recombination with the *his3* locus of chromosome 15. The L cross-over occurs to the left of the *his3*-532, while the R cross-over occurs to the right of this allele. The resulting structures are shown at the bottom. The YRp14 vector sequences which include *ura3*$^+$ *sup11*^{o} *ars3* are indicated by a solid line. Almost all the Ura$^+$ transformants were also His$^+$ Ade$^+$ while the His$^+$ transformants fell into two classes. The class of His$^+$ transformant that was also Ura$^+$ Ade$^+$ is genotypically equivalent to the Ura$^+$ transformants. In this case, the entire YRp14 hybrid molecule has integrated into the genome. As most of the homology between the transforming DNA and the genome is *his3* DNA, integration probably occurs at the *his3* locus; this was true for all cases tested explicitly. The transformants that arise by integration are due to a single L or R cross-over. The other class of His$^+$ transformant is *ade*$^-$ *ura*$^-$ and results from replacement of the *his3*-532 allele by the transforming allele, probably via gene conversion[15]. This class is equivalent to the double (L+R) cross-over. Both classes of transformants should have one copy of the transforming DNA per cell. For the integration class, multiple copies of the *SUP11*-containing transforming DNA per haploid genome should be lethal and for the replacement class, it is difficult to envisage mechanisms that could result in multiple copies of *his3* and none of *ura3*. Indeed, hybridization analysis supports the above contentions. It is possible that cross-overs occur between the *his3*-532 and the cloned *his3* alleles—this would generate either the wild-type allele and/or the double mutant. However, as these alleles are very close (less than 250 bp; see ref. 13) recombination between them is rare[5]. In this regard, note that the phenotype of each allele was tested in two independent transformants.

or downstream from −32 are unlikely to be involved because both *his3*-Δ26 (which deletes nucleotides −53 to −80) and *his3*-Δ18 (nucleotides −32 to −21 deleted) are regulated properly.

The structures of the remaining deletion mutations suggest a second regulatory site: *his3*-Δ28 (nucleotides −106 to −53 deleted) and *his3*-Δ29 (nucleotides −106 to −73 deleted) fail to regulate *his3* expression. However, the related pair that differ only in the upstream breakpoint (*his3*-Δ26 lacking −80 to −53 and *his3*-Δ27 lacking −80 to −73) are regulated properly. By subtraction, these results strongly suggest a second regulatory site that includes at least a subset of the sequences between −80 and −106. The upstream boundary of this site is defined further by deletions 32–35. These mutations remove sequences between −101 and −137, but do not prevent *his3* regulation. Some of them do seem, however, to have reduced basal levels of expression.

Thus, there seem to be at least two regulatory elements for *his3* expression separated by at least 30 bp. The downstream element maps between −32 and −52 and includes a region localized between −32 and −41, the upstream element maps somewhere between −80 and −100.

It is worth comparing the sequence of the *his3* regulatory regions defined here[4,7] with the nucleotide sequence of *his4*[8], a gene that is co-regulated with *his3*. The *his3* sequence between nucleotides −44 and −31, TATATAAAGTAATG, strongly resembles the *his4* sequence TATATAATAGATATG, which is located 46–60 bp before the mRNA start point[8]. These sequences contain 12 out of 14 identical base pairs if a single base pair is allowed to 'loop out'. With regard to the upstream regulatory element, the *his3* sequence between −97 and −90, ATGACTCT, shares 7 out of 8 base pairs with the *his4* sequence ATGACTAT located between −86 and −79. Furthermore, highly conserved variants of this sequence are found at *his3* sequences −139 to −132 (ATGCCTCG) and −178 to −171 (ATTACTCT) and *his4* sequences −137 to −130 (GTGACTCA) and −181 to −174 (GTGACTCC). This striking sequence homology supports the view that these regions are important in *his3* regulation.

Either of two simple models could account for the increased *his3* expression in conditions of amino acid starvation. In one, the gene interacts with positive regulatory factors that stimulate expression above the basal level; in the other model, the *his3* gene interacts with negative regulatory factors that maintain the basal level, and *his3* induction occurs by the inactivation of these factors. Proof of a positive and/or negative mode of *his3* regulation depends on the properties of purified regulatory factors with respect to the appropriate target DNAs. Nevertheless, evidence for the nature of *his3* regulation can be inferred from the phenotypes of regulatory mutations at the *his3* locus.

By definition, mutations at a positive regulatory site would result in basal levels of *his3* expression in all growth conditions. Indeed, five mutations (deletions 20, 22, 23, 24 and 28) have such a phenotype—this strongly suggests that at least some of the sequences deleted by these mutations comprise a positive regulatory site. The other four regulatory mutations result in constitutive expression below the basal level; thus it is difficult to assess their phenotype in terms of positive or negative control.

As for the possibility of negative control, so far I have obtained no *his3* mutations that result in constitutive *his3* expression at the induced level; these would be expected if the gene contains a site of negative regulation analogous to the

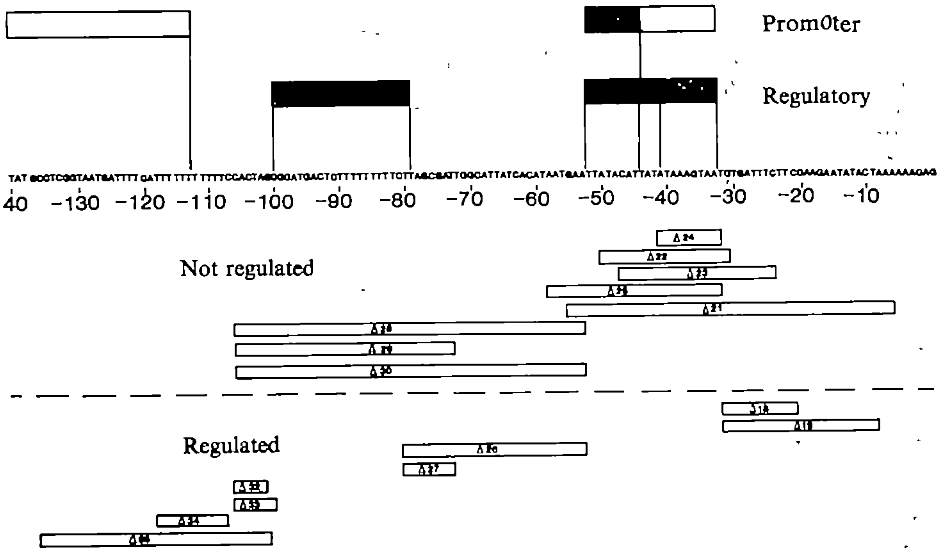

Fig. 2 *his3* promoter and regulatory elements. The open boxes on the top line indicate the extent of promoter elements defined previously[5,6] and the shaded boxes on the second line indicate the location of positive regulatory elements described here (the black regions within these boxes indicate sequences that are essential but not necessarily sufficient for promoter or regulatory function) These elements are placed with respect to the coding strand of the 5′ flanking region (nucleotides +1 to −140 defined with respect to the start of transcriptional initiation). The mRNA start was previously defined to an accuracy of ±1 bp[7]. The location of the deletion mutations used in this study are indicated below the DNA sequence. Deletions above the broken line do not allow for properly regulated *his3* expression, while the deletions below the line are regulated correctly.

operator of the *Escherichia coli* lactose operon. Nevertheless, it is possible that the five mutations expressing *his3* constitutively at the basal level could delete a negative regulatory site and simultaneously reduce promoter activity threefold. However, the principal advantage of deletion analysis is the ability to eliminate DNA sequences and hence genetic functions. For example, nine mutations described here eliminate regulatory behaviour, and 30 mutations (described in refs 5, 6) eliminate detectable *his3* expression. Thus, it seems unlikely that the five critical deletions fortuitously result in the same quantitatively minor defect, particularly considering the fact that nine deletions having full or partially reduced *his3* levels in normal conditions regulate the gene properly. Therefore, the mutants strongly support a positive control mechanism for *his3* expression as opposed to a negative one.

Table 2 Structures and phenotypes of *his3* derivatives

Fragment	*his3* allele	Upstream end point	Junction sequence	Downstream end point	Basal level	Induced level
Sc2605	Wild type	—	—	—	1.0	3.0
Sc2854	Δ18	−32	RI	−21	0.5	1.5
Sc2857	Δ19	−32	RI	−32	0.7	2.0
Sc3101	Δ20	−43		−31	1.1	1.0
Sc3102	Δ21	−56		−6	0.2	0.2
Sc3110	Δ22	−50		−31	1.2	1.3
Sc3111	Δ23	−47		−24	0.8	1.0
Sc3112	Δ24	−41	CC	−32	1.1	1.4
Sc3113	Δ25	−58	TCC	−32	0.2	0.2
Sc3121	Δ26	−80	RI	−53	0.9	2.7
Sc3122	Δ27	−80	RI	−73	0.6	1.5
Sc3125	Δ28	−106	RI	−53	1.1	1.0
Sc3126	Δ29	−106	RI	−73	0.2	0.3
Sc3129	Δ30	−119	RI	−53	0.2	0.1
Sc3138	Δ31	−106	RI	−109	1.0	3.1
Sc3159	Δ32	−106		−102	0.8	2.9
Sc3160	Δ33	−106		−100	1.2	3.2
Sc3161	Δ34	−118		−107	0.2	0.6
Sc3165	Δ35	−136		−101	0.5	1.2
Sc2884	Δ38	−80	RI	−32	<0.1	<0.1

All Sc fragments (first column) are derivatives of Sc2605 (see Fig. 1 legend). The *his3* deletion allele numbers and the end points with respect to the start of transcription (determined elsewhere by direct DNA sequencing) are indicated (columns 2 and 3). In some cases, there are junction nucleotides at the site of deletion (RI, *Eco*RI octanucleotide linker, 5′-GGAATTCC-3′). For each *his3* allele tested, 1 Ura$^+$ transformant (containing one integrated copy of the transforming DNA) and 1 His$^+$ transformant (in which the *his3*-532 allele is replaced with the transforming *his3* allele) were grown (see Fig. 1 legend for details). These always gave similar results; the values shown represent the averages of the two strains. To obtain the basal IGPD levels for a given mutation, strains were grown in complete medium. To obtain enzyme levels in starvation conditions, tryptophan was removed from the medium (see Table 1 legend for the methodology and reliability of the assay).

The data presented here suggest that the *his3* regulatory region consists of two separable positive control sites, each of which can be destroyed without apparently impairing promoter function. The conclusions represent the simplest formal description of the data, but have no bearing on the molecular mechanism by which *his3* expression is modulated in response to amino acid starvation. As induction of IGPD activity is accompanied by an increase in *his3* mRNA[9], it is likely that regulatory sites are involved in transcriptional initiation; this, however, has not been proved.

The key question is the nature of the 'positive regulatory factor'. Some possibilities are: (1) a protein product(s) that binds specifically to the sequence(s) defined as regulatory elements; (2) a conformational or covalent alteration in yeast RNA polymerase II that senses the regulatory sequences; (3) a structural feature of chromatin; and (4) a structural change in the *his3* transcript that affects its stability or translatability. Biochemical analysis of strains harbouring 'regulation-defective' *his3* alleles should be useful for distinguishing among these and other molecular models. Preliminary results with wild-type cells suggest that the chromatin structure and the mRNA structure are unchanged during amino acid starvation (ref. 4 and K.S., in preparation).

In considering molecular models for *his3* regulation, it is worth comparing the results obtained here with those of an analogous situation in *E. coli*. Amino acid starvation of *E. coli* results in increased expression of amino acid biosynthetic genes and decreased expression of those encoding stable RNA species such as the tyrosine-inserting tRNA. A mutation of this tRNA gene that changes sequences between the downstream promoter element (the Pribnow box) and the start of transcription retains promoter function but is regulated incorrectly[10]. Further, *in vitro* transcription of this gene using purified components suggests that regulation of the tyrosine tRNA promoter is mediated by the interaction of *E. coli* RNA polymerase with guanosine tetraphosphate[11]. It is striking that the *his3* regulatory site between −32 and −41 also maps between (or overlaps with) the TATA box region and the mRNA start. Whether this means that regulation in yeast occurs by a mechanism similar to that used by *E. coli* remains to be determined.

I thank Andrew Travers and Marvin Wickens for fruitful discussions. This work was supported by the Jane Coffin Childs Foundation and the National Institute of General Medical Sciences (grant GM 30186).

Isolation of a mouse pseudo tRNA gene encoding CCA—a possible example of reverse flow of genetic information

J. G. Reilly*, R. Ogden† & J. J. Rossi‡

‡ Department of Molecular Genetics, City of Hope Research Institute, Duarte, California 91010, USA

Transfer RNA genes offer an interesting system for studies of gene regulation. From experiments conducted with tRNA genes from eukaryotes, it seems that transcriptional regulatory regions are contained within the mature coding sequence of the DNA[1–4]. In tRNA genes of some yeast, *Xenopus* and *Drosophila*, intervening sequences located within the anticodon loop have been identified[5–8], thus adding a new dimension to tRNA expression. In contrast to the lower eukaryotes, relatively few mammalian tRNA genes have been studied. The genes obtained so far have been identified via cloned heterologous fragments, or labelled tRNA probes[9–11]. We sought to use synthetic oligodeoxyribonucleotide probes to isolate mouse phenylalanyl tRNA genes. We report here the isolation of a segment of DNA that is completely homologous to our 19-mer probe, as well as 38 nucleotides corresponding to the 3′ end of tRNA$^{\mathrm{Phe}}$. The 5′ end of the gene is not present in our 1.7 kilobase clone. In addition, this pseudo gene has an encoded CCA. Since CCA is added post-transcriptionally to all known eukaryotic tRNAs for which genes have been identified, we believe this pseudogene to be representative of RNA encoded information going back into DNA.

We chose to isolate a mouse gene coding for tRNA$^{\mathrm{Phe}}$ by using as a probe a synthetic oligodeoxyribonucleotide 19-mer complementary to a portion of the known mammalian tRNA$^{\mathrm{Phe}}$ sequence[12,13] (see Fig. 1*a*). The strategy utilized was the screening of a partially digested mouse DNA library inserted at the *Hin*dIII site of pBR322. This plasmid library was used to transform *Escherichia coli* and selection was made for ampicillin resistant colonies. The colonies were screened for the tRNA$^{\mathrm{Phe}}$ gene containing inserts as described in Fig. 1 legend. Figure 1*b*, *c* shows autoradiographs of colony hybridizations with the synthetic probe. Four putative positives were obtained by the colony screening, two of which gave positive hybridization results on rescreening. These two clones appeared to be siblings as judged by DNA restriction (not shown). One of these plasmids, designated as pMTF3, was chosen for further studies.

Figure 2*a* presents ethidium bromide stains of restriction endonuclease digestions of pMTF3. Digestion with *Hin*dIII yielded a 3.4 kilobase pair (kbp) vector band, and 1.2 and 1.7 kbp insert bands. It is not known if the two *Hin*dIII inserts were due to ligation of partially digested DNA or were the result of ligation of two separate fragments. To test which of the two *Hin*dIII fragments contained the sequence homologous to the 19-mer probe, the DNA in the gel was transferred to nitrocellulose[14] and then hybridized with the ^{32}P-labelled synthetic 19-mer probe. These results demonstrated that only the 1.7 kbp *Hin*dIII fragment contained a sequence homologous to the probe (Fig. 2*a*). Digestion of pMTF3 with *Ava*I (CPyCGPuG) gave three stained fragments that had summated fragment lengths equal to undigested pMTF3. No hybridization with the 19-mer probe was seen in the *Ava*I digest (Fig. 2*a*). This same lack of hybridization was observed with *Hpa*II (CCGG) and *Sma*I (CCCGGG) digests (data not presented). This failure to detect hybridization with the 19-mer probe in the *Ava*I, *Hpa*II and *Sma*I digests is due to the presence of these sites in the middle of the region of complementarity to the 19-mer probe (Fig. 1).

Fig. 1 Colony screening with a synthetic oligonucleotide complementary to tRNA$^{\mathrm{Phe}}$. *a*, The sequence of mammalian tRNA$^{\mathrm{Phe}}$[12,13] (above) with the 19 base oligodeoxyribonucleotide complementary to the 3′ region of the tRNA, and a 15 base oligonucleotide containing the same sequence as the dihydrouridine stem and loop region (below). Both oligodeoxyribonucleotides were synthesized using the phosphotriester method (38). *b*, Examples of colony screening using the synthetic 19 mer as a probe. Approximately 5 μg of mouse BALB/c liver DNA (partially digested with *Hin*dIII) was ligated with 1 μg of pBR322 DNA digested with *Hin*dIII and treated with alkaline phosphatase. This DNA mix was used to transform *E. coli* strain MC1061[39] from which approximately 1 × 10^5 transformants were obtained, about 90% of which were tetracycline sensitive. This represents approximately 15–20% coverage of the genome. These colonies were first replicated to dry, sterile nitrocellulose filters. The colonies on nitrocellulose were used to make replicas onto Whatman 541 paper[40]. The nitrocellulose replicas were incubated on L-agar plates containing ampicillin (30 μg ml^{-1}) and used as masters for retrieving positively hybridizing colonies. The Whatman 541 replicas were treated according to Gergen *et. al.*[40], and hybridized with 75 pmol (500 × 10^6 c.p.m.) ^{32}P-polynucleotide kinase labelled 19-mer. The hybridizations were carried out overnight at 45 °C in 3–5 ml per filter of 6 × SET (30 mM Tris-HCl pH 7.5, 0.9 M NaCl, 6 mM EDTA), 5 × Denhardt's medium, 0.5% Nonidet P40 following 2–3 hours of prehybridization in the same buffer. The filters were washed in 6 × SET at progressively higher temperatures, beginning with 20 °C, until background hybridization was satisfactorily eliminated[41]. The final wash was at 45 °C. After washing, the filters were autoradiographed at −70°C on Kodak XRP-1 film with a DuPont Lightning Plus intensifying screen. *b*, A small area (approximately 1 cm) corresponding to the region of a positively hybridizing colony was scraped, diluted, replated and rescreened with the 19-mer probe. *c*, Positively hybridizing, isolated single colonies from the rescreening were used for DNA isolations.

Using standard double and triple restriction endonuclease digestions, a restriction site map for pMTF3 was constructed (Fig. 2*b*). Since the *Sma*I site (Figs 1*a*, 2*b*) is in the centre of the region of complementarity with the 19-mer probe, the DNA sequences including and surrounding this site were determined by the chemical cleavage method[15].

The DNA sequencing results are summarized in Fig. 3. From these data we find a region of perfect homology to the probe. Comparison to the known tRNA$^{\mathrm{Phe}}$ sequence (Fig. 3) demonstrates that 38 contiguous nucleotides of the tRNA$^{\mathrm{Phe}}$ 3′ region are included in the cloned segment. This homology diverges within the region corresponding to the tRNA$^{\mathrm{Phe}}$ anticodon loop.

0028-0836/82/460287—03$01.00

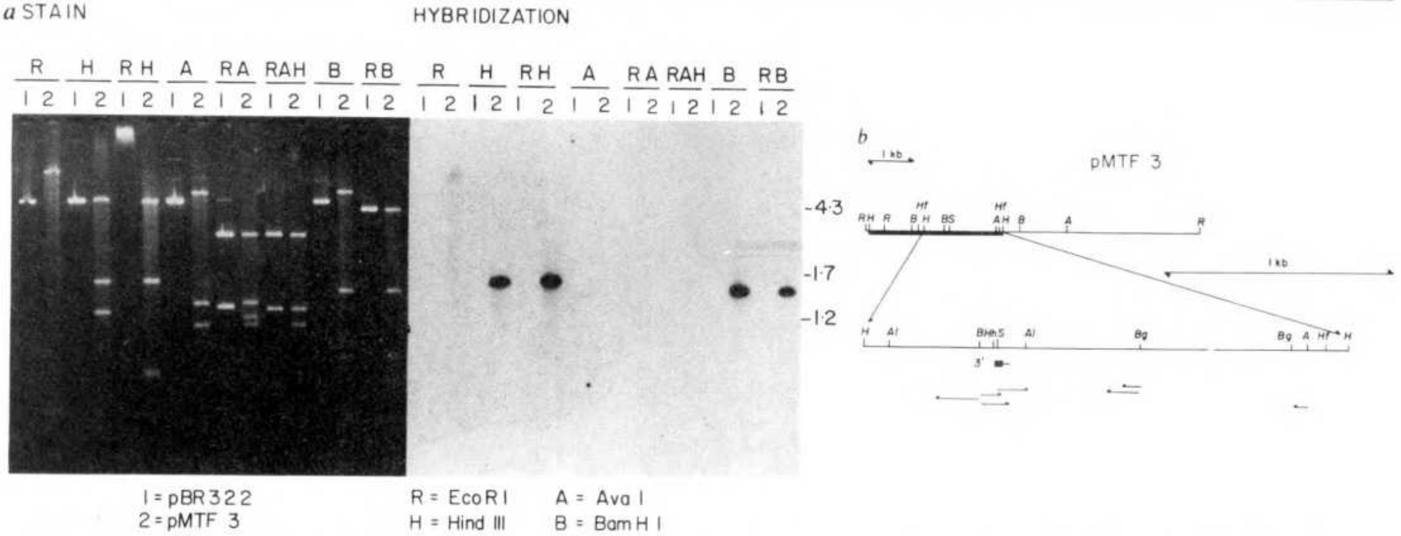

Fig. 2 *a*, Restriction endonuclease digestions and hybridization of the 19-mer probe to pMTF3. Plasmid DNA from pMTF3 was prepared and purified by ethidium bromide CsCl gradients[42]. This DNA was then treated with various restriction enzymes (as shown) under conditions described by Bethesda Research Laboratories (BRL). Samples were then subjected to electrophoresis through an 0.8% agarose gel. The gel was stained and photographed. Markers of *Hin*dIII, *Eco*RI and *Hpa*II digested λ DNA were run in adjacent channels (not shown). Transfer of the DNA to nitrocellulose was by the method of Southern[14]. Prehybridization of the filter was at 42 °C in 6×SSC plus 5×Denhardt's medium for 12 hours[34]. Hybridization was for 36 hours with 6×SET, 5×Denhardt's, and 50×10^6 c.p.m. ^{32}P-labelled 19 mer. After hybridization, the filter was washed four times for 1 hour each at 42 °C in 6×SSC and exposed to Kodak XAR-5 film at −70 °C with DuPont Lightning Plus intensifying screens. The faint hybridization of the 19-mer probe to the *Eco*RI digest was the result of poor transfer from the gel to nitrocellulose. *b*, A restriction site map of pMTF3. Shown is the pBR322 vector linearized at its *Eco*RI site and emphasizing the *Hin*dIII inserts. The position and polarity of the tRNA$^{\mathrm{Phe}}$ psuedogene sequence is shown (■). Also depicted are the restriction sites used for labelling and the direction of DNA sequencing. Restriction sites shown are R, *Eco*RI; H, *Hin*dIII; B, *Bam*HI; S, *Sma*I; A, *Ava*I; Al, *Alu*I; Bg, *Bgl*II; Hf, *Hin*fI; and Hh, *Hha*I.

No sequence completely homologous to the 5′ end of tRNA$^{\mathrm{Phe}}$ was found within 100 base pairs from this point of divergence (Fig. 3).

In an attempt to localize the 5′ end of tRNA$^{\mathrm{Phe}}$, a synthetic oligodeoxyribonucleotide containing the dihydrouridine stem and loop region sequences of tRNA$^{\mathrm{Phe}}$ (Fig. 1) was chemically synthesized. This 15-mer was used to probe DNA from pMTF3 as described above. The only hybridization observed generated a weak signal with a restriction fragment which maps to the 3′ side (downstream) of the region of the 19-mer homology (data not presented). DNA sequence analyses of this region did not demonstrate any region of complete homology with the 15-mer probe nor with the known tRNA$^{\mathrm{Phe}}$ sequence.

The presence of the 3′ end of tRNA$^{\mathrm{Phe}}$ and the apparent absence of the 5′ end suggests a pseudogene. The presence of an encoded 3′ terminal CCA in our cloned segment is also quite unusual. An examination of published sequences for over 50 nuclear tRNA genes from such diverse higher eukaryote sources, such as, *Bombyx*, *Drosophila*, *Xenopus*, rat and man, reveals no encoded CCAs[7,10,11,16–23]. Furthermore, none of the 22 mouse[45] or human[24] mitochondrial tRNA genes encode CCAs. All available evidence suggests CCAs are added post-transcriptionally in eukaryotes. Several other interesting features of the cloned mouse DNA segment in pMTF3 must be considered. The position at which the cloned sequence diverges from the known tRNA$^{\mathrm{Phe}}$ sequence is one base pair off from the site at which an intervening sequence has been localized in some eukaryotic tRNA genes[5–8]. The 5′ end of tRNA$^{\mathrm{Phe}}$ has some points of weak homology to pMTF3 in the region sequenced. These sequences are noted in Fig. 3. We do not know if these similarities represent divergence in the 5′ region or if they are random. The nucleotide sequence presented in Fig. 3 has been analyzed for tRNA-like secondary structures using the computer program developed by Staden[25]. No structures capable of forming stable tRNA secondary structures with the appropriately conserved nucleotides were predicted by this search.

In screening 15–20% of the mouse genome (see Fig. 1 legend), we obtained a single tRNA$^{\mathrm{Phe}}$ related recombinant (pMTF3). This yields a minimum estimate of five tRNA$^{\mathrm{Phe}}$ related sequences per haploid genome. We have not yet isolated the complete tRNA$^{\mathrm{Phe}}$ gene. This could be due to a lower than predicted gene copy number, or a bias in our cloning approach.

To determine if the cloned tRNA$^{\mathrm{Phe}}$ pseudogene was indeed derived from mouse, the *Hin*dIII 1.7 kbp insert fragment was used as a probe to mouse genomic DNA. The results presented in Fig. 4 show a smear of hybridization spread over the entire

Fig. 3 DNA sequence of pMTF3 in the region of 19-mer homology. The pMTF3 sequence is aligned with the known mammalian tRNA$^{\mathrm{Phe}}$ sequence using the tRNA$^{\mathrm{Phe}}$ CCA as the start point. Nucleotides in the pMTF3 sequence which are present in the corresponding position of tRNA$^{\mathrm{Phe}}$ are underlined. Note that the 5′ terminal tRNA$^{\mathrm{Phe}}$ sequence GCCGAAA is present as an inverted segment at the same relative position in pMTF3. Other areas of interest, such as direct (→ →), inverted (→ ←), pallindromic repeats (← →), and the position at which an intervening sequence would be expected to occur (∧) are indicated.

genomic restriction profile for each of the enzymes or combinations tested. Hybridizations done under identical stringent conditions with mouse ribosomal gene probes yielded specific banding patterns[26]. The broad hybridization distribution of the 1.7 kbp. *Hin*dIII band to numerous genomic fragments indicates the presence of repetitive elements in the clone. In a separate experiment (not shown), mouse genomic DNA was hybridized to restriction digests of pMTF3. The data indicate that there are repeated sequences located on both sides of the pseudo gene. The vector DNA showed no homology to mouse. It is not known whether these elements are tRNA genes or members of a mouse family of repeated sequences, or both.

The origin and functional significance, if any, of all psuedogenes is of interest. In *E. coli* several psuedogene sequences for tRNA$^{\text{Tyr}}$ which contain partial, but non-degenerate homology with the mature coding sequences are found distal to the mature coding sequences[27]. Some biological function is suggested since they are stably maintained in the chromosomes of several *E. coli* K12 strains[28] and are included in the tRNA$^{\text{Tyr}}$ containing primary transcripts[29]. Little is known concerning any possible functional role of eukaryotic pseudogene sequences. The *Xenopus* 5S RNA pseudogenes are 85% homologous with the 5S genes[30]. In one report the pseudogene sequence was observed to be transcribed following injection of the cloned DNA segment into *Xenopus* oocytes[31]. It is not clear whether these sequences are transcribed *in vivo*. Transfer RNA pseudogenes which share degenerate or incomplete homologies with the mature coding sequences, have been described for *Drosophila* tRNA$^{\text{met}}$ (ref. 20) and rat tRNA$^{\text{Gly}}$ and tRNA$^{\text{Glu}}$ (ref. 23). Unlike the tRNA$^{\text{Phe}}$ pseudogene sequence reported here, neither the *Drosophila*, nor rat pseudogene sequences contain an encoded CCA. Mammalian pseudogenes for globin, tubulin and immunoglobin have been reported which have structural and sequence features suggesting an RNA origin[32–34].

Any model used to explain the origin of the tRNA$^{\text{Phe}}$ pseudogene sequence must take into account the facts that this sequence is completely homologous with 38 3′-terminal nucleotides of tRNA$^{\text{Phe}}$ and has an encoded CCA. This region of homology is more extensive than the tRNA priming sequences found in retroviral DNAs (~18 nucleotides)[35], although we cannot eliminate a retroviral origin for this pseudogene sequence. Since we do not know the structure of the tRNA$^{\text{Phe}}$ gene itself, we can only speculate based on analogy with other eukaryotic tRNAs that the CCA is added post-transcriptionally, and therefore is not encoded.

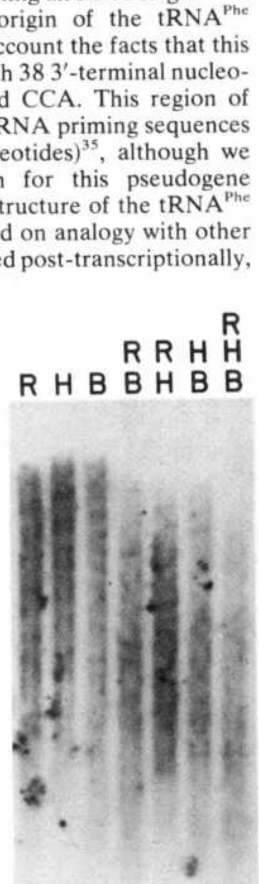

Fig. 4 Hybridization of pMTF3: *Hin*dIII A band to mouse genomic restriction digests. DNA from a male BALB/*c* kidney was prepared and digested with various combinations of *Eco*RI, E; *Hin*dIII, H; or *Bam*HI, B. Completion of the digests was verified using λ DNA as an indicator. The samples were then subjected to electrophoresis through 0.8% agarose, stained and photographed. Markers of lambda *Hin*dIII and λ *Eco*RI were run in adjacent channels. The DNA in the gel was then transferred to nitrocellulose by the method of Southern[14]. The probe was prepared by first digesting pMTF3 with *Hin*dIII, separating out the fragments depicted in Fig. 2, and recovering the *Hin*dIII A band via electroelution. The recovered band (0.5 μg) was then nick translated[43] with [α-^{32}P]dCTP. Hybridization of the probe to the filter was by the method of Wahl *et al.*[44], with modifications of Reilly *et al.*[26]. The final wash was at 65 °C in 0.2 × SSC. Autoradiography was as described for Fig. 2.

The presence of an encoded CCA suggests that the information of the mature tRNA was reverse transcribed and integrated into the mouse genome. A similar phenomenon is suggested for tubulin[33] and immunoglobulin pseudogenes[34]. We do not know the mechanisms by which RNA characteristics, such as poly(dA) stretches, attached to intron-less coding regions (as seen in tubulin and globin pseudogenes) or the encoded CCA in pMTF3 arose. To explain the origin of such pseudogene sequences, mechanisms of the reverse transcription and genomic integration of the segments must be understood. In the absence of any clearly identified primer, we find it difficult to understand how a reverse transcript of only the 3′ end of tRNA$^{\text{Phe}}$ arose. With regard to integration of this pseudo-gene into the genome, repeated family sequences could be involved. The recent discovery of mammalian nuclear extrachromosomal circular DNA containing *Alu* family sequences suggests a possible intermediate[37]. In the case of several small nuclear RNA pseudogenes, the pseudogene sequences are flanked by short (16–19 bp) direct repeats[36]. We do not observe these types of repeats flanking the tRNA$^{\text{Phe}}$ pseudogene, although pMTF3 does contain repetitive sequences (Fig. 4). Any further insight into the origin of this pseudogene must await isolation and analysis of the complete tRNA$^{\text{Phe}}$ gene.

Effect of interferon on protein glycosylation and comparison with tunicamycin

Kenneth Olden*†, Bruno A. Bernard*† Willie Turner‡ & Sandra L. White*‡

The present wide interest in the mechanism of action of interferon (IFN) stems from its antiviral and anticancer potential. Possibly one of the more interesting insights into the antiviral action of IFN was recently described by Maheshwari *et al.*[1]. These authors, including one of us (K.O.), reported that IFN-treated cells release viral particles with low infectivity, and that this low infectivity seems to be related to the reduced amount of membrane protein glycosylation. The implications of this suggestion are exciting because inhibitors of glycosylation have antiviral properties, and also selectively kill transformed cells (see ref. 2 for review). An effect of IFN on the sysnthesis and cell-surface expression of glycoproteins could have an important role in its antiviral, anticancer and immunoregulatory actions. We have examined, for the first time, the effect of IFN on glycosylation of cellular proteins. We used murine fibroblasts (L-cells and NIH-3T3), plasmacytoma cells (P3 × 63 Ag8) and vesicular stomatitis virus (VSV) to compare the action of IFN with tunicamycin (TM), a known inhibitor of glycosylation[2]. Our results indicate that IFN does not inhibit the glycosylation of cellular or viral glycoproteins. Cells treated with IFN do not produce nonglycosylated species of glycoproteins nor the 'glucose/glycosylation regulated proteins'[3] (GRPs), in contrast to cells treated with tunicamycin[4].

Fibroblasts were grown in Eagle's minimal essential medium (MEM) as described by Maheshwari *et al.*[1,5–8], and plasmacytoma cells in Dulbecco–Vogt[9] modified Eagle's medium containing high glucose (4,500 mg l^{-1}). Cells were infected with VSV at a multiplicity of 0.5–10 plaque forming units (PFU) per cell as previously described[1,5–8], and radiolabelled substrates were added 3 h post-infection. Plaque formation was determined according to standard assay procedure[10] with confluent cultures of L-cells.

First, we compared the effects of IFN and TM on the glycosylation of cellular protein by monitoring the rate and total incorporation of D-[U^{14}C]glucosamine and D-[2^{3}H]mannose into the total trichloroacetic acid-insoluble fraction of the cell. The results of a representative 48-h incorporation experiment are shown in Table 1*a*. It is apparent that none of the concentrations of IFN were effective in inhibiting glycosylation of cellular protein, in marked contrast to TM. Similarly, no differences were found in the rate of incorporation into cultures monitored at hourly intervals for up to 3 h. Likewise, IFN had no effect on the glycosylation of specific proteins as evident by inspection of the fluorogram shown in Fig. 1*a*. This conclusion is also supported by the finding that IFN-treatment does not induce the synthesis of the GRPs, in contrast to cells treated with TM (Fig. 1*b*, and refs 4, 11).

To investigate further the effect of IFN on the glycosylation of specific cellular glycoproteins, metabolically labelled fibronectin (FN) and immunoglobin G (IgG) were isolated by immunoprecipitation and analysed by SDS-polyacrylamide gel electrophoresis (SDS-PAGE). Inspection of the fluorograms in Fig. 2 shows that IFN does not decrease the glycosylation of either protein as shown by similar incorporation of radiolabelled carbohydrate precursor and by lack of shift in electrophoretic mobility as would be expected if the proteins were depleted of carbohydrate[12].

To determine if treatment of cells with IFN had any effect on the size or structure of the oligosaccharide chains of an asparagine-linked cellular glycoprotein, glycopeptides of FN were isolated from control and IFN-treated 3T3 cells and subjected to exhaustive digestion with pronase. The glycopeptides were analysed by Bio-Gel P4 filtration, treatment with *endo-β-N-*acetylglucosaminidase H (*endo* H), and by their

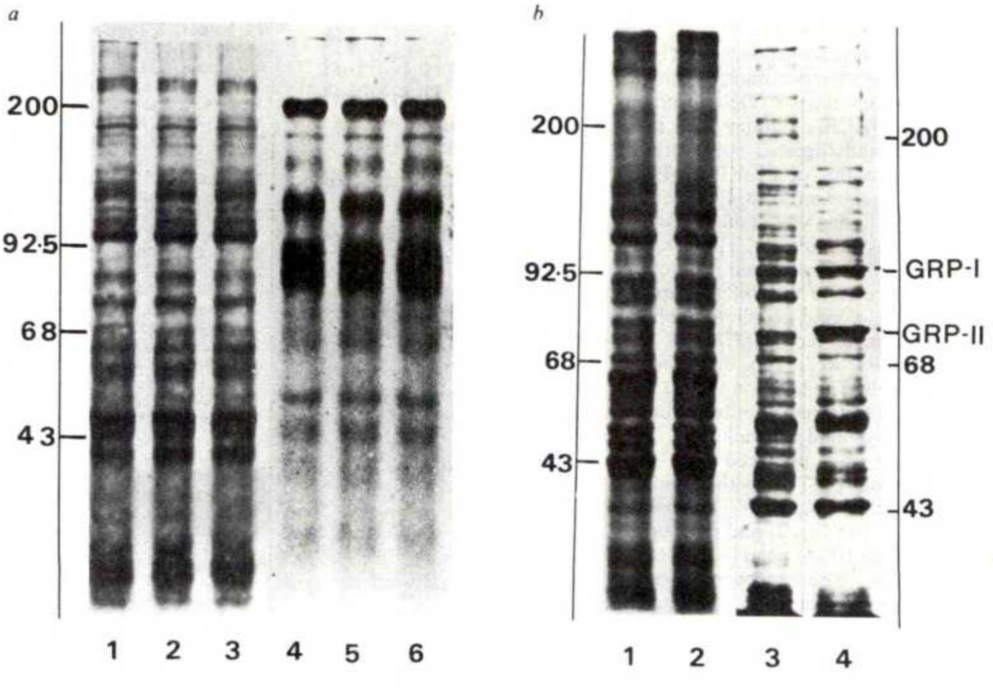

Fig. 1 *a*, Effect of IFN on glycosylation of plasmacytoma cellular proteins. Lanes 1, 2 and 3 represent ^{14}C-leucine (2 μCi ml^{-1}, specific activity 2 Ci mmol^{-1}) labelled cells incubated with 0, 30 and 250 U ml^{-1} of mouse fibroblast IFN (specific activity >4 × 10^{7} mouse reference units per mg protein) respectively. Lanes 4, 5 and 6 represent parallel cultures treated with similar amounts of IFN, but labelled with ^{14}C-D-glucosamine (5 μCi ml^{-1}, specific activity 238 mCi mmol^{-1}). Cells were preincubated with IFN for 16 h, then radioactive precursors were added and incubation was continued for 48 h. SDS-PAGE and fluorography were performed as previously described[23,24]. Protein was determined by the Lowry procedure[25] with bovine serum albumin standards. Similar results were obtained with IFN concentrations up to 1,000 U ml^{-1}, at 24 and 36 h, or with IFN purchased from Lee Biomolecular Research Laboratories. *b*, Effect of IFN and TM on the induction of the 'glucose/glycosylation regulated proteins'. Mouse L-cells were labelled with ^{14}C-leucine and incubated with IFN as described in Fig. 1 legend. Cells were pretreated for 6 h with TM before addition of ^{14}C-leucine. Lanes 1 and 2 represent cells treated with 0 and 30 U ml^{-1} IFN, respectively, and lanes 3 and 4 represent cells treated with 0 and 1.0 μg ml^{-1} TM, respectively. Similar results were obtained with IFN concentrations up to 1,000 U ml^{-1}.

0028–0836/82/460290—03$01.00

interaction with concanavalin A (Con A)–Sepharose. We found that glycopeptides from both the control and IFN-treated cells were resistant to *endo* H, reacted with Con A, and co-eluted on Bio-Gel columns with a molecular weight (~2,300) characteristic of the complex-type oligosaccharide (results not shown).

The above experiments provide strong evidence that IFN does not significantly alter the carbohydrate moieties of asparagine-linked cellular glycoproteins.

To determine if VSV produced in the presence of IFN contain surface carbohydrates, viral particles isolated from control and IFN-treated cultures were examined with respect to their specific binding to Con A–Sepharose. If viral particles released from IFN treated cells are depleted of the carbohydrate moiety on glycoprotein G, then they should not bind to Con A.

Table 1 Effect of tunicamycin and interferon on glycosylation of cellular protein (*a*) infectivity of VSV (*b*) and binding of VSV to concanavalin A–Sepharose (*c*)

a, Glycosylation

TM-treated	210,000	17 ± 5	2

a, Test cultures were preincubated for 6 and 16 h with TM or IFN, respectively, before the addition of radiolabelled precursors. Cells were labelled for 24 h with leucine (2 μCi ml^{-1}), glucosamine (2 μCi ml^{-1}) and mannose (5 μCi ml^{-1}), extracted once with 10% TCA and twice with 5% TCA. The precipitate was dissolved in 0.5 M NaOH, neutralized with HCl, diluted in Aquasol (NEN) and counted by liquid scintillation spectrometry. A representative experiment is shown; however, the experiment was performed several times by different individuals with similar results. In addition, incorporation of radiolabelled precursors was monitored for 48 h with IFN, and no inhibition of incorporation was observed. *b*, Cells were pretreated with IFN (30 U ml^{-1}) for 16 h. Virus production, purification and infectivity assay are described above in the legends to the figures. *c*, The amount of ^{14}C-leucine radioactivity associated with the purified viral particles was determined, and equal number of counts were applied to gels to show that these fractions contained equivalent amounts of virus-specific proteins (see Fig. 3). The total protein in these fractions was shown to be the same by the Lowry procedure. As IFN treatment (30 U ml^{-1}) of the L-cells inhibited viral production by 10–20-fold, we had to use 10 times more IFN-treated than control cultures to obtain a similar yield of viral particles. Cells were treated with 1.0 μg ml^{-1} of TM. The binding to Con A was performed according to the procedure of Gibson *et al.*[15], except that the lectin-coupled gel beads were in suspension.

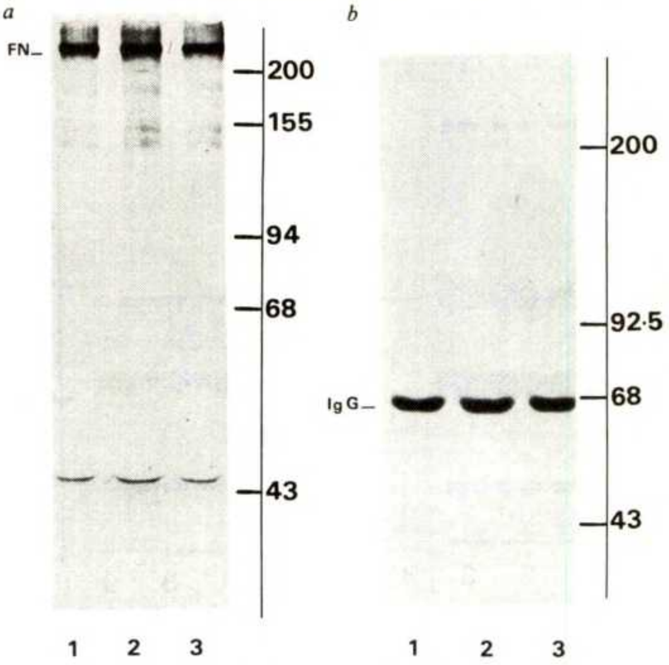

Fig. 2 Effect of IFN and TM on glycosylation of specific cellular proteins. *a*, 3T3 cells were treated with IFN and labelled with ^{14}C-D-glucosamine as described in Fig. 1 legend. FN was isolated by immunoprecipitation as described previously[3]. Lanes 1, 2 and 3 represent 0, 30 and 250 U IFN ml^{-1} respectively. *b*, Plasmacytoma cells were treated with IFN and labelled with ^{14}C-D-glucosamine as described in Fig. 1 legend. IgG was isolated by mixing 1.0 ml of the conditioned, cellular debris-free medium with 40 μl of goat anti-mouse IgG (160 μg protein; Cappel) and incubated for 60 min at room temperature. The precipitate was collected by centrifugation, and washed twice with phosphate-buffered saline. Lanes 1, 2 and 3 represent 0, 30 and 250 U ml^{-1} IFN. Similar results were obtained with IFN concentrations up to 1,000 u ml^{-1}.

However, we found that >94% of the purified viral particles, from both control and IFN-treated cultures, were specifically adsorbed to Con A as shown in Table 1*c*. As this lectin binds to mannose-containing oligosaccharides, this suggests that glycoprotein G is glycosylated in the presence of IFN. This was confirmed by direct fluorographic analysis of ^{14}C-D-glucosamine labelled viral particles (Fig. 3, lanes 4–6).

Previous studies have shown that the absence of the carbohydrate moiety caused a drastic reduction in the amount of G protein incorporated into the released VSV particles[13–15]. Because the infectivity of VSV is dependent on this protein[15–21], this was used as an indirect measure of G present on the released virions. An equivalent number of viral particles, isolated from control and IFN-treated cultures, was spread on a lawn of L-cells, incubated for 72 h at 37 °C and scored for PFU. The particles produced in the presence of 30 U ml^{-1} of IFN (the concentration used by Maheshwari *et al.*[1,5–8]) had the same specific infectivity as those produced by untreated control cultures (Table 1*b*). However, IFN drastically inhibited (10–20-fold) the production of VSV, and the viability of the IFN-treated, VSV-infected cells was not significantly compromised compared with infected cells not treated with IFN. Concentrations of IFN $\geq$150 U ml^{-1} did decrease infectivity, but had no effect on glycosylation. This finding suggests: (1) that IFN treatment does not selectively inhibit the incorporation of G into viral particles, and (2) that the primary mechanism of IFN's antiviral action is by inhibition of viral production as previously reported[22].

To demonstrate directly that the released virions are not defective in glycoprotein G, viruses were isolated from control and IFN-treated cultures and analysed by SDS-PAGE. The four viral proteins (L, G, N and M) are clearly visible in the fluorogram of ^{14}C-leucine-labelled viruses produced in either the presence or absence of IFN (Fig. 3, lanes 1–3), and the relative amounts of the four proteins are unaffected by IFN treatment. Careful inspection of the published data of

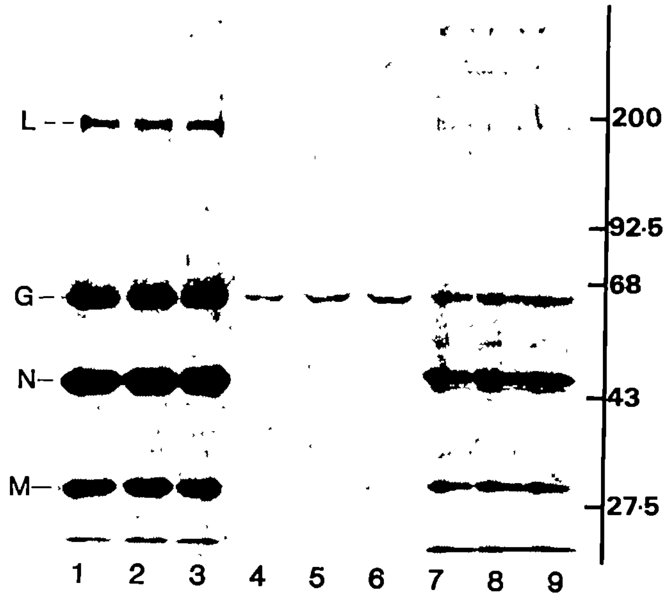

Fig. 3 Effect of IFN on protein G. L-cells were treated with IFN and metabolically labelled as described in Fig. 1 legend. To prepare purified viruses, the culture media were collected and centrifuged at 10,000*g* for 10 min to remove large cellular debris. The supernatants were centrifuged at 48,000*g* for 2 h. The pellets containing the virus were further purified by the sucrose density gradient procedure of Leavitt *et al.*[13]. The viruses were resuspended in MEM and centrifuged for 1 h at 100,000*g* to remove the sucrose. The viruses were then resuspended in MEM (without supplements) containing 100 μg ml^{-1} antifibronectin coupled to Sepharose 4B gel beads and incubated for 1 h at 5 °C on a rotatory mixer. The gel beads with the fibronectin containing membrane particles were removed by centrifugation at 10,000*g* for 10 min. The purified virus particles were stored in MEM at −70 °C, or immediately analysed by SDS-PAGE. Lanes 1, 2 and 3 represent the highly purified viral particles from cells treated with 0, 30 and 250 U ml^{-1} IFN. Glycoprotein G (lanes 4–6) was immunoprecipitated from 1 ml of a 1% Triton X-100 extract of viral particles (100 μg protein) by the addition of 50 μg of affinity-purified anti-G, and processed as described in Fig. 2 legend. Lanes 7–9 represent the crude viral particles from cells treated with 0, 30 and 250 U ml^{-1} IFN.

Maheshwari *et al.* (ref. 1, Fig. 1) shows that one likewise cannot make a strong case for a significant and specific decrease in glycoprotein G, contrary to their previous reports[6,7].

The results shown in lanes 1–3 of Fig. 3 are with viral particles that have undergone extensive purification, hence it is possible that virus with altered G protein was preferentially lost during purification. This possibility was evaluated by two different approaches. First, we determined the rate of G protein synthesis and glycosylation by pulse labelling with ^{14}C-leucine, ^{3}H-mannose or ^{3}H-glucosamine for 1 h at 3, 6 and 9 h post-infection of L-cells. Cells containing the newly synthesized viral protein were homogenized and analysed by SDS-PAGE. The polypeptide band corresponding to the G protein was cut from the gel, dissolved in 30% hydrogen peroxide and the radioactivity determined by liquid scintillation spectrometry. There was no apparent difference in the specific activity (^{14}C c.p.m./^{3}H c.p.m.) of carbohydrate precursor incorporation in the presence or absence of IFN (30–500 U ml^{-1}). The second approach involved the rapid isolation of viral particles without extensive purification. Media from VSV-infected cells, cultured in the presence or absence of IFN (30–500 U ml^{-1}), was centrifuged at 10,000*g* for 10 min, and the resulting supernatant at 100,000*g* for 30 min. The pellets containing the virus were homogenized and equal amounts of protein were electrophoresed. The fluorograms are shown in lanes 7–9 of Fig. 3. It is apparent that similar results are obtained with crude and highly purified viral preparations.

The results presented here show that IFN does not inhibit the glycosylation of asparagine-linked glycoproteins as previously reported[1]. When [2-^{3}H]mannose was used as an alternative labelling substrate for glycoproteins, similar results were obtained. Therefore, the results obtained with ^{14}C-D-glucosamine are not experimental artifacts. We conclude that the antiviral, antitumour and immunomodulatory actions of IFN are probably unrelated to glycosylation.

The present study does not agree with earlier reports by Maheshwari *et al.* claiming that IFN is an inhibitor of glycosylation[1] and that VSV released from IFN treated cells is deficient in glycoprotein G[6,7] and, as a consequence, is less infectious than virions released by untreated cells[1,5–8]. The basis for the apparent discrepancies in results are not immediately obvious as we used what we believe to be the same cells, virus and IFN as the previous investigators, and as we also used the same general procedures. Also, we were able to repeat the above results with a similar preparation of IFN obtained from Lee Biomolecular Research Laboratories. There is a major difference in experimental approach relative to viral purification; however, the apparent contradictions cannot be due to the isolation procedure as we were unable to repeat their findings even when we used less pure viral preparations. It is also important to point out that Maheshwari and Friedman[1,5–8] never studied the effect of IFN on the synthesis of host cell glycoprotein. Also, we have no information relevant to their finding that IFN inhibits the transfer of *N*-acetylglucosamine from UDP-*N*-acetylglucosamine into glycolipids[1].

We thank Dr Surinder Singh for technical assistance, Dr Edgar Hanna for plasmacytoma cells, and Mrs Lucy Kane for typing the manuscript. This investigstion was partially supported by the following grants: 5S07-RR05361 and R01–GM–29804–01 from NIH, and IN–132 from the American Cancer Society. Corrigenda

In the letter 'Crystal structure of a microbial ribonuclease, RNase St' by K. T. Nakamura *et al.*, *Nature* **299**, 564–566 (1982), four residues are shown incorrectly in Table 1. In RNase St, residue 212 should be 'Q', in RNase Ms residue 32 should be 'D', in RNase Ba residue 49 should be 'K' and in RNase U_2 residue 75 should be 'D'.

In the article 'Fossil mammals and artefacts from the Middle Awash Valley, Ethiopia' by J. E. Kalb *et al.*, *Nature* **298**, 25–29 (1982), the acknowledgements section should include thanks to the Boise Fund (Oxford University) for supporting one of the authors (Dr P. Whitehead).

MATTERS ARISING

The homing mechanism of pigeons

THE review by Gould[1] misrepresents essential aspects of our knowledge about pigeon navigation. Within the limited space available, I cannot substantiate this for the whole article, but can only enumerate the most drastic shortcomings concerning my own work.

In aviary (palisade) experiments: (1) The related papers[2–4] primarily deal with recoveries which comprise sufficiently large numbers (totalling 691!) to prove statistically significant differences between many of the differently treated pigeon groups. Gould discards all these data and considers only initial bearings, although it has been explained why those data are much less reliable (ref. 4, pp. 215–216). (2) Gould's Fig. 2 is meaningless (i) because of the generally restricted value of those initial bearings, (ii) because the semi-louvred palisade used at first[3] cannot be directly compared with the open aviary (ref. 4, p. 216), (iii) because the figure mixes different release and home sites in an unbalanced way, and (iv) because it does not even coincide with the published data[2,3].

(3) Gould lumps the data of two 'glass and open lofts' and two 'wood and louvred lofts' irrespectively of the orientation of the corridors open to airflow although just this alignment has been shown to influence the pigeons' behaviour[4]. (4) Gould's site-by-site calculations of angular deviations of experimentals from controls (Table 1) conceal rather than disclose the net homeward orientation, as the relation to home is abolished. (5) "These effects" (of the hybrid aviaries) "are generally interpreted as disrupting the pigeon map sense." I wonder where Gould read this. I stressed the influence of the corridors on the preferred compass direction only, but not on homeward orientation, the part requiring a functioning 'map'.

(6) Real differences in homeward orientation have been found between pigeons from completely open or louvred aviaries and much poorer oriented pigeons from aviaries completely shielded with glass walls[4]. These findings, however, primarily concern the "small proportion" of recoveries (sample sizes 58 and 63) and thus are neglected by Gould. (7) The corridor–aviary results[4] do not contradict "the olfaction hypothesis", but only a specific version that was published at that time[5,6].

Concerning the role of olfaction: (1) Gould writes that in my experiments the nerve-sectioned birds were "slower to home" than untreated pigeons. In fact, they did not home at all[6]. (2) It is well known that anosmic pigeons are not disoriented, but that their preference for a particular compass direction persists[6–8]. When homing is concerned, however, the level of homeward orientation is crucial[6,8], and the parameters extracted by Gould (vector lengths 0.8 and 0.4, average deviation 38°) include no information on that. Homeward components of anosmic pigeons (initial bearings as well as recoveries) are drastically and significantly reduced[6,9].

(3) Gould quotes Keeton's mention of a few nasal-tube pigeons that had landed after a short flight[10], but ignores the much more conclusive 75 recoveries of anosmic pigeons (and 61 of controls) at distances ranging from 10 to 700 km reported in my paper[6]. Differences between experimentals and controls in flight directions, yet not in distances, are highly significant. There is no "contrast to the disoriented birds in other" (which?) "experiments who continue gamely flying".

(4) In the nasal-tube experiments of Keeton *et al.*[11], "no disorientation was evident". This is true, but appropriate data analysis revealed significant differences between experimentals and controls in initial homeward orientation[6], and this is the crucial point (see above). (5) Gould confuses the matter when he mixes the primary question of whether olfaction is a substantial component of pigeon homing with the secondary question of how it might be integrated into the navigational system. By considering one specific hypothesis[5] about this secondary problem, and thus many experiments merely indirectly concerned with olfaction, he creates unjustified doubts also with respect to an affirmative answering of the primary question. After recent extensive discussion of the related problems[6], this kind of review of the field is obsolete.

The examples selected may warn the reader against trusting this review. Related literature published in the meantime is quoted in ref. 12.

IN his recent article on the homing mechanism of pigeons, Gould[1] says that when I replicated experiments with anosmic pigeons in Germany[2] no effect on initial orientation was evident, though homing speed was slower than in controls.

I would like to point out that, in my first series, pigeons made anosmic by inserting nasal tubes were homeward oriented and performed rather well in homing from a familiar site, whereas, when released from an unfamiliar site, they were randomly oriented, unlike the homeward-directed controls (the difference in homeward directedness was significant). To say that the homing speed of experimentals was slower is an overindulgent assessment of their performances; 12 out of 16 birds were lost (against 2 controls out of 18).

In my second series, both controls and experimentals underwent the section of one olfactory nerve and the plugging of one nostril (the contralateral in experimentals, the ipsilateral in controls). Despite this minimization of differences in treatment, homing performances were significantly worse in experimentals, with 61 birds out of 92 lost (against 36 controls out of 90). In this case no differences in initial orientation could be found for the simple reason that bearings of both controls and experimentals were randomly distributed. In this particular respect my experiments were inconclusive, whereas the rest of my results support the olfactory hypothesis.

2. Benvenuti, S *Z Tierpsychol* **51**, 406–414 (1979)

GOULD[1] writes that certain results obtained by my colleagues and myself, which support the olfactory hypothesis, "admit of simpler non-olfactory explanations". According to a first, "simpler" explanation, pigeons with nostrils plugged or olfactory nerves cut are slower in homing because of "a generalized, distracting trauma". Besides the fact that anosmia affects not only homing speed but also homing success[2–4], Gould fails to mention other important findings. (1) Homing capacity is strongly reduced in anosmic birds as compared with controls subjected to the same trauma (one nerve cut, one nostril plugged[5,6]). (2) Birds not subjected to trauma are indeed impaired in homing when prevented from smelling by nasal tubes[2,3,6], and disoriented after treatment of the olfactory mucosa with local anaesthetic, provided that smelling during transportation has been prevented[7]. (3)

0028–0836/82/460293—02$01 00

Anosmic pigeons are greatly impaired in homing from unfamiliar sites, but are not "distracted" by trauma when released from familiar ones[2,5,6,8]. Thus, anosmia affects navigation, not motivation or capacity for homing by using familiar landmarks[4].

The rotated orientation of deflector-loft birds[9-11] is attributed by Gould to the rotation of polarized light and of other visual cues rather than to that of incoming wind (another "simpler" explanation). Unfortunately, he drastically misinterprets the findings of Waldvogel and Phillips[12-14]. As these authors showed, pigeons raised in special lofts, which rotated wind and visual cues in different directions, were strongly deflected in accordance with wind-borne cues (Gould has probably got mixed up between pigeons raised in the deflector-lofts and foreign birds kept in them for a short time).

Other experiments of our group, Gould states, "cannot be repeated" or "have proved difficult to replicate". However, among the replications of our experiments performed abroad there is at least one for each kind of experiment that was successful. Fiaschi and Wagner[15] obtained positive results by applying masking odours to the beaks of pigeons, and the detour experiments of Schmidt-Koenig *et al.*[16] were successful. In fact, when one pools the bearings that were expected to deflect to the left or right in all the tries, one obtains two distributions which are different ($P < 0.005$) and rotated as predicted.

Three more of Gould's statements must be challenged. (1) It is incorrect to say that homeward orientation in anosmic pigeons has never been abolished. When releases were performed avoiding the effect of directional biases, initial orientation did not turn out to be homeward or showed a very poor homeward tendency[4,17,18]. (2) It makes no sense to say that we found that "homing speeds in the strong-odour experiment were unaffected", since untreated controls for comparing homing speeds were not used[19]. (3) It is not true that we found that "rearing birds with no olfactory experience whatsoever does not affect orientation". In the case[20] quoted by Gould, the experimentals were oriented randomly or in a direction different from that of home and controls.

Pigeon homing is a complicated, intriguing problem, but I do not feel that Gould's review contributed to its clarification. The part of his report concerning the olfactory theory appears to be more biased than one might honestly expect from the supporter of a rival hypothesis.

GOULD REPLIES—Wallraff's unusual techniques, data analyses and conclusions have always been found difficult to interpret. My approach was to apply a more conventional analysis to such of his original data as could be extracted from his papers. As indicated in the review, this included correcting the data for release-site bias—the "correct" orientation of birds is that adopted by controls rather than the actual map bearing—and considering only that universally used measure, the vanishing bearings. Viewed in this light, Wallraff's data begin to make sense to me. Wallraff, however, prefers his own methods.

Benvenuti, in the abstract of the paper cited, states "the poor initial orientation in either controls or experimentals in many single experiments and in pooled data was an insufficient basis for evaluation of the influence of olfactory deprivation on homeward directness". In other words, there was no clear effect on initial orientation.

As indicated in the review, Papi's results generally could not be replicated by either Keeton or Schmidt-Koenig. Even a casual reading of the papers cited removes the force of Papi's present remarks—in no case do the experiments cited clearly support the olfactory hypothesis to even a mildly sceptical mind. This is not to say that odour may not play a part in homing.

My conclusion, then as now, after reviewing all the evidence, is that "the olfactory hypothesis, though initially very exciting, has lost some of its lustre as a result of these many problems. It may yet turn out to be true . . ." The interested reader should examine the original papers bearing in mind (for what they are worth) the criticisms of the various methods and conclusions outlined in my review.

Incorrect colicin sequence

In response to an enquiry from Mr R. Parker of New Haven, Conneticut: In 1979, Dr D. H. Watson and I reported N-terminal and C-terminal amino acid sequences for colicin E1[1]. In the same paper we also described a cell-envelope-associated proteolytic activity that cleaved colicins E1, E2, E3 and K specifically to yield fragments that had either biological 'killing' activity or cell-binding properties. We suggested that such proteolysis might normally function to facilitate the transport of a colicin fragment to its target site for killing.

Early in 1980, Dr S. Luria, at the Massachusetts Institute of Technology, informed me that the N-terminal data obtained by Dr Watson were not consistent with those obtained in his laboratory, and in the summer of 1980, I circulated a note to a number of laboratories working with bacteriocins and similar proteins, informing them of our questionable data. Subsequently, direct sequencing of the colicin E1 gene[2] has confirmed that our published sequence data are erroneous. Moreover, although cell-envelope-mediated proteolysis of colicins of the kind described in our report has been demonstrated by several laboratories, its specificity and role in normal colicin function are not proven by our experiments.

Matters Arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 500 words and the briefest of replies, to the effect that a point is taken, should be considered.

BOOK REVIEWS

Fools and pedants

Fred Dainton

Universities, Politicians and Bureaucrats: Europe and the United States. Edited by Hans Daalder and Edward Shils. Pp.510. ISBN 0-521-23673-8. (Cambridge University Press: 1982.) £37.50, $74.50.

FIFTEEN years ago student unrest was widespread. Those of us who experienced it think of that period as a bygone age and speculate what those students, now in their mid-30s, are doing. But that is not the only question to be asked. More important are: Why was the movement in the United Kingdom so mild relative to those in Germany, France and the United States? Was it because it was managed better at the university level, that vice-chancellors are better than rectors and presidents at student relationships? Was it that the internal structures of the British universities and their interdigitation with central government were more adaptable, better able to absorb the assault on their values and to turn the anger into something more productive? And perhaps of greatest importance: What did this unrest imply for the prospects of universities in the future?

In so far as Britain is concerned the answer to at least one aspect of the last question is plain. As a former chairman of the University Grants Committee cast in the role of securing resources for universities, I can assert categorically that nothing made my task harder than the inanities and the behavioural extremes of those tiny groups of militant students and their unwillingness to allow free speech by others. They damaged the student image and with it the cause of university education.

Many books have been written about the causes of student unrest and the forms it took. By and large the techniques of "direct action" — the "sit-in", the attempts to give it legitimacy through the "general assembly", the trappings of a participatory democracy and so on — were common to all countries. So too were the characteristics of the activists, being drawn largely from the upper rather than the lower socio-economic groups and prone to fragment into doctrinally distinct groups — Maoists, Anarchists, Trotskyites, orthodox communists and those flirting with Laingian psychology or the drug subculture. The immediate causes seem to have differed from country to country; protest against the Vietnam war in the United States, nuclear power in Japan, the military–industrial complex generally.

This book is quite different. It is concerned principally with the way in which the universities and the governments in the United States and Europe reacted to student unrest. It was commissioned in 1974 by the International Council on the Future of the University (ICFU), which had grown out of the concern of a group of individual academics who met in 1970. They were convinced that a crisis existed in universities and that some fundamental academic and social values were threatened because, at least in the view of some of ICFU, governments and universities in some countries were accommodating to the unrest to extents which compromised those values. ICFU therefore asked Hans Daalder, Professor of Political Science at the University of Leyden, to bring together a group of scholars of high reputation, each of whom would be able to write about a particular country with scholarly objectivity.

The result of the labours of this group, mainly political scientists or sociologists, together with a lawyer and an economist, is a series of interesting essays concluded by a masterly, succinct and lucid survey by Daalder himself. There is no anger; just calm and judicial appraisal of the evidence after it had been subjected to the scrutiny of real professionals. Once started on it, I found the book extremely difficult to put down. Even setting aside what I acknowledge must be a deep personal interest in the subject, I believe that it would make enjoyable and profitable reading for anyone who cares about universities and their role in society. Indeed, I would recommend it to all who work in universities whether as administrators or as teachers, scholars and researchers, and to bureaucrats and politicians whose decisions have such a powerful influence on universities, especially in Europe. Daalder apologizes for the delay in the publication of these essays, but, in my view, that delay is a positive advantage. Not only has it allowed the writers a better perspective, the making of judgements in a more dispassionate manner than would have been possible when the phenomena being examined were also being experienced, but also the book appears at a time when the world recession has caused a reordering of social priorities and, for the students, of their personal priorities. The time has now come, as Rutherford said in the 1930s, when "We have less money, we must think harder".

The reaction in British universities to student revolt went through several phases. First there was the shock and hurt felt by academics that some students distrusted them and did not reciprocate the proffered friendship of the teacher. Then came annoyance at the disruption of work followed by resolve to identify and remove any genuine causes of grievance. Over the ensuing years adjustments were made at many levels within the universities but no vital principles were surrendered. Students were brought into governance and, like the professors, some made useful contributions and some did not; their verbosity was and remained in inverse relationship to the significance of their utterances. The essential academic freedoms of selection and assessment of students, of the hiring, firing and promotion of academic staff and of the control of the curriculum and how it should be presented were reserved as the exclusive responsibilities of the dons. Government did not intervene because it had no *locus standi* under the charter and statutes of each university and the most that it could have done would have been to persuade the Queen to revoke the Royal Charter or to instruct the University Grants Committee to withhold grants from a particular university. Either of these acts would have taken far too long to bring about and would have damaged the interests of the vast majority of students who were going about their business in the way that students have always done.

How very different was the situation in Europe, in some countries of which, unlike Britain, many universities were and are subject to special laws and professors were officials whose appointments were ultimately in the hands of the state. The disruption was greater, the student protest more violent and destructive, and there were many justifiable complaints about the manner in which many universities were run, which was more appropriate to the nineteenth century and quite unable to meet modern needs. In essence, professors were all powerful, running their institutes like private baronies; their assistants had little status and little influence in shaping the policies of either the institute to which they belonged or the university of which it formed a part. Because they did not share in this responsibility they felt no compelling reason to show loyalty to the institute or to the university when the troubles began. With no limitations on the number of students entering, and with very long courses before graduation, student numbers were high and teaching was mainly didactic, with the formal lecture to extremely large audiences the predominant mode. There was little small-group teaching and virtually no tutorials and, therefore, little personal contact with the full professors until the student proceeded to the level of serious research and the preparation of a thesis. Reforms were certainly overdue in Germany, France, Italy, Belgium and Holland. These reforms seemed beyond the imaginative power of the academics, at least during crisis, and even if the reforms could have been devised they would have been likely to be beyond the legal power of the university to implement. Therefore the state had to intervene. The forms that this intervention took in different countries are described and assessed in the book.

The overriding impression these accounts give is one of general ineptness on the part of politicians and bureaucrats; in matters of university governance they overreacted and overshot the mark by a large margin. They did so in part because they themselves were unsure of what universities should be and in part because of a rather pervasive mood that participatory democracy was a recipe for harmony in all orgaizations. A typical result was the imposition of the *Dreigruppenprinzip* on universities by which the governing body was made equally tripartite between elected academics, elected non-academic staff and elected students. The result was predictable; interminable and inconclusive meetings and the obfuscation of the basic truth that university education, whether vocational or non-vocational, is a partnership between the old and experienced and the young and inexperienced in which the former put their knowledge and experience at the disposal of the latter in a way which draws out their talents of intellect and personality as well as providing mental discipline, knowledge and skills. There is a memorable passage in one of A.N. Whitehead's lectures delivered 55 years ago:

> Youth is imaginative, and if the imagination be strengthened by discipline, this energy of imagination can in great measure be preserved through life. The tragedy of the world is that those who are imaginative have but slight experience, and those who are experienced have feeble imaginations. Fools act on imagination without knowledge, pedants act on knowledge without imagination. The task of a university is to weld together imagination and experience.

Readers of this book will classify the actors — the professors, the politicians and the bureaucrats — in their own way. They will not always agree with the perceptive comments on this brief but exciting episode in university history, but they will find much food for thought.

Bioenergetics: is there any demand for quantum mechanics?

Terrell L. Hill

Biology and Quantum Mechanics. By A.S. Davydov. Pp.229. ISBN 0-08-026392-5. (Pergamon: 1982.) $45, £22.50.

AT THE end of the introductory chapter, A.S. Davydov states the theme of his book:

> Undoubtedly the effective use of the chemical energy from food products by living organisms for muscle contraction, the production of concentration gradients, the conduction of nerve impulses, protein synthesis, etc., is associated with the excitation of special weakly relaxing degrees of freedom.

Davydov is referring here to excitons and solitons, especially in one-dimensional molecular systems (for example, the α-helix). If, however, he had used "conceivably" in the above quotation in place of "undoubtedly", he would have been on much firmer ground.

As it stands, most readers with some understanding of modern bioenergetics will be put off by some of the claims in the preface and first chapter. This is a pity because most of the book is, in fact, devoted to a review of assorted subjects in molecular biophysics and bioenergetics. Such a review could prove quite useful in providing a first glimpse of this field for a physical scientist. It is notoriously difficult for many physicists, especially theoreticians, to acquire the necessary background and perspective in order to move into biological research; a guide written by a distinguished physicist ought to ease the pain.

The potential reader should be aware, however, that the discussion of almost every individual topic stops well short of the present state of knowledge and understanding at the molecular level. The treatment of most subjects covered here is roughly five years out of date, that of muscle contraction models and theories even more so. A physical scientist who begins with this book would do well to turn next to the second edition of Lubert Stryer's *Biochemistry* (W.H. Freeman, 1981) to obtain a more thorough and current treatment of most of these topics.

To return to the initial criticism: conventional kinetic, thermodynamic and statistical mechanical concepts provide a completely adequate theoretical foundation, at the molecular level, for the understanding of all of the special biological topics treated in this book. This foundation has to be supplemented, of course, by still incomplete mechanistic and structural details in each individual case. It is not necessary to invoke any relatively exotic quantum mechanical explanations, as the author does (for example, for muscle contraction). This is certainly not to say that such approaches are untenable: rather, elementary and straightforward explanations should be retained and tested until there is evidence that more complicated theories are a necessity. There is no such need in bioenergetics at the present time.

A class apart

William Hodos

Brain and Intelligence in Vertebrates. By E.M. Macphail. Pp.423. Hbk ISBN 0-19-854550-9; pbk ISBN 0-19-854551-7. (Oxford University Press: 1982.) Hbk £20, $29.50; pbk £10.95, $14.95.

THE histories of comparative studies of brain anatomy and of intelligence in vertebrates have followed parallel, but for the most part independent courses during the past century. Each began with anecdote, followed by a slow accumulation of hard facts. The past two decades have seen a dramatic increase in the amount of data generated in both disciplines and breaks with theoretical tradition.

Euan Macphail's book is an attempt to achieve a fusion of these two fields. Although written with considerable clarity, much of the book does not lend itself to effortless reading. Nonetheless, the exertions of the reader will be amply rewarded by an understanding of the salient issues in the brain–intelligence field and by an awareness of the fallacies, gaps in knowledge and intellectual pitfalls that have bedevilled it since its inception.

Apart from the introductory and concluding sections, each chapter is devoted to a single class of vertebrate and has the same general organization. First, the evolutionary history of the class is briefly reviewed followed by a short account of the taxonomic organization within the class. Next, the author presents a description of the anatomy of the forebrain of some individual species characteristic of the class, before turning to a critical survey of the various types of learning procedures that have been attempted with members of the class. Each chapter ends with a summary and conclusions.

The two introductory chapters discuss the measurement of intelligence in animals and human beings, offer a classification of learning tasks, summarize the evolution and classification of vertebrates and review the literature on general morphological brain indices. The two concluding chapters, which deal with the relationship between language and intelligence in human beings and the evolution of the brain and intelligence, include an analysis and critique of the studies of language and communication in non-human animals and their relationship to human and animal intelligence.

This final section also contains the author's evaluation of the current state of knowledge of comparative studies of the brain and intelligence, which he characterizes in two working hypotheses to be tested by future research. The first is that, with the exception of human beings, neither qualitative nor quantitative differences in intelligence exist between vertebrate species; the second, that the capacity for language so affects the human's approach to problems of all kinds that the result is a qualitative difference in intelligence between humans and non-human vertebrates. Moreover, the influence of language is so pervasive in human reasoning that one may be unable to assess the role of non-linguistic reasoning in humans for comparison with non-human animal intelligence. These hypotheses are refreshing departures from conventional wisdom and will be the basis for considerable discussion.

While there is much to commend in the book, the treatment of certain topics falls short of perfection. For example, the only region of the brain that is discussed consistently is the forebrain and then usually only the telencephalon. Macphail justifies this emphasis by pointing out that it is this region that appears to undergo the greatest growth and development in evolution. Although his point is well taken, critics could argue that the telencephalon does not function in isolation and has important connections with the diencephalon and mesencephalon; moreover, to ignore the role of the mesencephalon in processing information about the spatial properties of the external environment may be to disregard an important aspect of the brain–intelligence problem.

Another area that may disappoint some readers is Macphail's limitation of his account to certain types of formal laboratory studies of learning. Phenomena such as tool-use and learning by imitation are not discussed, the vast ethological literature and its implications for assessing the nature of animal intelligence being specifically excluded. Macphail makes a case for the latter omission, but I suspect that readers with an ethological bent may not be fully convinced.

Such disappointment as the reader might feel will nonetheless be soothed by the wealth of well-organized information, original interpretations and challenging ideas presented in this volume. I recommend it highly to anyone with a serious interest in the brain and intelligence. ☐

William Hodos is a Professor of Psychology at the University of Maryland, College Park.

View of Kew from the inside

S.M. Walters

Kew: Gardens for Science and Pleasure. Edited by F.N. Hepper. Pp.195. ISBN 0-11-241181-9. (HMSO/Stemmer House: 1982.) £9.95, $24.95.

THIS handsome and lavishly illustrated book consists of a series of essays by sixteen past and present members of the staff of the Royal Botanic Gardens under the editorship of Nigel Hepper, himself a senior taxonomist in the Kew herbarium. The subject-matter covers all three parts of the Kew empire, namely: the public gardens themselves; the herbarium and other research institutions not normally visited by the public; and Wakehurst Place, the magnificent "satellite" garden in Sussex, which became part of Kew in 1965.

The introduction explains that the essays "are intended to convey a broad view of Kew's history and the horticultural and scientific work that have given the Gardens their world-wide reputation". Ray Desmond, formerly Chief Librarian at Kew, contributes the first chapter, which sketches the history of the Royal Gardens, and the remaining essays are grouped into three sections: "Gardens for Pleasure" (3 chapters); "Living Botanical Collections" (9 chapters); and "Botanical Research" (7 chapters). The decision to integrate Wakehurst with the "old Kew" by devoting chapters to the new garden in each of the main sections, though logical, has not been entirely successful; in particular, the description of the memorial garden to Sir Henry Price, last private owner of Wakehurst, seems out of place in the first section.

Tropical splendour in Surrey — interior of the Palm House at Kew (1852).

Illustrated London News

A welcome feature of the book is the treatment of aspects of Kew as a botanical research establishment. Chapter 17, devoted to multidisciplinary studies of *Crocus,* represents a brave attempt by no fewer than five staff members to explain at a popular level mysteries such as cytotaxonomy: fortunately, the genus lends itself to attractive colour photography! Another important chapter deals with Kew's new, explicit conservation role, the most urgent of all its tasks in face of the threat to the world's flora.

Reading the essays produces a strong impression that the authors are all loyal Kew people. A measure of how parochial their view is can be obtained by looking up other botanical gardens in the index: for example, Edinburgh, by any standards one of the world's most important scientific gardens, gets only a single, oblique reference, on page 31. Even in those few areas where the outside world has dared to question the morality of Kew's activities — such as the manner of acquisition of stocks of rubber plants in South America a century ago — the loyal Kew man says only (p.131): ". . . popular accounts indicating that Wickham dishonestly smuggled out the *Hevea* seeds are unfair both to the collector and to Kew". At least a strong antidote to such sycophantic writing is available (if in very extreme form) in the recent study by Lucile Brockway (1979) cited in the select bibliography at the back of the volume. Kew still awaits a good, definitive study, preferably by a reasonably sympathetic and well-informed outsider, who can ask questions about policy and aims such as are hardly touched on in this work, even in the interesting final essay on "Kew in the Future" contributed by the retired Director, Professor Brenan.

The world of book publishing presents increasingly baffling questions to the layman. Just at the time when we are told that Her Majesty's Stationery Office will no longer subsidize official publications of any kind, that same Office publishes such a lavish, popular book as this at a price which implies a large subsidy or great optimism and an enormous print run. Whatever the explanation, we can only express our appreciation, and wish the venture success.

S.M. Walters is Director of the University Botanic Garden, Cambridge, and author of The Shaping of Cambridge Botany *(Cambridge University Press, 1981).*

A few fruits from a large orchard

John B. Furness

Biology of Serotonergic Transmission. Edited by Neville N. Osborne. Pp.522. ISBN 0-471-10032-3. (Wiley: 1982.) £30, $69.

IN MAN, serotonin (5-hydroxytryptamine) nerves have been implicated in the control of various functions, including sleep, temperature regulation, pain and the secretion of pituitary hormones. At the other extreme, serotonin nerves in annelids and molluscs have been extensively studied because their prominent cell bodies can be identified by size and position in any individual animal. Serotonin is also found in other invertebrates, and, in the various vertebrate classes, is present in both the CNS and peripheral (intestinal) nerves.

The declared purpose of this book is to provide an up-to-date report of the state of serotonin research in the 1980s and, to a large extent, the various authors have done well by the topics covered in their individual chapters. However, in that the book only partly covers the field, Dr Osborne might well have referred his readers to other books and reviews — for example to the massive five-part work *Serotonin in Health and Disease*, edited by W.B. Essman and published by Spectrum Publications in 1978–1979.

Broadly, the articles in the present volume can be placed in one of two groups — those dealing with the (mainly biochemical) properties of serotonin neurones and those dealing with serotonin neurones in particular organs, species or life stages.

In the first group there is excellent coverage of the biosynthesis of serotonin, its storage and release, axonal transport, turnover, and uptake into axons and storage vesicles. Except for the chapter on axonal transport, which also deals with molluscs and makes occasional comparisons with platelets, these contributions are concerned with the properties of serotonin neurones in the CNS of mammals, principally the rat. This imbalance is only partly redressed in the final chapter of the book where some of the biochemical characteristics of serotonin neurones in gastropods are described.

Included in the second group is a succinct but commendably clear summary of the arrangement within the mammalian CNS of serotonin nerve cells and their processes. Another chapter documents the use of radioactive ligand-binding studies to distinguish between 5-HT_1 and 5-HT_2 receptor types in the CNS. These studies may eventually provide a basis for interpreting differences in the behavioural effects of drugs acting at serotonin receptors. Possible roles of 5-HT in the mammalian central nervous system are dealt within a group of three further contributions; this is one of the weak parts of the book because so much is left out. The first summarizes the putative roles of serotonin but is disappointingly brief. And only two aspects of serotonin's central roles are dealt with at length in the other two chapters, namely serotonin and learning, and serotonin involvement in dyskinesias (the latter subject also appears at the end of a separate article on serotonin neurotoxins).

Serotonin nerves of the mammalian gastrointestinal tract (with some reference to other classes of animal) are reviewed next. As the existence of serotonin nerves in the gastrointestinal tract has been difficult to establish, the author gives proper emphasis to evaluation of the evidence for their presence. Another subject of some controversy, namely the proposed presence of serotonin neurones in the vertebrate retina, is covered in the following contribution. Finally, two chapters give lucid accounts of current research on serotonin neurones in leeches and gastropods.

Perhaps more than anything else in this field, a comprehensive and critical review of the pharmacology of serotonin receptors is needed. Yet in the only chapter explicitly dealing with drugs acting on serotonergic neuronal systems, a mere two pages and a table are given to a disjointed discussion of the subject. Not only is there a failure to do justice to receptor classification, but the very real problems of the additional actions of serotonin antagonists are overlooked; for example, the agonist actions of methysergide and LSD are not mentioned, nor is the antihistaminic action of cyproheptadine. Most of the "non-specific" actions of other drugs acting on serotonin systems are also ignored.

Patchy coverage and lack of cohesiveness are common in edited works of this sort. But here they have reached such a pitch — inhibitors of the synthesis of serotonin are dealt with in four separate articles without cross-referencing, for example — that most of the contributions might just as well be in review journals. In mitigation there are some excellent chapters which are valuable works of reference in their own right. However for only a part of its potential audience will these chapters justify purchase of the entire book. ☐

John Furness is Associate Professor in the Centre for Neuroscience and the Department of Human Morphology at Flinders University, South Australia.

Coming out of the long tunnel

British universities have weathered enforced economy better than many feared. The return to normalcy may be more testing.

In the two years since the British government told its dependent universities that they would have to share in a general reduction of public expenditure from which only the armed services and the police were excepted, many British universities have learned some unacademic tricks. Half-way through the adjustment period, due to end with 1983-84, most universities have been able to reduce their payrolls by natural wastage and because of the attractions to those older than 50 of the early retirement schemes sanctioned by the Treasury. Only when the dust has settled will it be known whether the academics who have left include an undue proportion of those who can be least spared — and whether the cost of paying for these early pensions, a charge on future budgets, will be supportable. At the same time, many universities have made deals with industry or commercial concerns that help both to maintain the scale on which research is undertaken and to shed some of the cost of the tenured payroll. Again, it is too soon to know how seriously these developments will compromise the quality of teaching — or the impartiality of the universities concerned. But especially because the research councils have also done their best to rally round, and with the prospect of extra government money for the appointment of younger people to university faculties, it is natural that academics should be looking forward to the ending of this long period of deprivation.

That temptation should be resisted. The months between now and September 1984 could yet bring trouble. The announcement last week that the University of Aston (in Birmingham) is planning to fire tenured academics is a sign that the university has exhausted the supply of academics willing to settle for early retirement. Other places could yet find themselves in the same boat. It is also likely that the universities that have been unable or unwilling to comply with the new (reduced) targets for student numbers put out in June 1981 by the University Grants Committee will find themselves in further trouble before the present adjustment period is over. The British government is unlikely to condone such cheekiness, while the grants committee will probably find itself having to punish the transgressors on the grounds that they are making an inequitable claim on national resources. Precisely how these issues are resolved will depend to some extent on the appointment of the next chairman of the grants committee. Quite apart from the administration of a shrunken budget, the successor to Dr Edward Parkes will have to shoulder two less tangible burdens — keeping up the spirits of British academics and making good the erosion of academic standards in British universities.

Structure

Grappling with these problems would be easier if the structural problems that afflict the British university system had been solved. On past form, however, that is unlikely without external intervention. William Waldegrave, the minister at the Department of Education and Science with responsibility for higher education, was right last week to remind his audience at Westfield College, London, that British universities and academics should have been worrying about the way in which the system is run at least since 1977, when Mrs Shirley Williams, then in charge of the Department of Education and Science, sympathetically spelled out her version of what was wrong. Broadly speaking, British universities ignored or denied that warning; they have since found themselves coerced by the government instead. The intelligence that even the previous Labour government was alarmed at the rising cost of educating students from overseas evoked from British academics an opinion that to change the previous practice of equal access would be illiberal. The Labour government's imaginative offer of a system of scholarships for overseas students was not seriously discussed, with the predictable result that the Labour government's successor, the present administration, impatiently instructed British universities that fees should be paid by students from overseas. Much the same is likely to happen if British universities now continue to pretend that persisting anomalies in higher education are no concern of theirs: the government (this or the next) will intervene again.

Support

The cost of supporting students in higher education is plainly bound to be a running sore in the years ahead. Present arrangements require that local authorities should pay the tuition fees of all students accepted for places in higher education and provide them with maintenance grants as well. Local authorities recover almost all the cost of these subventions from the central government, which is why the government complains that higher education (not just universities but polytechnics and colleges of further education) has an open claim on public funds. This feature of the present arrangements for educating young people in Britain is the reason why the University Grant Committee was compelled, in June 1981, to instruct every British university that, by 1983-84, the numbers of home students should not exceed some arbitrary quota. Universities are well within their rights to argue that the consequences are often uneconomic. Universities would also be technically within their rights if they complained that the government has been slow to set up a mechanism for regulating the cost of other sectors of higher education. They will, however, be unwise if they continue to insist that their decisions on which students they are prepared to teach are financially binding on the central government; that position could easily be turned if the government decided that students would automatically be provided with maintenance grants calculated only to be enough to allow them to attend their neighbourhood university, but with a loan scheme allowing them to go further afield if they have the chance. That, or a system of competitive scholarships for potentially able students, is likely to be forced on the British universities if they find nothing better.

The structural problem occasioned by the uniformity of the British university system, and its ideological separation from the rest of British higher education, also needs attention. As is well known, British universities seek to be like Oxbridge but will occasionally settle for a different kind of self-image if it happens to be something equally distinctive, that of Imperial College, London, for example. Farcically, all British universities count themselves at least one rung higher on the ladder of intellectual opportunity than the polytechnics. That conceit, however, is mistaken. Many polytechnics provide their students with a better education (a more employable skill) than some universities. Some polytechnics are more distinguished than some universities at research. So is it wise of the universities to continue to insist that the rest of higher education is untouchable? That difficulty would

0028-0836/82/470301-02$01.00

become especially hazardous for the weaker universities if, as seems probable, the British government finds a way of ridding the universities of the quota system under which they now have to labour, for then the weak among them would be known not merely in common-room gossip but from their success (or the opposite) in attracting students.

Another abiding problem of British higher education which academics stolidly refuse to contemplate is educational. British universities, insistent as they are on the equation between academic excellence and academic freedom, and used to equating freedom with the right to do what they have always done, pay very little attention to the way in which they educate their students. Prepared though they are to go to the barricades whenever the grants committee should suggest that one or other of them should abandon its degree course in agriculture or Portuguese, their willingness to delegate the selection of the students whom they will teach to a computer centre in Cheltenham is a proof that they are only half-serious. If British universities hope to survive, they must set out to choose their own students by their own devices, snapping their fingers at the cumbersome apparatus of school-leaving examinations but saying instead that they will provide a higher education for sufficiently able if ill-prepared students even if that means teaching them for four years and not just three. The government would not welcome such a development, but would not be qualified to resist.

But are British universities not autonomous institutions, whose academics collectively decide what kinds of places they should be? That is the theory, but no longer the practice. In an ideal world, or even in the United States, universities conscious that their reputations leave something to be desired would think of strengthening their claims on student and academic attention by offering good teachers attractive terms of service. In Britain, there is instead a nationally agreed scale of salaries for academics from which Oxbridge is to some extent exempt. The result is that even when some provincial university is able to create a superb department in some field, the advantage is bound to be short-lived; the people concerned will eventually be hired away to a more prestigious or congenial place. If on the other hand some university should model itself on some place that is not Oxbridge but, say, the University of Aachen or the Massachusetts Institute of Technology, it would quickly find itself regarded by its peers as a kind of jumped-up polytechnic — and would equally be prevented from keeping its academics by the uniformity of the terms of service under which it (and they) labour.

The agenda accumulating for the next chairman of the University Grants Committee is therefore formidable: how to share out a government subvention while providing those who depend on it with an incentive towards diversity, how to educate most students more broadly without sacrificing the service now provided by those universities that are already excellent, and how to make a bridge between universities and other higher education establishments without humiliating either. There follows from this a simple recipe:

- Pensioner universities should be compelled towards autonomy, told in advance what their budgets will be for as many years ahead as can be managed but then subjected to an intellectual rather than procedural review of their academic attainments.
- Universities should be reminded (some have forgotten) that the reason for their existence is the education of the young; the opportunity for research follows from that, and is not capable of being institutionalized by itself. Getting hold of suitable entrants to undergraduate courses should therefore be central to most universities' concerns (in which case the abandonment of school-leaving examinations and the disbandment of UCCA will come naturally). Teaching elementary courses (and worrying about how well they are doing) will naturally frighten British academics (in which cases they should be fired).
- Making bridges with the rest of higher education should be relatively simple: why should not the University Grants Committee provide support for the infrastructure of good research whenever it may be carried out?

Biting off others' tongues

The UK Medical Research Council seems to be irrationally sensitive about a planned clinical trial.

The blank space on page 310 is intended to be spectacular. Earlier this week, the space was occupied by a reasonable letter replying to an earlier piece of correspondence from Dr Arthur Wynn (see *Nature* 11 November, p.102) raising doubts about the British Medical Research Council's plan to carry out a controlled study of the utility of folic acid as a dietary supplement in the prevention of recurring embryonic neural tube defects, usually manifested as spina bifida in human births. After the page concerned had been readied for printing, the author of the letter asked that it should be withdrawn on the grounds that its publication would acutely embarrass the Medical Research Council, but for reasons that he did not fully understand. As it happens, the same disputed page of *Nature* had earlier on the same day been adorned with yet another item of correspondence on the same subject arguing that the disputed trials had needlessly been delayed for two years, during which time it had become apparent that the balance between the risks of folic acid supplements, and the benefits thereof, had shifted towards the latter. That letter had also been withdrawn, again at the request of the Medical Research Council.

Objectively, there should be no problem about the plan to mount a controlled study in Britain of the influence of folic acid on the incidence of neural tube defects (spina bifida) in human births. Two years ago, the UK Department of Health seems to have taken that view, calling a meeting to plan how the trial should be carried out. Delay has allowed three categories of ethical concerns to flourish — protests that if there is evidence that folic acid will prevent spina bifida, it is unfair to deny the mothers in the control group the appropriate supplement of their diet, the claim that unnaturally large amounts of folic acid in the diet may be harmful (shades of fluoride in the drinking water) and legalistic but unrealistic worries (in a country in which abortion is permissible but not entirely free) that for a mother to consent to membership of the control group denied folic acid supplement would be to infringe the rights of a child unborn or even not conceived.

None of these arguments is absolute. The case that folic acid will prevent recurrences of spina bifida is strong but not overwhelming; it would be more persuasive if there were a convincing tale to tell of how this supplement, rather than some other, were effective. The chance that folic acid might be harmful would be more persuasive if the chemical were cheaper. The challenge to the rights of the unborn child is philosophically powerful but only to the extent that putative parents sense that unborn children could be cured of putative spina bifida by a suitable dose of folic acid.

Resolving such issues patently requires nothing less than what the Department of Health had in mind two years ago — a controlled trial set up in such a way that it could be abandoned quickly. The Medical Research Council should resolve on such a course when it meets next, on 7 December. It should not be deterred by what the politicians have to say.

Meanwhile, innocent bystanders should ask themselves why *Nature* should be printing several square inches of empty space, and why the authors of the words that would ordinarily have filled them have at the last minute been frightened away from publication. In each case, the groups concerned have said that the pressure came from the Medical Research Council. By all accounts, it would be entirely unworthy to suppose that any component of that pressure is concerned with future research grants or their availability. But can it really be sensible that a research council already sufficiently entangled with muddy and muddled political issues beyond its competence should also seek (and successfully) to suppress what its own people have to say, if not openly in its defence then in the cause of helping the understanding of a tendentious issue?

Biotechnology patent challenged

Ex-colleague seeks share of the credit

Washington

Dr Robert Helling will formally press a claim of co-inventorship of the Cohen–Boyer genetic engineering patents (see *Nature* 11 November, p.95). Helling, now at the University of Michigan, worked with Dr Herbert Boyer at the University of California, San Francisco, during a sabbatical in 1972–73 and co-authored the 1973 paper in *Proceedings of the National Academy of Sciences* that forms the basis of the patents. He has consistently refused to sign a disclaimer of co-inventorship as requested by Stanford University and the University of California, but decided only last week to press his claim actively.

The decision seems likely to delay further the issuing of the second Cohen–Boyer patent, at present in limbo after the patent office tentatively rejected it, in part because of the unresolved role of Helling. It may also increase pressure for a re-examination of the first patent, issued in December 1980.

The decision last week came after the University of Michigan agreed to take up the case on Helling's behalf. James Dautremont, the university's intellectual property counsel, said the matter would be discussed with both the patent office and the two universities involved "in a completely cooperative effort to determine where the legally proper inventorship lies".

It is not clear whether Helling or the University of Michigan has a financial stake in the outcome. Helling did sign a patent agreement with the University of California covering his term there that appears to assign any patents to that university; if that is so, all he could gain would be the recognition of having his name added to the landmark patents. On the other hand, if it turns out that he was covered by the University of Michigan's patent regulations at the time, he would divide his share of the royalties equally with the University of Michigan.

In the response of 1 November to the patent office's proposed rejection of the second patent, the attorney for Stanford and the University of California argued that Helling's failure either to claim or to disclaim co-inventorship in the eight years since the patents were filed should not be permitted to hold up the patent. But Dautremont counters that "inventorship can be challenged or modified as appropriate according to the facts at any time". The question, he says, is whether "Professor Helling in fact made a significant contribution to the invention as recited in the claims of the patent. I'm sure that will become clear from written records, lab notebooks, and so on".

Dautremont emphasized that "we're not in a fight at all" and said he expected the matter to be resolved "amicably". And he suggested that it would be in the best interests of Stanford University and the University of California to add Helling's name to the patent if the facts warrant it in order to remove a "cloud over this issue".

Stephen Budiansky

Strike response to French reform

The plans of M. Alain Savary, French minister of national education, to set in motion what he described in early October as a "global reform" of the universities and their prestigious sisters, the *grandes écoles,* seem to be meeting with an equally global resistance.

The university trade union SNE-Sup (Syndicat National de l'Education Supérieure) has this week, therefore, called a two-day national strike, demanding that the reform be given "new life"; while the *grandes écoles,* engineering schools well represented in the government administration and traditionally regarded as providing the best education in France, have been applying their own behind-the-scenes pressure to ensure that real life does not affect them. Given M. Savary's gentlemanly approach to politics, the result may be something closely approaching the *status quo.*

Meanwhile, the water is being muddied by the ministry, which appears reluctant to reveal exactly what the minister has in mind. First, there is the unpublished — but circulating — "Jeantet report", described by conservatives as the work of a "radical dreamer". It foresees the absorption of some *grandes écoles* by the universities, and attacks élitism. It is the result of M. Claude Jeantet's questionnaire to the universities, *grandes écoles* and other institutions and was intended to form the basis of the reform, but it now it seems the minister is distancing himself from it.

Then there are three other texts, all published within two weeks in October, which purport to outline the minister's views. Two of these are speeches by Savary himself, and one — the last — is an "information note" from the ministry. All are partly contradictory. They appear to indicate an evolution towards conservatism; but the information note fails to touch on many key issues — such as research, or reform of higher degrees — and leaves room for the reform to be radical in some respects. (For example, universities are defined as including "schools" — by implication the *grandes écoles* — but *grandes écoles* are also defined outside the universities; thus *grandes écoles* directors are asking themselves which kind of school their own will be.)

As if further to confuse the issue, the director-general for higher education and research at Savary's ministry, the newly-appointed and activist M. Jean-Jacques Payan, said last week that he had been taken fully into Savary's confidence over the final shape of the reform and that it will reveal "many new things" when it is published, he predicts, on 10 December. For example, he says, the reform will allow

IIASA struggles on in hope

The International Institute of Applied Systems Analysis (IIASA), the East-West systems analysis centre in Vienna, has had a reprieve from the United States, and a partial reprieve from Britain.

In both countries, the member institutes of IIASA — the National Academy of Sciences in the United States and the Royal Society in the United Kingdom — had withdrawn as of 1 January 1983, and the problem was to find new members that could pay the subscriptions for IIASA's total budget of around £5 million (in 1981). Now the American Academy of Arts and Sciences has agreed to take over the US membership, raising the money needed from private foundations and industry.

In Britain, the situation is less clear. The Fellowship of Engineering, a body with few funds of its own, is debating whether to join IIASA, but it will have to find the whole subscription outside — either in industry or in government departments other than the Department of Environment, which originally paid the bill and whose lack of interest in IIASA led to the Royal Society's withdrawal.

Meanwhile, IIASA — crossing its corporate fingers — has drawn up its research plans for 1983. Project titles include: patterns of economic structural change and industrial adjustment; national agricultural policies; energy development, economy, and investments; structural change in the forest sector; institutions and environmental policies; population — ageing and changing lifestyles; integrated regional and urban development; adaptation and optimization; and negotiations and interactive decision making.

Robert Walgate

0028-0836/82/470303-02$01.00

all universities to teach engineering, and grant *Diplômes d'ingénieur,* previously the jealously guarded preserve of the *grandes écoles,* and not previewed in any ministry text so far.

The next step, however, is the presentation of a near-final text to the advisory Conseil National de l'Education Supérieure et de la Recherche (CNESER, the national council for higher education and research) which was scheduled for Thursday 25 November — the first day of the planned SNE-Sup strike. However, the unions have requested that the CNESER meeting be postponed, and on Monday a new date had not yet been arranged. CNESER is reported to be very closely divided between radicals and conservatives, and may vote for a text close to Jeantet — which would set the cat among the *grandes écoles* pigeons, unless Savary were entirely to ignore CNESER's advice — something that would be politically inadvisable. CNESER, in fact, along with M. Payan himself — who is *ex officio* president of CNESER — may be the main element of volatility in a situation long since frozen by the traditional conflicts between the *grandes écoles* (broadly on the right) and the universities and unions (broadly on the left). Whether the strike will influence either CNESER or Payan is still to be seen.

Robert Walgate

West Bank universities

Request for pledge withdrawn

The Israeli government has abandoned an earlier regulation demanding that foreign lecturers working in universities and colleges on the West Bank should sign a pledge not to assist the Palestine Liberation Organization (PLO). The announcement that the regulation would be suspended (and unofficial hints that it could be formally rescinded in the near future) came a few days after a swingeing attack by US Secretary of State George Shultz, who last Thursday called the regulation a threat to academic freedom reminiscent of the McCarthy era in the United States.

Israeli officials nevertheless deny that the events are related. Instead, they suggest the relaxation was made possible by quiet diplomacy between the civil administration of the West Bank and the university authorities. The only purpose of the regulation, they stress, had been to preserve the function of the universities as centres of higher learning and to avoid their politicization.

It is clear, however, that the Israeli government was somewhat taken aback by the strength of the international reaction to its move. One senior official reportedly expressed "surprise" at Mr Shultz's appeals to Israeli academics to join in the protests. In fact, the Israeli academic community has on several occasions come out in support of the West Bank universities — in November 1981, when the Bir-Zeit University in Ramallah was temporarily closed, a group of lecturers and research students at the Hebrew University of Jerusalem attempted, perhaps cosmetically, to organize fill-in courses for students who otherwise would have had to interrupt their studies.

The constitution of the West Bank universities and colleges under Israeli administration is complex. At the time of the Israeli take-over, there were three such establishments, Bir-Zeit (near Ramallah), El-Najah (near Nablus) and the Kadouri Agricultural College (at Jenin). These were accorded full academic status by the authorities (Bir-Zeit College became a university in 1975) and two further colleges were founded, the Islamic College in Hebron and the (Catholic) College-Frères (now the University of Bethlehem). All these are financed, indirectly, by the Israeli government, through its budget for the occupied territories, which is distributed by the civil administration of the West Bank.

Just how many lecturers refused to sign the pledge is not clear — Mr Shultz put the figure at around 120, of whom, he said 22 have already been expelled from Israel and 30 others suspended from teaching, while others were told that they would be required to leave the country when their three-month tourist visas expired. (This latter category presumably refers to new arrivals who took up their teaching posts in October this year). The Israelis, on the other hand, claim that only three lecturers were actually expelled, and that the rest were merely told that their residence permits were being withdrawn. They admit, however, that even to the newest arrivals the pledge was something that they had not foreseen when they accepted the post, and that the lecturers' refusal to sign the pledge was inspired not by a desire to assist the PLO but as a matter of principle.

"Freezing" the pledge, in the case of lecturers, however, could make difficulties with other foreign workers on the West Bank, all of whom, a government spokesman announced last week, were required to sign the pledge and had already done so in "hundreds if not thousands".

Vera Rich

International conferences

Anti-Israel moves

Rehovoot

Recent events in Lebanon threaten seriously to undermine relations between Israeli scientists and their colleagues overseas. This is one reason why Israeli scientists were relieved to hear from Weizmann Institute physicist Shalheveth Freier that despite a prolonged and often acrimonious debate on events in Lebanon at the recent Pugwash meeting in Warsaw, the organization did not adopt an anti-Israel resolution.

Instead, Pugwash adopted, after a full 20 hours of discussion in working group and plenary sessions, a far more balanced resolution than seemed possible at the outset. The resolution called for "the withdrawal of all non-Lebanese forces and the creation of a strong Lebanese government acceptable to all factions".

Freier's reception in Warsaw was thus less hostile than that of many other Israeli scientists attending international meetings in recent months. Thus one young Israeli neurobiologist arrived at a scientific conference at a French university to find a sign posted outside the cafeteria which read: "The Israelis are assassins". Many delegates echoed this view and flatly declared that they would never visit Israel again so long as the country remained "aggressive".

Strangely enough, the neurobiologist (from Tel Aviv) says he found greatest understanding from a Syrian scientist who had once lived in the city of Homs, and who was all for "smashing the PLO and the Syrian Army", presumably because several members of his family had been among the 10,000 people killed when the Assad government put down an uprising of devout Moslems in that city last year.

Some Israeli scientists have even found themselves "disinvited" from meetings during the summer and autumn. One chemist, for example, has received the following communication from a colleague in Europe: "The current situation in Lebanon is causing deep concern here. In particular, the recent actions waged by Israeli forces against the city of Beirut appear cruel and unnecessary. For that reason my group is unanimous in feeling that we cannot maintain your visit here as planned. Please understand that this is not directed against you personally."

In his reply, the Israeli chemist said that his erstwhile hosts had "the unquestionable right" to cancel the invitation, but he wondered whether they had also boycotted Iraqi scientists in the wake of their government's brutal attacks on the Kurds, Palestinian Arab scientists after the massacre of Israeli bus passengers near Tel Aviv and Israeli schoolchildren in the Galilee, or Soviet scientists because of events in Afghanistan and Poland.

Many overseas researchers seem also to have boycotted conferences held here in recent months. Thus there were only 150 participants (instead of the expected 250) at the International Symposium on Recent Developments in Perinatal and Childhood Infections and 800 participants (against 1,000 expected) at the Sixth International Congress on Hormonal Steroids. Many bodies that were thinking of Israel as a conference site for 1986–88 have also, after the furore over Lebanon, altered their plans.

0028-0836/82/470304-02$01 00

In this situation, Israeli scientists find themselves fighting two battles at the same time. On the one hand, they are trying to convince their overseas colleagues that the common judgement of Israeli policies is too harsh. On the other hand, most of them are trying to convince their fellow citizens of the need to change many of these policies.

Prominent scientists — including Professor Ephraim Urbach, president of the Israel Academy of Sciences and Humanities, and Professor Ephraim Katzir, former President of the State of Israel — played a prominent part in the successful attempt to force the appointment of a commission of judicial inquiry to probe the massacre of Palestinian refugees in Beirut. Many of these same scientists actively oppose the don't-give-back-an-inch views of the Begin government.

Even they however, are split over the question of a separate Palestinian state. Some think the emergence of such a state inevitable (or even desirable), while others would agree with what Shalheveth Freier said at the Pugwash meeting in Warsaw, where he declared: "If the general atmosphere in the Middle East continues to be uncompromisingly hostile to Israel, I suppose I should feel compelled to resist the creation of another hostile state. If, however, peace were to descend on this area, I believe that all honourable options would be open." **Nechemia Meyers**

Academic consultancy

Mass. General placates Hoechst

Washington

Massachusetts General Hospital (MGH) is going to unusual lengths to ensure that faculty consulting with outside firms does not conflict with the terms of its 10-year $50-million agreement with Hoechst AG, the German chemical company.

In the case of one faculty member just appointed to the department funded by Hoechst, MGH is demanding that his consulting with other firms be on a non-confidential basis, a condition apparently not required of other MGH faculty.

The 1981 agreement between Hoechst and MGH represents the largest joint venture so far between industry and an academic institution. Hoechst agreed to provide the money for a new department of molecular biology in exchange for an exclusive licence to any patents that result from the department's research. The agreement also requires any faculty collaboration or consultation with for-profit firms to be cleared with Hoechst.

MGH has now apparently taken it upon itself to negotiate the particulars of consulting contracts that molecular biology faculty members have with outside firms to ensure that they are acceptable to Hoechst. In the case of Dr Brian Seed, the newly-appointed faculty member, MGH has engaged the services of a prominent Boston law firm, Ropes and Gray, to negotiate changes in his consulting arrangement with Genetics Institute. Genetics Institute, the spin-off from Harvard University's short-lived plan to form its own profit-making genetics engineering company, is negotiating through its own prominent Boston law firm, Hill and Dorr.

The MGH lawyers are demanding that since Seed is free to pass on information from his Hoechst-supported work at MGH to Genetics Institute, he should similarly be free to pass on to Hoechst any information gleaned through his consultations with Genetics Institute. Seed, who says he has heard nothing about the current status of the negotiations, says the basis of MGH's position is Hoechst's concern over its ability freely to exercise its patent rights under the agreement: "Hoechst is worried that as a result of my consulting for another company I might take up in my lab some work based on proprietary information". Thus Hoechst might end up supporting some research that it could not patent.

MGH officials deny that their actions reflect any special policy towards the department of molecular biology or Hoechst. "We want to make sure that their consulting activity is consistent with the hospital's policy", says Dr Ronald Lamont-Havers, deputy general director for research. "Any consultative agreement needs to be cleared with the hospital to ensure that there is no conflict of interest."

But Lamont-Havers did acknowledge that while the hospital has advised other faculty members that their consulting contracts need to be changed, it has only actively negotiated those changes in the case of department of molecular biology faculty. And he appeared surprised to learn of the non-confidentiality requirement that MGH's own lawyers are demanding in Seed's case. "Usually, in our consulting agreements, we expect that they would receive proprietary information and would not be free to discuss proprietary information", he said.

Dr Howard Goodman, director of the department of molecular biology, denies that anyone in his department has been required to give up any consulting or that appointments have been made contingent upon modifications in an appointee's consulting contracts. And Seed seems confident that an accommodation will be reached in his case. "I doubt that my relationship with Genetics Institute will be severed", he says. But the lingering question is whether the conditions being demanded by MGH — and which Genetics Institute reportedly considers unacceptable — will make it impossible for at least some faculty consulting arrangements to continue. **Stephen Budiansky**

US defence research

Computer plan

Washington

The US Department of Defense (DoD) is adding to its existing investment in computer research several new programmes designed to counter possible Japanese domination of the field. The budget for fiscal year 1984, which is now under negotiation behind closed doors, is likely to include hundreds of millions of additional dollars for special programmes in supercomputer research and software. DoD is already supporting research in Very Large Integrated Circuits, the technology of gallium arsenide as a replacement for silicon, and other computer-related programmes.

In a speech to a professional meeting in Orlando, Florida, Robert S. Cooper, director of the Defense Advanced Projects Research Agency (DARPA) announced that he would counter the Japanese computer effort with a research programme aimed at achieving the extraordinary speed of 10,000 million floating point operations per second by 1990. Present "supercomputers" such as the Cray III and Control Data's Cyber 205 attain speeds of 100 megaflops, while the Japanese programmes aims at achieving 1,000 megaflops. DARPA's programme is rumoured to have initial costs of $150 million.

"WE WANT A WARHEAD THAT THINKS FOR ITSELF —AND GOES FOR TOKYO!"
DEPARTMENT OF DEFENSE

DARPA supports basic research and exploratory development for the directorate of Defense Research and Engineering and would not, therefore, be involved in applications. Possible defence applications include warhead delivery systems capable of "deciding" for themselves which targets to attack, and thus not dependent on vulnerable telemetry systems.

There is also to be a substantial new programme in the development of software to be managed by a new office to be established within the Defense Research and Engineering directorate. According to a report from the office of Dr Edith Martin, the deputy under-secretary at the Pentagon with responsibility for research and engineering, it is planned to spend an extra $30 million on software development in the financial year beginning on 1 October 1983, to provide further funds in succeeding years and to establish a military software institute. It is estimated that between $5,000 million and $6,000 million worth of software is already "embedded" in defence systems, and that the amount will rise to $32,000 million by 1990.

Increased funds are also likely to be

0028-0836/82/470305-02$01.00

made available for the Very High Speed Integrated Circuits programme as well as for the research and development programme based on gallium arsenide, a material that offers faster semiconductor devices and may be more resistant to disturbances such as electromagnetic pulses.

The Pentagon's efforts to match the Japanese effort in advanced computers is mirrored by two initiatives by the computer industry. However, the plan of 15 computer companies under the leadership of the Control Data Corporation to invest between $50 and $100 million a year in software and hardware development has not yet become a reality even though the founders are confident that the US Department of Justice will decide that the proposed consortium, the Microelectronics and Computer Technology Corporation, does not violate anti-trust laws.

The non-profit Semiconductor Research Corporation, set up by 13 computer companies earlier this year, has however begun making grants to academic institutions considered to be centres of excellence in computer development. Last week, the corporation announced grants for developments in large-scale integrated circuit technology to Cornell University, the University of California at Berkeley and the Carnegie-Mellon University.

Deborah Shapley

French win contract

The British Central Electricity Generating Board (CEGB) has commissioned the design and safety study of the pressure vessel for the planned Sizewell B pressurized water reactor (PWR), Britain's first, from Framatome, the main constructor of the 40 or so French PWRs.

Thus Dr Walter Marshall, now director-general of CEGB, has proved true to his word. In March, when he was chairman of the United Kingdom Atomic Energy Authority, and head of the PWR task force that tidied up the Sizewell safety design, he was questioned about the problems that Framatome had had with cracks under the pressure vessel cladding. This would be just the time to buy from the French, said Marshall — because "they have been caught with their pants down". The problem was one of heat treatment, and has now been solved, Marshall believed, probably leaving Framatome with a better understanding of such vessels than other manufacturers.

From his position as head of CEGB, Marshall has now approved the offer of the design contract, worth £213,000, to Framatome. This will not be complete until May 1983, after the January 1983 Sizewell inquiry, but — according to Framatome sources — a report amounting to "the bulk" of the study will be ready in time for the inquiry.

Robert Walgate

MRC annual report

Universities stand to gain

Like publishers, heads of research councils are usually a gloomy bunch when it comes to public statements on the financial position of their organizations. But at last week's launch of the annual report of the UK Medical Research Council (MRC), the council's secretary, Sir James Gowans, was remarkably cheerful about MRC finances and even offered a helping hand to the universities.

The hand-out, which all told could amount to 1 per cent of the annual budget of MRC, is offered to university research teams, in particular those already within the system of dual support by MRC and university, whose cutting edge has been dulled by diminished support from the university. To restore their competitiveness until such time as university finances are again healthy, MRC is offering to convert such teams into MRC Groups, providing them with up to £50,000 per annum.

The scheme, advertised earlier this year, has attracted some twenty applicants, almost all of them already substantially financed by the MRC. To ensure that the money is awarded to cases of genuine hardship, the vice-chancellor of the university has to make the application and to promise that he is not trying to free resources which will be redeployed into unrelated activities. Although no decisions have yet been made it is likely that the support awarded to MRC groups will cover such items as radiochemicals, an electron microscopist, an animal-house technician or even a departmental secretary.

MRC seems willing to spend up to £1 million a year in this way. Where will the money come from? Nowhere in particular, according to Sir James Gowans. Nevertheless, two main sources seem likely.

The first would be the £1 million that would be saved were MRC to withdraw its support of the European Molecular Biology Laboratory (EMBL) in Heidelberg. The suspicion that it might do so arises from an instruction from the Advisory Board for the Research Councils telling MRC to review its participation in EMBL. Asked why he thought the review was called for, Sir James Gowans would say only that the question should be addressed to the Advisory Board — of which he is a member.

Alternatively, it might be surmised, MRC could support its proposed groups by spending less on project and programme grants to university teams. According to the annual report, "the growing volume of applications for support . . . suggests . . . that some good work will continue to go unfunded" but in fact no really good project ever seems to fail to be supported.

Looking ahead, Sir James Gowans drew attention to the review next year of the five-year agreement between MRC and the biotechnology company Celltech. The agreement runs until 1985 and Sir James thinks "it is going all right". He also mentioned the National Institute of Medical Research (NIMR) which this year will consume about £9 million of the £106 million MRC budget. Sir James expects Dr D.A. Rees, formerly principal scientist at Unilever's Colworth laboratory but director of NIMR since 1 October, to increase the links between NIMR and industry and to open facilities at NIMR to university researchers. In addition, the structure of NIMR will be reorganized during 1983.

Peter Newmark

Rostow a "dove"

Washington

Part of the reason for the apparent stalemate of the Geneva arms control negotiations seems to be a dispute between a group of conservative senators and Mr Eugene V. Rostow, director of the Arms Control and Disarmament Agency (ACDA). The dispute may come to a head as soon as 29 November when a group in the Senate led by Senator Jesse Helms (Republican, North Carolina) will try to send Rostow a warning that he is too doveish towards the Soviet Union — and put the President on notice as well.

The Helms group first signalled its discontent in March, when the Senate Foreign Relations Committee considered the nomination of two long-term ACDA officials kept on by the Administration at Rostow's urging. Helms complained that Robert Grey, nominated as deputy director, and Norman Terrill, nominated as assistant director for nuclear weapons policy, were hold-overs from the Carter Administration and too doveish.

Since then, confirmation of the two nominees has been held up in the Senate because of Helms's objections. When Congress reconvenes on 29 November for about a month, there will be a move to bring the nominations to the floor of the Senate, which is possible only if Helms withdraws his objection. There is a rumour that only the Grey nomination will be called up. The Helms faction, which would prefer General Edward Rowney to have Rostow's job, seems to have calculated that postponing Terrill's confirmation as acting assistant director will continue to embarrass Rostow and, in particular, prevent him from taking a decisive position on arms control.

If the two nominations are not confirmed by the time Congress finally disbands, the whole nomination process will have to begin all over again in the new Congress next February.

Soviet psychiatric abuse

Allegations met by red tape

The Soviet All-Union Society of Psychiatrists (AUSP) has adopted a new approach to accusations by human rights groups about the confinement and "treatment" of dissidents in Soviet mental hospitals. Instead of rejecting all such allegations out of hand, it has supplied the World Psychiatric Association (WPA) with details of two alleged cases and has promised information on four more.

The fact that the data appear incomplete, and the extreme slowness with which they have been made available, have evoked considerable suspicion among some members of WPA. Is this a genuine change of heart or simply a delaying tactic on the part of the Soviet Union to forestall moves by several member bodies — including the Royal Collge of Psychiatrists and the American Psychiatric Association — to have AUSP expelled or suspended from WPA?

This is not the first time that AUSP has professed itself willing to cooperate with WPA over allegations of psychiatric abuse. During the last world congress, in Honolulu in 1977, the Soviet delegate to the general assembly handed round a substantial document containing "confidential" clinical data on twelve dissidents whose cases had frequently been cited as "alleged victims of psychiatric abuse", in the hope of convincing the delegates that the dissidents were in fact suffering from severe psychoses. The Honolulu congress narrowly passed a motion of censure against the Soviet Union, and set up a special review committee to monitor allegations of political use of psychiatry.

AUSP, however, has never acknowledged the competence of this review committee, and the executive committee has had to assume much of the responsibility for investigating allegations involving the Soviet Union. The work of the review committee so far was presented at an executive council meeting in Marrakesh earlier this month in a special report by the secretary general, Professor Peter Exner, which was reportedly condemned by the Soviet observer Professor Marat Vartanyan as being "too negative". For those member societies that have submitted allegations of psychiatric abuse to WPA, follow-up of the original complaint is hindered by what the complainants see as an unreasonable insistence on professional confidentiality.

Whether this strict insistence on professional ethics is a result of Soviet pressure is not clear. Ironically, in many cases, the complaints have been originated by the victims themselves asking to have the diagnoses made public, in order to reveal their dubious medical basis. There are growing fears among member societies of WPA that the executive council's over-scrupulous stance on confidentiality may unwittingly be going against the interests of other individuals whose cases are under review.

Vera Rich

Romanian emigrants

Cash demands

A decree promulgated earlier this month by the Romanian Council of Ministers seems certain to hamper the movement abroad of Romanian scientists. The decree requires that Romanian emigrants should repay (in hard currency) the costs of their secondary and higher education.

The decree is reminiscent of that in the Soviet Union some ten years ago designed to recover higher education fees from Jews wishing to emigrate to Israel. The Soviet ruling evoked widespread protests abroad, including the imposition of credit restrictions by the United States, and was allowed to lapse less than a year later.

The Romanian decree is likely to attract even more vehement criticism. Already the US State Department has called it a "draconian measure", contrary to the letter and spirit of the Helsinki accords, and has hinted that it could hamper the renewal, next year, of Romania's recently acquired "most favoured nation" status.

The condition that higher education costs, however calculated, should be repaid in hard currency, will be virtually impossible to satisfy. (It is illegal for Romanian citizens to have hard currency in their possession.) The most probable objective of the decree is to clamp down on emigration, a conclusion borne out by the reports from Bonn that the Romanian government has given notice to end the agreement under which up to 10,000 Romanians of German origin are allowed to emigrate each year.

The effects of the new decree, moreover, are liable to be felt in all countries that have scientific exchange programmes with Romania. The decree, for example, lays down that a scholar allowed to travel to an international conference who fails to return on schedule will be treated as an illegal emigrant, and will be sued for the cost of his or her education both at home (presumably with the confiscation of assets) and in the new country of residence. The relevant clause of the decree is phrased ambiguously, and could be construed to apply retroactively to those who have left the country in recent years, especially since the mid-1970s.

Vera Rich

British Astronomer Royal

Professor F. Graham Smith, now the director of the Nuffield radio-astronomy observatory of the University of Manchester at Jodrell Bank and until earlier this year director of the Royal Greenwich Observatory, was this week appointed Astronomer Royal of England. He succeeds Sir Martin Ryle, who resigned the post as from October. One of the ironies of the new appointment is that Sir Martin's appointment as Astronomer Royal was intended to mark a separation of that post from the directorship of the Greenwich Observatory.

EEC research council

Cash injections planned

Brussels

Despite the row over the budget for Super-Sara, the project for investigating what happens when light-water reactors lose coolant (see *Nature* 11 November, p.99), the November meeting of the EEC science ministers approved a near-record number of research programmes. With one or two minor reservations the pilot stage of the Esprit programme on long-range research on information technologies (see *Nature* 3 June, p.352), the 4-year indirect action programme in favour of developing countries, a programme for the development of a translation machine and finally the experimental phase of the project to stimulate the European Community's scientific and technical potential were all given the green light.

The programme to stimulate science and technology is to last 2 years and will have a budget of 7 million European Currency Units (£3.7 million), an increase of 40 per cent over the amount originally demanded. Before the programme can be implementated, however, the European Parliament must be given time to express an opinion and a formal proposal must be made by the Commission.

The money will be used to test out the Commission's plans to operate a new fund which it can invest rapidly in any projects considered promising without having to resort to the usual cumbersome system of elaborating formal programmes. The experimental phase will test out this concept in seven areas which are considered important and in need of "stimulation" — pharmacobiology, solid state physics, optics, combustion, photometry, photoacoustics, interface phenomena and climatology.

Under the new system, a consultative committee (CODEST) made up of outstanding authorities in science and technology will advise the Commission on how to spend the money. Applications for research grants, subsidies for laboratory twinning, development contracts, subsidies for research teams, seminars and workshops will all be considered.

If the experimental phase is successful, the scheme will be extended for the years 1984–87 and a figure — perhaps as much as £12 million, or 5 per cent of the Community's joint annual research expenditure, will be set aside each year.

The scheme was first agreed in principle at the last Council on 30 June, as was the Esprit programme, for which a pilot stage was agreed by the November Council, with 11.5 million ECU (£6 million) available from the EEC budget. Universities and companies will be expected to contribute at least 50 per cent of the cost if they seek support in carrying out research. Money has been set aside for pilot projects in advanced electronics (two projects), software technology (three), advanced information processing (three), office automation (four), computer integrated manufacturing (three), and information exchange systems. Each contract must contain at least one industrial participant.

A 5-year programme budgeted at 16 million ECU (£8.5 million) will now also start, aimed at building an advanced translation machine to "extend the frontiers of computational linguistics". The advantages of such a machine are evident when one considers that about a third of the 16,000 EEC civil servants are currently involved in translating or interpreting the seven Community languages.

And for the first time, the EEC will have a joint research programme in aid of developing countries (see *Nature* 15 July, p.218); 40 million ECU (£21 million) will be spent on two sub-programmes between 1982 and 1986: tropical agriculture and medicine, health and nutrition in the tropics. The programme has raised doubts in the minds of some delegations and at the European Parliament, since despite its title the programme will mostly benefit laboratories in the EEC rather than directly helping developing countries. However, the agreement to have the programme at all is an important step towards realizing the ambition of Viscount Etienne Davignon, European Commissioner with responsibility for research and development, to make work dedicated to assisting the developing world one of the seven pillars of the EEC's research and development strategy for the 1980s. **Jasper Becker**

French research and development

Can the good times last?

France's foreign debt is now estimated to be FF 300,000 million (£25,000 million), double the figure of a year ago, and the balance of trade deficit was running at FF 12,000 million (£1,000 million) a month in September. But still France continues to promise to spend, spend, spend on research and development. Earlier this month the National Assembly voted the government civil research budget for 1983: it will be FF 52,200 million (£4,300 million), 28 per cent up in money terms over 1982, and 17.8 per cent up in real terms. This is not a jot different from that previewed in the July "law for research" but the economic problems are raising fears that the figures will prove, in the end, a mere façade.

For instance, this year the finance minister ordered a freeze on government spending which — so far as science was concerned — held back a quarter of the planned budget for new research equipment. Caught unawares, laboratories which had already made orders found themselves falling rapidly into the red — until the minister of research and industry was able to claw back the 25 per cent just a few weeks ago. Other ministries, such a the ministry of national education, wer not so successful. There is talk next year o a freeze of 30 per cent. Will the researc minister claw that back too? Some dout it, despite the fact that in France, researc and technology appear to have become th new faith.

Nevertheless the budget figures ar worth analysing as indicators of intentio Jean-Pierre Chevènement, the researc and industry minister, plans to cut his cak of FF 52,200 million (£4,300 million) fo 1983 into FF 32.5 million for civil researc and development, and FF 19.7 million i support of his industrial and energy polic

The research budget proper — mone for the research councils — will be up 1 per cent to FF 23,500 million. The figur includes many salaries. There will also b fiscal support to companies undertakin more research (in particular a rather back handed relief from a new "tax o fortunes"). This and other measures ar intended to help industry boost its ow research budget by 8 per cent next year, a envisaged in Chevènement's grand plan.

Basic science is not the principal ben ficiary of the increases, although it is no neglected. The French government fundamental objective is the renewal o industry through long-sighte government-managed investment. So th greatest increase — 62 per cent — with the FF 32.5 million goes to Chevènement seven "*programmes mobilisateurs*" which cover new energies, electronics, bi technology, research and innovation f the Third World, research on the co ditions of labour, the promotion of th French language in science and technolog and general support for industri innovation. These are the workhorses Chevènement's policy, although nobo seems sure exactly how the cash will harnessed to research. **Robert Walga**

French civil research and development budget (thousand million FF)

	Budget 1982	1983	Increase (per cent)

In vitro fertilization

MRC tests the climate

A set of guidelines that gives qualified approval for researchers to perform experiments on human embryos obtained through *in vitro* fertilization was issued last week in a statement by the Medical Research Council (MRC). The guidelines are likely to please scientists working in the area, but the British Medical Association (BMA) has expressed concern that they may be too liberal for its members.

The MRC statement, published in the *British Medical Journal,* states that clearly defined research on embryos which are not intended for return to the uterus is ethically acceptable if it is "directly relevant" to clinical problems. It also allows the deliberate fertilizing of human ova *in vitro* for specified and approved research projects, as well as the use of fertilized ova left over from therapeutic programmes, provided that informed consent is obtained from both parents.

The guidelines were drawn up by an MRC advisory group under Professor Geoffrey Dawes. They are intended to apply only to MRC-supported scientists, who must in any case obtain specific approval for any proposed experiment from local scientific and ethical committees. Nevertheless, MRC's ideas are likely to be influential as a basis for discussion within the numerous other committees set up to consider the implications of recent developments in the field of human fertilization, such as the British government's Warnock committee (see *Nature* 29 July, p.408).

The MRC proposals allow *in vitro* culture of human embryos only up to the implantation stage, a clearly defined phase of development corresponding roughly to the time at which embryonic tissues become distinct from those of the placenta and organs start to form. This stage is reached at 13–14 days after fertilization, considerably older than the 9-day-old embryos that were at the centre of a recent storm after Dr Robert Edwards announced that he had kept and observed "spare" embryos initially produced for reimplantation. The new guidelines also permit experiments on interspecies formation — valuable for studying defective sperm — but in this case it is recommended that embryos should not be allowed to develop beyond the early cleavage stage. Experiments on techniques for freezing embryos for storage will be allowed provided that embryos are not stored for future unspecified research.

Dr Anne McLaren, director of MRC's Mammalian Development Unit at University College London, and a member of the advisory group that drew up the guidelines, has pointed out that research aimed at increasing the safety and the success rate of "test-tube baby" programmes is concerned with the embryo before implantation; workers in this area should not therefore find the guidelines overly restrictive.

The BMA, while accepting the MRC guidelines as "a valid contribution to the debate", appears to have reservations about how acceptable they will be to its members: a spokeswoman expressed the view that the MRC guidelines "will do nothing to allay public fears".

The BMA has its own committee under the chairmanship of Professor Peter Quilliam, seeking to establish guidelines for the medical profession, and is unwilling to make specific comments until the committee has made its report; however, it seems possible that the adoption of the implantation stage as what is in effect a criterion for the start of a human life could be a point of disagreement. In the meantime, BMA members are not banned from involvement in MRC projects. There is clearly a lot of arguing still to be done: in the foreseeable future there are going to be strong reasons for wanting to experiment on embryos considerably beyond the implantation stage. **Tim Beardsley**

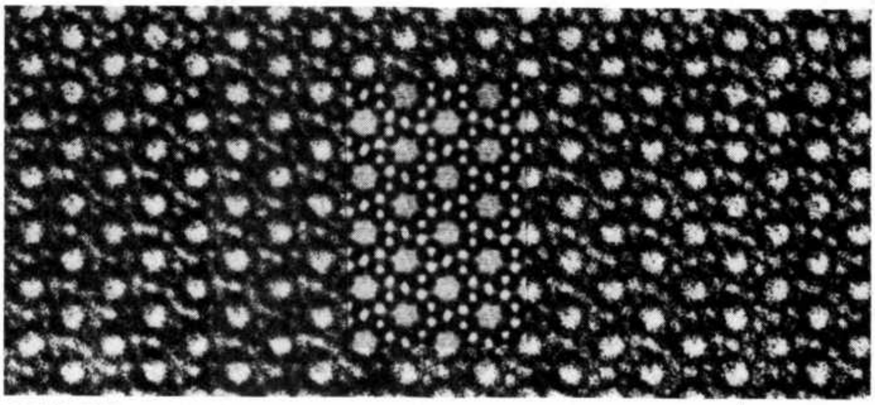
Research article triggers dispute on zeolite

Washington

An experimental result published in the 8 April 1982 issue of *Nature* has set off a legal battle between Union Carbide and Mobil Oil that may involve hundreds of millions of dollars in patent royalties.

The dispute is over synthetic minerals known as zeolites, which have become increasingly valuable as catalysts in the production of chemicals and liquid fuel from coal. The zeolites, which are crystalline aluminosilicates, have large regular pore structures making them highly selective in binding molecules of a desired size.

In 1977, Union Carbide obtained a patent for what it claimed was a novel form of zeolite called "silicaltite". But according to the analysis reported in the *Nature* article (C.A. Fyfe, J.M. Thomas *et al., Nature* **296**, 530), silicalite is in fact "identical" to a family of zeolites patented by Mobil in 1972. Mobil's zeolites, known as ZSM-5, are vital to Mobil's methanol-to-gasoline process.



Mobil's ZSM-5 zeolite. The diameter of the largest pores, lined with active sites, is 5.5 Å. A computer-simulated image is inset. (Photo: G.R. Millward/J.M. Thomas, University of Cambridge.)

Mobil then informed Union Carbide that it considered silicalite an infringement on its patent; Union Carbide responded on 21 September by suing Mobil in the Federal District Court in New York City, asking for a declaratory judgement that silicalite does not infringe on Mobil's patent. In a counterclaim filed 2 weeks ago, Mobil officially entered its charges of infringement.

Neither side is willing to discuss the case in any detail; Mobil has refused even to provide a copy of its response and counterclaim, which are part of the public record. But an industry expert on zeolites gave *Nature* the following explanation of the facts surrounding the case. Mobil's ZSM-5 patent covers zeolites with silicon-to-aluminium ratios from 10 to 4,000. Union Carbide claims that silicalite is 100 per cent silica within the zeolite framework; any aluminium that happens to be present in silicalite, Union Carbide says, is outside the framework, and thus does not play a part in silicalite's essential properties.

What Fyfe *et al.* showed, however, is that aluminium is present in silicalite in least two distinct tetrahedral environments — which means that aluminium *is* in the framework. Aluminium outside the framework is octahedral. "The silicalite structure is shown to be essentially indistinguishable from that of the siliceous zeolite catalyst ZSM-5", Fyfe *et al.* concluded. Their work involved the use of ^{29}Si and ^{27}Al NMR spectroscopy.

The speculation is that Union Carbide made the preemptive strike of suing Mobil after receiving an order for silicalite. The threat of a patent infringement suit would have to be removed from Union Carbide and the purchaser before a sale could go through. Union Carbide refuses to say whether an order has been received or whether any silicalite has been sold.

CORRESPONDENCE

This space was occupied by a letter withdrawn after the press deadline (see page 302)

South African ban

SIR — I do not wish to enter the debate about British participation in astronomy in South Africa but I must object to some statements in the letter from Dr David Evans (*Nature* 11 November, p.102).

He states that boycotts of the type proposed are usually ineffective. The only boycott properly applied to South Africa has been in the field of sport, and this has been most effective, leading to integration in most branches. Many of us believe that the same kind of pressure applied to academic circles would achieve a similar result with beneficial consequences for the education of non-whites in that country. An academic boycott might be a blow to some sections of the community (almost all white) but would be welcomed by many others (almost all black) who derive great moral encouragement from manifestations of external sympathy with their cause.

He is of course right when he says the South African government has a problem of "terrorist activity", although this is a term one prefers not to apply to people who are simply trying to achieve equal rights for themselves. It must of course be evident that South Africa has brought this activity on itself; the problem would not have existed had it not chosen to suppress the majority of its people by refusing to provide ordinary democratic rights. Dr Evans is most certainly a victim of South African propaganda when he refers to the activists as being "inspired by the Soviet Union". Has he learned nothing at all from events in Zimbabwe? African people want independence and self-determination, not replacement of one dominant force by another.

Finally, he may believe that the best hope for a peaceable solution lies in an increase of cultural links from abroad. He must know that South Africa used to enjoy these links fully as part of the British Commonwealth and a respected member of the international community. It chose to isolate itself by inflicting a policy of apartheid on most of its inhabitants. Why should increased contact with the rest of the world achieve more now than it did 35 years ago? R. HOFFENBERG

University of Birmingham,
Birmingham, UK

Naming enkephalins

SIR — It is easy, as Morley (*Neuropeptides* **1**, 231-235; 1981) has pointed out, to be misleading in attempting to specify the structures of enkephalins and their analogues. The commonest confusion may be caused if [Met]enkephalin, for example, is written as Met-enkephalin. This is because IUPAC-IUB recommendations, used throughout peptide chemistry, specify square brackets for substitutions and forms such as "Met-" for N-terminal extensions. Thus the form "Met-enkephalin" might well be necessary for extension of the basic sequence Tyr-Gly-Gly-Phe-Xaa to Met-Tyr-Gly-Gly-Phe-Xaa. The form [Met]enkephalin seems convenient as a simplification of the strictly systematic [Met^5]enkephalin, which should be used in contexts where ambiguity is conceivable.

The recommendations for C-terminal extension and for partial sequences are illustrated by the identity of [Leu^5]enkephalinyl-Arg-Arg with dynorphin(1-7) peptide.

References to the many printings of the 1966 IUPAC-IUB recommendations are given by Morley. They are now under revision, but there is no proposal to change appreciably any of the methods of designating N- and C-terminal extension of peptides, substitutions, deletions and partial sequences. The new recommendations are likely to be published in 1983. H.B.F. DIXON

Chinese seismometry revisited

SIR — I write with reference to an article on a Chinese seismometer featured in "*Nature* 100 years ago" (ref.1). You may be interested to learn that the original article carried some errors. According to Joseph Needham[1], "Choko" was the Japanese version of the name of Chang Hêng (AD 78-139), a noted astronomer, and his seismometer dates from AD 132 rather than AD 136. Several reconstructive drawings are illustrated in Needham's book and in 1910 another illustration was presented to this museum by the Japanese Imperial Department of Education.

We currently exhibit a sectioned reconstruction of the seismometer (see below), given by the BBC, which has been demonstrated on television. In 1980 the Chinese Seismological Association presented a small statue of Chang Hêng to the Science Museum; this too is on exhibition. The seismometer is also figured on one of a set of Chinese postage stamps, on display alongside Chang Hêng and his seismometer in our Geophysics Gallery.

What future for the chaos concept?

Is classical chaos a kind of premonition of quantum uncertainty or something separately? Now it may be possible to tell by means of an experiment, not endless argument.

What is chaos? During the past few years, physicists (not to mention philosophers of science) have been much preoccupied by the recognition — "discovery" would be the wrong word — that there are many macroscopic systems whose future behaviour cannot be accurately predicted. The old saw is that fourteen-day weather forecasting is impractical because, over such a time-scale, disturbances initially as negligible as the flapping of a single seagull's wings may turn out to have a worldwide effect. In meteorology, the problem is to know which seagull's flapping wings matter. There are two opposing answers to this absorbing question. Some will hold that the difficulty of calculating the effect of a pair of flapping seagull's wings is temporary; better mathematics, or larger computers, will make it possible to tell whether a seagull's wings have a greater effect when the Sun is at its zenith than at night, or whether mid-latitudes are more sensitive to disturbance than either tropical or polar latitudes. Others, however, take a different view. There are so many seagulls, so randomly distributed over the surface of the Earth but so constantly flapping their wings, that even if the mathematics of the meteorological problem were exactly soluble, the initial conditions would be intrinsically unknowable and the time-course of the development of the macroscopic system therefore intrinsically indeterminate. In this strictly classical sense, physical chaos is a way of referring to circumstances in which applied mathematics is imperfect — either the differential equations cannot be solved with sufficient accuracy or they (or the boundary conditions that should apply) cannot be accurately defined.

Inevitably, such circumstances are reminiscent of what happens in quantum mechanics: indeterminacy abounds. But to suppose that the similarity is meaningful would be mistaken. Quantum chaos is, after all, well-defined. You can measure the position of a particle but then not its momentum, or its momentum but then not its position, or some mixture of the two with uncertainties determined (apart from numerical constants) only by the mass of the object and Planck's constant. Chaotic macroscopic physics is distinct from that line of experiment (or *Gedanken*-experiment) but not unconnected with the reason why the generalizations of thermodynamics were fashionable in the nineteenth century, before people pretended to be able to solve complicated differential equations exactly. That, surely, is how sober physicists would argue.

But if quantal and classical chaos are independent phenomena, should it not be possible to find evidence of some kind of analogue of classical chaos in the behaviour of quantum systems? This is the question taken up by R.V. Jensen of Yale University in one of this month's issues of *Physical Review Letters* (**49**, 1365). Such problems are potentially important, as can easily be told by asking what will happen in the course of time to a large polyatomic molecule whose total vibrational energy is, say, either just above or just below the energy necessary to break one of the covalent bonds that hold the vibrating structure together. If the threshold is not quite surpassed, on classical physics the molecule will never shake itself apart. In a quantum framework, however, there will be a finite chance that the molecule will tunnel through from an entirely cohesive state to one in which there are two separate pieces. If the total vibrational energy is just greater than the threshold, quantum mechanics has nothing fresh to say — the rate of transition from one state to the other is greater, but the chance of sliding over a shallow barrier is not very different from that of tunnelling through it. On the face of things, only the case of a classical polyatomic molecule whose energy is just above the binding energy of its weakest bond is interesting; then, on the face of things, it can only be a matter of time, perhaps a long time, before the molecule falls apart. The argument about the classical problem of chaos is essentially that of whether the equations of motion or the initial conditions can ever be sufficiently well-defined as to make the calculations of a single molecule's fate determined. Most people would settle for an ensemble of molecules and some form of thermodynamics, statistical or otherwise.

Jensen's question is different — that of whether a quantum system can be expected to behave with a degree of unpredictability transcending what Heisenberg uncertainty would require. In principle, such questions could be resolved by experiment. How frequently does a polyatomic molecule whose Hamiltonian is well-defined choose to shake itself apart? How easily can an electron be detached from a polyelectronic atom? Unfortunately, such systems, in which the quantum numbers are necessarily large, are complicated by the inherent quantal uncertainty. What Jensen has done is to devise a hypothetical experiment in which it should be possible to search for quantum chaos without the interference of quantum uncertainty in Heisenberg's sense. Moreover, Jensen even promises that his experiment will be carried out.

The system considered is unusual, to say the least, and consists of the free electrons that must be supposed to exist above the surface of liquid helium. Such an electron is attracted to the surface by its electrostatic image charge, but prevented from penetrating the surface by the Pauli exclusion principle. Accordingly, in classical language, the electron oscillates between the surface and a distance (say a nanometre) determined by its kinetic energy. In quantum language, however, the electron is bound loosely in a potential well and, like an electron in any other kind of box, has a series of stationary states whose energy levels can be calculated by the manipulation of Schrodinger's equation. (Technically, the problem is not as simple as it sounds, for the potential energy is inversely proportional to the distance from the surface, as with any other electrostatic charge attracted by its image.) Jensen solves the problem by transformation of the dynamical coordinates to action-angle variables; those with an algebraic interest will discover that the Hamiltonian (total energy expressed as momentum position) can validly be written in terms of a pair of other variables one of which is the square root of the maximum amplitude of the electron's excursion from the surface, in which case the corresponding Hamiltonian variable is an angle.

The upshot is intriguing. Jensen supposes that electrons bound in this way near the surface of liquid helium are also perturbed by microwave radiation (whose wavelength is necessarily greater than the maximum excursion of the electrons and whose spatial variation can therefore be neglected). In classical language, electrons bound like this should be shaken free by the processes that lead to classical chaos. The interesting question is whether classical chaos persists in the quantum regime or whether it merges with it. The recipe that follows from Jensen's work is to point a beam of microwave radiation at a liquid helium surface and to observe the rate at which electrons are shaken loose, or microwave power absorbed. The phenomenon should be evident at about 320 GHz if the measured dielectric properties of liquid helium are applicable. Rarely can a point in the philosophy of physics have been reduced to such a simple measurement.

Mantle methane — fool's gold?

from the Planetary Sciences Unit, University of Cambridge

THE controversial idea perpetrated by Professor Tommy Gold of Cornell University that hydrocarbons have their origin in the outgassing of methane from the Earth were the subject of a recent discussion meeting* at the Geological Society. Gold believes that the Earth contains in its interior a vast reservoir of primitive methane (CH_4) incorporated at the time when the solid body first formed. He suggests that over geological time, higher-molecular-weight hydrocarbons might be formed from a gradual leak of this primordial gas — non-biological petroleum appears from gas on its way out of the Earth's interior rather than being formed from increasing maturation of biological debris on the way down from the surface.

Gold's ideas have provoked a lively debate in the scientific community (speakers against included G. Eglinton, University of Bristol; J. Watson, Imperial College, London; and M. Schoell, Hannover) and, not surprisingly, have generated interest within the oil and gas industries. Although a general air of scepticism among both academics and commercial companies prevails, convincing evidence to negate the idea completely does not seem to be forthcoming. Since it is Gold's habit to dismiss arguments against as depicting special circumstances, the often heated exchanges continue. The Natural Environment Research Council has opted to maintain an open mind and a committee has been formed to consider deep-source gas under the chairmanship of Sir Peter Kent, who, in his policy statement to the meeting, pointed out that the wide range of geological circumstances in the UK provides a very suitable platform for appropriate investigations.

Gold proposes that methane, which is stable at high confining pressures and low oxygen fugacity, rises to the surface, not in a continual stream, but through a series of isolated traps. When the pressure in a particular enclosure exceeds a certain value, some of the gas is discharged into the next higher level by a momentary opening of the interconnecting pore spaces. Depending on the pressure–temperature–oxygen fugacity relationships experienced by the ascending gas, it will either reach the surface as methane (which may even spontaneously ignite if large volumes escape into the atmosphere) or carbon dioxide.

Gold's theory gains support from several independent lines of evidence. First, methane has been found outgassing from mid-ocean ridge zones, crustal rifts, volcanoes and other areas of tectonic activity and also from a Russian deep drill-hole. The presence of methane at certain mid-ocean ridges correlates with that of ^{3}He (J. Welham and H. Craig *Geophys. Res. Lett.* **6**, 829; 1979) which is universally accepted as a primordial telluric gas component incorporated at the time of the Earth's formation. The inference therefore is that methane is primordial in origin, exists deep within the mantle and perhaps even acts as the 'carrier' of the ^{3}He.

Second, he argues that various He–CH_4–N_2 relationships across some oil and gas fields cannot be explained unless two pre-existing, two-component reservoirs are mixed together in a deep location.

Third, at certain localities, Gold envisages that methane outgassing through the crust, is converted to CO_2 by methylotrophic bacteria and is then incorporated into carbonate cements. These deposits have unusually light carbon isotopic composition (-35 to -25°/oo), thereby making them distinct from normal carbonate sediments. The methane from which they are produced shows a depth-dependent increase in δ^{13}C (from -80 to -40°/oo) which can be explained by the continual removal of relatively heavy carbon to form carbonate as the methane rises to the surface. (All isotope measurements herein are relative and defined according to the δ convention, where

$$\delta^{13}C\ (^\circ/_{oo}) = \left[\frac{(^{13}C/^{12}C)_{sample}}{(^{13}C/^{12}C)_{std}} - 1\right] \times 1000).$$

Thus, a single methane source is invoked to interpret the data. Opponents of the idea allude to the possibility of two methane origins to explain the trend — a deep thermogenically produced gas from a sedimentary source and a near-surface methane resulting from bacterial processes. Gold maintains, however, that the quantities of methane needed to produce some of the known carbonate deposits (for example, Cement, Oklahoma) would be vast (enough to fuel America at its current rate of consumption for 1,000 years) and therefore cannot have been generated by bacteria or cracking of higher hydrocarbons. If one accepts the Gold hypothesis that primordial methane alone is responsible for carbonate generation, then it is extremely interesting to note that in all cases the deposits lie directly above oil reserves. (Gold considers this as 'smoking gun' evidence that non-biogenic methane contributes to hydrocarbon formation.) However, even though only five per cent of all organic material produced in the geological environment (G. Eglinton) can be proved by specificity of carbon skeleton to have a biological origin, the idea that the remaining material has been produced non-biogenically has still not found favour.

It is by no means universally accepted that the carbonaceous gases escaping from the Earth's surface are primordial in origin. The alternative view is that they are from recycled material — unfortunately the residence time for carbon in this recyling event is estimated to be greater than 10^8 years (M. Javoy *et al. Abstr. 5th int. Conf. on Geochronology, Cosmochronology and Isotope Geology,* p.173, Japan, 27 June–2 July 1982) and so no useful information would be yielded by ^{14}C measurements. However, the stable isotope composition of methane (both D/H and ^{13}C/^{12}C determinations) may help to resolve the issue. Schoell certainly argued convincingly that the isotope systematics of methane in Lake Kivu cited by Gold as correlating with ^{3}He could be accounted for by reduction of magmatic carbon dioxide together with gas derived by fermentation.

It may be ironic that Gold believes that some of his strongest evidence for a primordial origin (as above) derives from stable isotope data, given the paucity of relevant information. Traditionally, the primordial δ^{13}C value of the Earth is quoted as being between -5 and -7°/oo. However, diamonds, which are undoubtedly of deep-seated origin and might be expected to have once resided close to the primordial carbon reservoir, display a range in δ^{13}C values from 0 to -30°/oo (D. Deines *Geochim. cosmochim. Acta* **44**, 943; 1980) for reasons as yet unknown. Furthermore, the δ^{13}C value of ^{3}He-correlated methane outgassing from mid-ocean ridges is found to be about -18°/oo (J. Welham *EOS* **61**, 996; 1980). How these data relate to δ^{13}C values from the other major carbon reservoirs [-7, -27, -41°/oo for atmospheric CO_2, CO and CH_4, respectively, or about 0°/oo for most carbonate deposits, around -25°/oo for organic matter (-35°/oo in the Precambrian) and around -25°/oo for the reduced carbon in magmatic rocks] remains an enigma mainly because of the small numbers of analyses of total carbon and gases in critical samples (δ^{13}C measurements are needed from deep-seated rocks, diamonds and kimberlites, fluid inclusions and locations such as basement fractures, kratons, subduction zones, back-arcs, fore-arcs, transform faults and so on).

Methane is a stable form of carbon in the early solar nebula and therefore should have contributed to the primitive Earth. Unlike the primordial noble gases, most of

0028-0836/82/470312-02$01.00

which are thought to have been lost early in the Earth's history, the other volatiles (H_2O, carbon-containing compounds and so on) were largely retained. Whether one likes Gold's hypotheses or not, and the man confessed to being 'as slippery as oil', he left his audience with many unresolved issues. The possibility that primordial methane still outgasses from the Earth, forms commercially exploitable accumulations and is involved with higher hydrocarbon formation cannot be dismissed out of hand; constructive research and exploration is necessary. □

An enlarged view of intracortical connectivity

from Nicholas V. Swindale

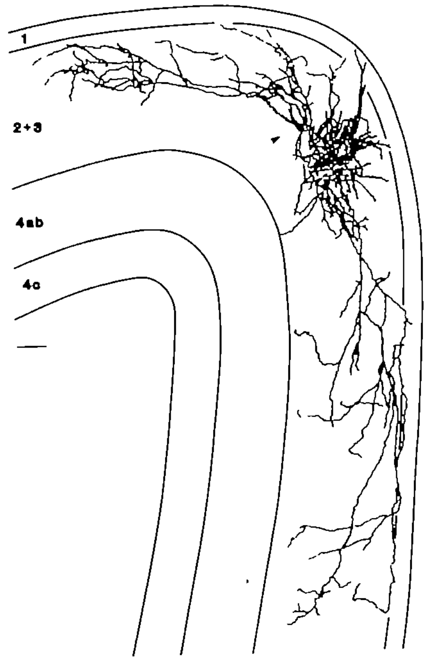
THE conventional view of intracortical connectivity, derived from the results of Golgi[1] and degeneration studies[2], is that lateral connections between nerve cells in the cortex are confined to distances of 1–2 mm or less. However, recent work involving studies of the transport of the enzyme horseradish peroxidase (HRP) following either extracellular[3-5] or intracellular[6,7] injection into the cortex suggests that some intracortical connections may extend over much larger distances. The functional significance of these long-range connections is unclear, but they do seem to be related to some aspect of columnar organization since, like many of the inputs to the visual cortex from other cortical and sub-cortical areas, they are organized into regularly spaced patches with a periodicity of about 1mm or less.

The clearest evidence comes from some experiments of Gilbert and Wiesel[6,7] in which they recorded intracellularly from neurones in the visual cortex of the cat, and then filled them with HRP so that their axonal and dendritic morphology could be reconstructed. Many pyramidal cells were found to have axons that extended laterally over distances of up to 3–4 mm, making periodically spaced clusters of connections (see the figure). The clusters of any one cell may be present in more than one cortical layer, and when they are, they are often in register, suggesting a relationship to some aspects of columnar organization. One reason why this observation has not been made before is that the intracortical axons are often myelinated, and thus fail to impregnate with the Golgi stain; another is that the patchy distribution of axon terminals is often only clearly evident when three-dimensional computer graphics techniques are used to rotate the reconstruction of an axon so that it can be viewed from a particular direction.

Another demonstration of what seems to be the same phenomenon comes from some experiments performed by Rockland and Lund[3-5] in which small extracellular injections of HRP were made into the visual cortex of tree shrews and monkeys. The HRP is transported into periodically spaced patches of cells and axons extending for distances of several millimetres in the upper layers of the cortex surrounding the injection site. Interpreting these results in terms of connections between different columns poses something of a problem however. Suppose that the long-range connections only link up columns of the same type — that, for example, columns of vertically orientation-selective cells only make connections with other such columns, and that columns for horizontal and oblique orientations are similarly interconnected. An HRP injection that was small enough to label the projections and inputs of only one such column would show the observed patchy distribution of HRP transport to similar neighbouring columns. But Rockland and Lund believe that their injections should have been big enough to label the connections with not just one such column, but many of them. As different columns occupy complementary regions of tissue, the pattern of HRP transport expected, on this line of reasoning, should have been much more uniform than was observed. Rockland and Lund's interpretation of the patchy HRP transport therefore is that the long-range connections link up only some regions of cortex and not others — something they refer to as a fixed-position connectional lattice.

Other explanations of Rockland and Lund's result cannot be ruled out at this stage however. One possible complication is that the HRP injection sites might be much smaller than they seem. Much more HRP might be taken up from the very small region of damage caused by the injection than from intact cells. Another possibility is that some cells are intrinsically more likely to take up HRP than others, and that these cells have a patchy distribution. This might conceivably be related to differences in transmitter type, or metabolic activity, for which there is evidence of a patchy variation in the monkey[8,9].

Even if these complications can be ruled out, patchy local uptake of HRP from a large injection does not necessarily imply that some regions of cortex possess long-range connections while others do not. Mitchison and Crick[10] have recently proposed some simple and plausible rules of connectivity between orientation columns that could explain the Rockland and Lund result. They suggest that connections between columns are not distributed radially, but are oriented in a direction that is related to the orientation selectivity of the cells that are being connected. As an example of why this might be so, consider Hubel and Wiesel's proposal[11] that complex-cell receptive fields are made by connecting together a number of simple-cell receptive fields. As a complex cell will respond to a line anywhere in a roughly circular receptive field, and the simple-cell receptive field is elongated, it would be necessary to join together a row of simple cells, the row running perpendicularly to the receptive field orientation. In the cortex therefore, the connections between columns would have to be made in a direction at right angles to the orientation preference of the cells in the columns, mapped onto the cortical surface. In the case where the columns form parallel stripes running in a horizontal direction in the visual field (as they do in both cats and tree shrews), vertically selective cells would have axonal fields elongated in the same direction as the stripes, while horizontally selective cells would have axons cutting across the stripes and making patchy connections. Given this pattern of connectivity, one can predict the local distribution of HRP uptake from an injection large enough to label the pro-



A pyramidal cell in layer 2+3 of the visual cortex of the cat traced by intracellular injection of horseradish peroxidase. Some axons extend laterally over distances of up to 3–4 mm.

Nicholas V. Swindale is in the Kenneth Craik Laboratory, Department of Physiology, University of Cambridge, Cambridge CB2 3EG and is currently working at the Department of Psychology, Dalhousie University, Halifax, NS B3H 4J1.

0028-0836/82/470313-02$01 00

jections to and from many adjacent columns. It is perhaps not intuitively obvious what this would be, but computer simulations show that the distribution of label would resemble that observed by Rockland and Lund, the patches having the same spacing as the orientation columns and running in a similar direction.

Mitchison and Crick's hypothesis of course applies to any system of long-range intracortical projections whose direction in the cortex bears some consistent relation to the orientation preference of the cells being connected (for example, to a system of connections designed to produce very elongated receptive fields by joining them end to end rather than sideways on). In this broad sense the hypothesis seems, *a priori*, more likely to be correct than not. Gilbert and Wiesel's anatomical results do provide some support for the idea, since they show that the axonal fields of cortical neurones are often elongated, though exactly how the direction of elongation relates to the receptive field orientation is not yet quite clear.

At this stage it might be better to wait for more experimental results before speculating further on the nature and function of the patchy intracortical connections. One needs to know, for example, how the HRP patches relate to other columnar systems, such as those for orientation and ocular dominance, and whether the patches formed by one cell innervate columns with similar, or different properties from those of the cell itself. It should also be a fascinating exercise to discover whether the patchy intracortical connections follow the same rules that characterize the development of the geniculo-cortical projection, and whether visual experience can similarly alter their morphology. □

Catch a passing monopole

from John Ficenec and David Olive

THE first international workshop to focus exclusively on both the theoretical implications and experimental techniques relevant to the detection of magnetic monopoles (isolated magnetic charges) was held recently at Wingspread*. More than 80 experts from an enormous spectrum of physics subdisciplines were brought together in Frank Lloyd Wright's last and largest prairie home through the courtesy of the Johnson Foundation. The meeting was called in response to an observation this spring by Blas Cabrera (*Phys. Rev. Lett.* **48**, 1378; 1982) of an event whose interpretation was consistent with the passage of a magnetic monopole.

The observation has not been corroborated either by Cabrera or others. The flux limit placed on the monopole after collecting more data and a refined analysis was 10^{-10} monopoles cm^{-2} sr^{-1} s^{-1}. This flux remains uncomfortably high when compared with the so-called Parker bound (E.N. Parker *Astrophys. J.* **160**, 383; 1970) of 10^{-15} monopoles cm^{-1} sr^{-1} s^{-1} at which galactic monopoles would dissipate the observed magnetic field of the Galaxy faster than it could be regenerated. Theoretical scenarios to resolve this discrepancy and to explain the candidate event were presented and debated. Numerous experiments, many in the development stage, were discussed. The topic remained in a state of flux with numerous theoretical and experimental questions unanswered, but the participants were optimistic that many problems could be resolved within the next few years.

One of the aims of physics is unification — the organization of the forces of nature, nuclear/strong, electromagnetic, weak and perhaps even gravitational, as different facets of a single symmetrical entity. Calculations indicate that the symmetry is only apparent at energies of 10^{14} GeV, and the characteristic differences between forces at ordinary energies arise because of symmetry breaking. Although this theory is elegant, the enormous disparity in scale between 10^{14} GeV and the proton rest mass energy of 1 GeV is unsettling, particularly since the high-energy regime is inaccessible to any conceivable particle accelerator. However, one consequence is that protons will decay (see *News & Views* **299**, 295; 1982) with a lifetime of $10^{31\pm2}$ yr which should be observable in large-volume experiments already set up and running.

Another prediction of the grand unified theories is the existence of magnetic monopoles which elementary text books tell us do not exist (see *News & Views* **277**, 174; 1979). One of these might weigh as much as 10^{16} protons and, hence, be too heavy for production by particle collisions except in the first 10^{-35} seconds of the life of the Universe, if the latter was indeed created in a big bang as is currently believed. These monopoles would be expected to survive unscathed until the present day but their signature was not observed before this year.

Several suggestions were made to reconcile the discrepancy between Cabrera's upper limit and the Parker bound. One was that the monopole was as heavy as the Planck mass — 10^3 times heavier than previously assumed — thereby increasing the Parker limit. Another was that the distribution of monopoles is not uniform in the Universe, clustering, for example, in the galactic haloes near where we reside or near massive objects such as our Sun.

The experimental challenge was seen to be the detection of a monopole flux as low as the Parker figure. Coincidence experiments using superconducting coils in 10^{-8} G with area 10^2 cm^2 and in 10^{-2} –1 G with area 10^2–10^4 cm^2 were described. These detectors are sensitive to the passage of a magnetic charge, whatever its velocity. Large-area (10^6 cm^2) scintillators and Cherenkov counters, such as those used in proton decay experiments, are being adapted, and a 'football field' size (10^8 cm^2) acoustic detector is being planned. Yet another approach attempts to discover monopoles trapped in matter by positioning a superconducting coil under an iron ore plant conveyor belt, thereby monitoring more than a million tons of ore per year.

Due to the effect of the galactic magnetic field the velocity of a free monopole is expected to be less than about 10^{-3} of the speed of light, which is somewhat less than the speed of an electron in an atom. This limits the type of energy-loss mechanisms available to the passing monopole, and the optimization of detector materials depends on a better understanding of the effect of these slow monopoles. The detectors based on superconducting coils neatly avoid these difficulties.

Physics thrives on paradoxes created by interactions between different ideas, in this case the commonly accepted pictures of cosmology and particle physics. Hence, one theoretical challenge was the construction of a combined cosmology and particle physics theory which did not overproduce monopoles. It seemed that an inflationary universe is an essential ingredient at least at very early times (J.D. Brown & M.S. Turner *Nature* **298**, 801; 1982).

John Ficenec is in the Department of Physics, Virginia Tech, Blacksburg, Virginia 24061. David Olive is on leave from the Blackett Laboratory, Imperial College, London, at the Departments of Mathematics and Physics, University of Virginia, Charlottesville, Virginia 22901.

---

*The 'Magnetic Monopole Workshop' held at Wingspread near Racine, Wisconsin, on 14–17 October was sponsored by the North Atlantic Treaty Organization, the US Department of Energy, the US National Science Foundation and the Johnson Foundation. The proceedings will be published in early 1983 by Plenum, New York.

0028-0836/82/470314-02$01 00

Another theoretical challenge was the elucidation of a new effect which could change the previous estimates for proton decay if monopoles were abundant. It has been known since the last century that the relative angular momentum of an electric and a magnetic charge has a term equal to the product of their charge times the unit vector pointing along the line joining them. If the projectile passes straight through the target in a collision, then conservation of angular momentum means that the sign of electric charge must reverse in order to balance the reversal of the unit vector. This means the monopole must absorb two units of charge. In a theory including the strong interaction gauge group, baryon number could also be absorbed by the monopole, thereby catalysing proton decay to give a distinctive experimental signature. ☐

Recent (1981–82) evolution of galactic haloes

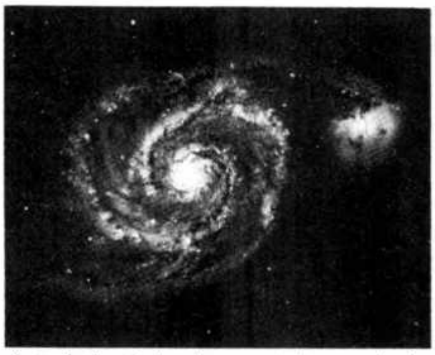
from Virginia Trimble

THE halo of our Galaxy is perhaps a bit older, a bit richer in heavy elements, a bit less massive and undoubtedly a bit more complicated than it was before the recent meeting* of the International Astronomical Union in Greece.

A typical spiral galaxy, whose most conspicuous component is a flat, rotating, armed disk, also has a halo of stars which includes the oldest stars in the galaxy, and which bears at least a passing resemblance to the other major class of galaxy, the ellipticals. Many halo stars are still gravitationally bound in globular clusters of 10^5–10^6 stars in which they formed. There is also a 'scattered field' star population, generally advertized as consisting of fugitives from the clusters.

Among the things we would like to know about the haloes of our own and other galaxies are (1) the ages of the oldest stars (because this sets a significant lower limit to the age of the Universe), (2) their chemical compositions and how they acquired their heavy elements (since, after all, stars formed out of virgin big bang material should be pure hydrogen and helium, and we see no stars like that), (3) whether the globular cluster and field stars are really part of a single population, (4) whether the dynamical structure of haloes is similar enough to that of elliptical galaxies to suggest a common origin (this would considerably simplify the difficult problem of making galaxies out of lumps in the early Universe) and (5) whether there is anything in the haloes besides the stars we see, and, if so, how much of what (because significant mass there will affect our estimate of the average density of the Universe and so its future evolution). New evidence bearing on these questions appeared at the meeting and in recently published papers.

How old are the stars? Rather older than is entirely convenient! The standard method of measuring the age of a star cluster is to compare the positions of the stars in a graph of brightness against surface temperature or colour (HR diagram) with calculated versions of what those positions ought to be as a function of the age of the cluster stars (and, unfortunately, their chemical composition and other variables also). The integrated brightness and colour of a cluster can be used somewhat similarly. These methods have yielded values of 7–25×10^9yr in the past. R. Cannon (Royal Observatory, Edinburgh) and B. Carney (University of North Carolina) reviewed eight more-or-less independent recent applications that concur on ages of 15–18×10^9 yr, at least for the metal-poor clusters. If stars this old are to be fit into a standard Friedmann model of the expanding Universe, then the Hubble constant, H_0, must be less than about 65 km s^{-1} Mpc^{-1}; and if H_0 is to be $\gtrsim 50$, then the Universe must be a low-density (ever-expanding) one as well. According to Carney, the likely errors go in the direction of making these ages, if anything, underestimates. On a related topic, S. Faber (Lick Observatory) discussed evidence from UV photometry of elliptical galaxies indicating that star formation in them also stopped some billions of years ago (though not necessarily so many as 15).



A typical spiral galaxy contains two basic components: a flat, rotating armed disk and a spherical halo of stars which, at their most concentrated, form the central bulge of the disk.

What is the chemical composition of the halo stars? It varies. There has been agreement for some years that the more metal-poor of the globular clusters have about 1 per cent of the solar heavy-element abundance. At the other end of the scale, there has been a continuing discrepancy between photometric studies, which found the most metal-rich clusters to come within a factor of three or so of solar abundance (like the oldest disk stars), and spectroscopic studies, which found much lower abundances. G. Gustafsson (University of Uppsala) drew attention to several sources of uncertainty in both methods, and reported spectroscopic work by M. Bessell (Mt Stromlo Observatory) that yields abundances close to the photometric (higher) values. If this is the right answer, then evidently chemical processing (birth and death of stars) continued in the halo until the remaining gas collapsed down into a disk and began forming stars there. This is rather easier to understand than a picture in which there is a large gap in composition between the youngest halo stars and the oldest disk ones.

Is there a single halo population? Apparently not. The field and globular cluster stars seem to have the same dynamical characteristics, ages and range of metal abundances, but there are detailed differences. R. Kraft (Lick Observatory) suggested that the field stars have, on average, smaller amounts of nitrogen, larger amounts of carbon and a narrower range of abundances of both than do cluster members. This implies either that the field stars are less highly evolved (less thoroughly mixed), meaning that they are younger or less rapidly rotating or something, or that the cluster members have been more thoroughly contaminated by heavy elements made in supernovae in the clusters themselves. Differences between field and cluster stars in the ratio of barium to iron[1] at least weakly support the first, evolutionary, sort of hypothesis. A difference between cluster and field stars in the maximum metal abundance to be found among RR Lyrae and type II Cepheid (pulsating variable) stars is not easily explained by either mechanism[2]. Thus, if the field stars have merely escaped from the clusters, they have not done so at random.

Are elliptical galaxies and the spheroidal parts of spirals the same sort of thing? Again, apparently not. The general shape and ranges of compositions and ages are similar, but there are significant differences. Spiral bulges (the central part of the spheroidal component) have fewer globular clusters per unit luminosity than do ellipticals[3]. This could only be fit into a unified model if clusters were somehow torn apart by the process of disk formation, which seems unlikely. In addition, ellipticals typically show a steeper gradient of composition, from metal-rich at

*The meeting was held in Patras, Greece on 16–26 August 1982.

0028-0836/82/470315-02$01.00

the centre to metal-poor at the edges, than do spiral bulges[4]. This might just mean that chemical evolution operated longer or more efficiently in them. But, finally, well studied haloes show overall net rotation[5], which is not found in most elliptical galaxies and could not very well have been introduced after galaxy formation was complete.

Finally, what, if anything, is in the haloes besides the stars we see? Probably, though not certainly, up to 90 per cent of the mass of the Universe. J. Ostriker (Princeton University) reviewed observational evidence of measured galactic masses that increase roughly linearly with the radius out to which the measurement is made, from the inner 10 kpc sampled by rotation curves, through the 20–100 kpc range sampled by orbits of globular clusters and satellite galaxies, out to the 1–3 Mpc sampled by dynamics of rich clusters (see ref. 6 for another recent summary).

The implication is that a typical large galaxy has associated with it about 10^{12} $M_\odot$ (mass of the Sun) in some form, of which we can see only about 10 per cent in disk and halo stars. D. Schramm (University of Chicago) reviewed the arguments indicating that the invisible material is quite likely to be in the form of exotic particles such as non-zero-rest-mass neutrinos, photinos, or gravitinos. This evidence is largely negative — adequate amounts of ordinary matter could not have escaped detection, either directly or through their influence on big bang synthesis of helium and deuterium.

But two noteworthy arguments against extensive invisible mass, at least in some galaxies, surfaced at the meeting. First, J. Hunter (University of Florida; see also ref. 7) presented a rotation curve for the barred spiral NGC3992 showing 2×10^{11} $M_\odot$ within the inner 19.7 kpc (on the de Vaucouleurs 'short' distance scale) and velocities of satellite galaxies around 3,992 indicating at most 4×10^{11} $M_\odot$ within 59 kpc, so that *M(R)* must increase much less steeply than linearly with *R*, and might stop increasing entirely beyond about 20 kpc. The most relevant response to this is that other galaxies with satellites do show rising *M(R)*, and that even HI profiles (roughly, rotation curves) yield masses of order 10^{12} $M_\odot$ for some galaxies, when the data extend out far enough, as witness the line widths near 800 km s^{-1} for NGC5635 and IC4553 (ref.8).

Second, A. Kalnajs (Mt Stromlo Observatory) showed results of his calculations of the rotation curves produced by various sorts of mass distributions. The result most impressive to his audience is that it is quite possible to get a flat rotation curve, in which velocity versus radius does not drop off at large radius, without invoking a massive, unseen halo component. The secret is a model in which halo and disk have the same constant ratio of mass to luminosity (3–7 in solar units for the galaxies he fit) out to the last measured point, where both end sharply, so that we cannot measure the rotation curve out where we would expect velocity to be dropping with increasing radius in a kepplerian way. The four galaxies fit in this way have data extending out to 5,8, 12 and 25 kpc from their centres; and the fits do not much constrain what is going on outside that. The mass distributions may, indeed, end sharply as in the models or may continue out to 100 kpc or more without distorting the rotation curve near the centre. Which is right must be determined from data that probe further out, such as those from satellite galaxies, binary galaxies and rich clusters, invoked by Ostriker and others in support of massive haloes. Many participants nevertheless came away feeling that the evidence for massive haloes had largely disappeared. This is, perhaps, a natural over-reaction to having had the arguments in favour presented so vigorously at so many previous meetings! ☐

Human monoclonal antibodies

from Karol Sikora and A. Munro Neville

Now that the application of monoclonal antibodies to the diagnosis and treatment of human disease has become the major goal of many investigators, a limiting factor is the availability of human rather than mouse or rat monoclonals. Human monoclonal antibodies are particularly needed for administration to patients for diagnosis and therapy in order to minimize the problems of administration of a foreign animal protein, with the risks of anaphylaxis and the clinical manifestations of immune complex formation, as well as abrogation of the antibody's effects.

The short history of human monoclonal antibody production has been fraught with technical difficulties but several novel systems now hold out promise. Initial attempts used available mouse and rat myeloma lines for fusion[1-3]. Unfortunately the resulting hybridomas preferentially lose human chromosomes, eventually eject the chromosomes coding for immunoglobulin production and thus lose the ability to produce monoclonal antibodies. Although early and repetitive cloning of the hybrids can reduce the shedding of human chromosomes, the development of more stable human–human hybridoma systems seems desirable.

Accordingly several groups have developed human systems from which hybridomas may be created. Unfortunately many human myelomas are difficult to grow in tissue culture and have low growth rates and poor immunoglobulin secretion. Nonetheless, certain lines have been 'adapted' to grow in culture in genetic selection conditions in which the growth of the myeloma is suppressed but the hybridomas continue to propagate. There have, however, been difficulties with mycoplasma infection in myeloma stocks. Indeed many investigators have been unable to obtain any hybridomas at all with lines donated by certain laboratories, causing considerable controversy.

The use of several human myeloma or lymphoblastoid lines was discussed at a recent workshop in Cambridge held under the auspices of the Ludwig Institute for Cancer Research (LICR). The ideal properties of such a cell system include high fusion frequency, high cloning efficiency, the ability to grow rapidly in non-stringent serum conditions, no secretion of myeloma or lymphoid cell immunoglobulin, and yet the production of large amounts of immunoglobulin after fusion to suitable lymphocyte donors. M. O'Hare (LICR, London) described his experience with the cell line LICR-LON-HMy2 (ref.4) — a derivative of the human 'myeloma' ARH77 (ref.5). This lymphoblastoid line expressing Epstein–Barr virus (EBV) antigens appears to be the best available system. Reasonable fusion frequencies have been obtained from a variety of human lymphocytes but the immunoglobulin secretion rate is low at 0.2–8.0 µg ml^{-1} in 24 h.

K. Sikora (LICR, Cambridge) reported that use of the same line. Intra-tumoral and regional node lymphocytes from the tumour-draining nodes of 180 patients resulted in the successful production of new immunoglobulin-producing hybrids in 24 cases[6]. When these were screened for antitumour antibody activity, weak binding was detected in only nine hybridoma supernatants. More success was achieved when fusing intra-tumoral lymphocytes from patients with malignant glioma, and three monoclonal antibodies to lung cancer were obtained by fusing lymphocytes from intra-thoracic lymph nodes removed at the time of surgical

TOPOGRAPHIC RELIEF FROM SEASAT ALTIMETER MEAN SEA SURFACE
JULY 7 - OCTOBER 10, 1978
PARKE, STAVERT AND HUSSEY (1982)
NW - SE GRADIENT, METERS/DEGREE
-5
0
+5

THE gravitational signature of tectonic features can be clearly seen in the topographical relief maps of the world's ocean surface shown above. Data from the Jet Propulsion Laboratory's Seasat oceanographic satellite were used to produce the map after processing to emphasize steep, small-scale features that tilt towards or away from the north-west.

The Mid-Atlantic Ridge and the trenches along the west and north-west margins of the Pacific Plate are clearly visible, as are the chain of Hawaiian seamounts.

The extent to which a seamount affects the local gravity field depends on the age of the underlying crust when the seamount was formed. If the seamount formed on young flexible crust, the crust deforms around the seamount, compensating the effect of the seamount's extra mass. Seamounts formed on older, more rigid crust are not compensated in this way, resulting in a gravitational signature that is more apparent at the sea surface. For use of similar GEOS-3 altimetric data to investigate sea basin formation see *Nature* **299**, 117; *News and Views* **299**, 104; 1982. ☐

---

treatment[6]. Again, the secretion rate of patient-derived immunoglobulin was low. None was tumour type specific.

Coté (Sloan Kettering Institute, New York) described his work involving over 80 fusions with three different hybridoma systems — SK007 (which had been rendered free from mycoplasma infection[7]), LICR-LON-HMy2 and NS1, the standard mouse myeloma[8]. Immunoglobulin secretion rates varied from 1 to 100 μg ml^{-1} with no consistent differences between the three fusion systems. Early cloning and stringent culture conditions seemed to be important prerequisites for success with inter-species hybrids if continued production of human immunoglobulin for long periods was to be achieved. Some human antibodies with interesting specificities to tumour cytoskeletal components were demonstrated by elegant immunohistological studies using human tumour lines. Using the lymphoid cell lines UC729-6, I. Royston (University of California, San Diego) was able to produce monoclonal antibodies which reacted with various cancer cell lines, but not normal lymphocytes, granulocytes, red cells or fibroblasts. These antibodies, although binding weakly to a variety of tumour cells, were in no way tumour specific. S. Clark (University of Glasgow) used diethyl pyrocarbonate[9] in concentrations near the mean lethal dose for myeloma cell lines as a selection mechanism for cells whose enzyme components were complemented after fusion. This allowed the outgrowth of hybridomas. He described work using the human myeloma RPMI 8226 and a sub-line of the EB4 myeloma — SJR22C. Again, there were problems of low fusion frequency and poor cloning efficiency.

Perhaps most interesting was D. Crawford's (Imperial Cancer Research Fund, London) account of making monoclonal anti-influenza and anti-rhesus D antibodies by infecting peripheral blood lymphocytes from donors with EVB. Several groups have tried this technique over the last few years without much success, the main stumbling block being the cloning of the EBV-transformed lymphoblast. Using a combination of *in vitro* stimulation by immunizing antigen and early cloning by limiting dilution, Crawford was able to demonstrate that not only could useful antibodies be produced but also the concentration of immunoglobulin produced was at least equivalent to the best human hybridoma systems now available. The necessary ingredients in the recipe for success are still unclear. Several groups are investigating the possibility of initial EBV transformation, selection of cells with the required antibody specificity and subsequent immortalization by cell fusion in a hybridoma system.

We are still unfortunately plagued by technical problems in the production of human monoclonal antibodies, not least in discovering ways of collecting those lymphocytes that produce antibodies with the specificities being sought for different experimental purposes. It is too early to know whether all the current efforts will result in biologically interesting molecules with fundamental and clinical potential or just additional reagents with little difference from other available rodent monoclonal antibodies that can be obtained with significantly less effort. Nonetheless, the prospect of the former result will stimulate many groups to study and develop human hybridoma systems in the near future. The outcome could be exciting. ☐

The recovery of Halley's Comet

from David W. Hughes

AMERICAN and European astronomers have been competing with each other to be the first to sight Halley's Comet. It was last seen at the end of May 1911, heading away from the Sun and passing below the orbit of Jupiter. It reached aphelion in 1948 and has been racing back towards the inner Solar System ever since.

The Americans have won. *International Astronomical Union Circular*, number 3737, reported that D. Jewitt, G. Danielson, J. Gunn, J. Westphal, D. Schneider, A. Dressler, M. Schmidt and B. Zimmerman recovered the comet on the night of 16 October 1982. They used a charge-coupled device at the prime focus of the 5.1 m (200 inches) Hale telescope at the Palomar Observatory, California. Charge-coupled devices are much more sensitive than photographic plates and with the 5.1 m telescope can detect objects fainter than 25th magnitude, some 50 times fainter than the photographic limit. Five 8-min exposures were taken through a broad-band blue filter. An object was detected near the expected position of the comet, moving in the expected direction at the expected velocity. It had a magnitude of 24.3±0.2 (a change of unity in magnitude is equivalent to a factor of 2.5 in brightness, so Polaris the Pole Star is 7×10^8 times brighter than Halley's Comet at present). Confusion with an asteroid is regarded as extremely unlikely. The recovery was confirmed by M. Belton and H. Butcher who obtained accurate cometary coordinates on the nights of 18 and 20 October using a cryogenic camera and charge-coupled device on the 4 m Mayall telescope at the Kitt Peak National Observatory (*IAU Circ.* no. 3742). Their report of the unsuccessful search during winter 1981–82 can be found in *Nature* (**298**, 249; 1982).

No coma was detected, but this is hardly surprising because the surface temperature of the nucleus is expected to be about 120K. The recovery brightness indicates that the nucleus of the comet, assuming that it has a geometric albedo of 0.05, is about 9 ± 1 km across.

Halley's Comet, now termed 1982i, because it is the ninth new or recovered one this year, is in the constellation of Canis Minor. On 16.47569 October it was at a Right Ascension of 7 h 11 min 01.9 s and a declination of $+9°33'03''$, putting it only 0.6 s west of the position predicted by D. Yeomans (*The Comet Halley Handbook*, JPL 400-91 1/81; 1981). The comet is early and will pass perihelion some 8.6 h before the expected time of 9.66128 February 1986. At recovery Halley's Comet was 11.04 AU away from the Sun, so it has broken two records — it is the most distant comet ever seen, beating Stearn's Comet (1927 IV) by about 1 AU, and the faintest comet ever recorded.

The fact that Halley has been recovered 3.3 yr before perihelion passage is also amazing. At its 1910 return it was first seen on 11 September 1909 about 7.5 months before perihelion by Max Wolf, who used a one-hour photographic exposure with the 72 cm Heidenberg reflecting telescope. It was then at the outer edge of the asteroid belt about 3.4 AU from the Sun and of magnitude 16. It was 10 arc min from the predicted position and the previously predicted perihelion passage time was 3.03 days too early.

The Europeans were also first at the return before that. Dumouchel, the director of the Collegio Romano Observatory, obtained the first telescopic view of the comet on the morning of 6 August 1835, 3.3 months before perihelion passage. At that time the comet was 17 arc min in declination and 7 arc min in Right Ascension away from the predicted position, giving a predicted perihelion passage time 5 days too early.

So it seems that congratulations are in order. Yeomans' positional predictions have been proved to be extremely accurate, even though the comet is three times fainter than estimated. And the team who recovered the comet have pushed astronomical techniques to the limit and succeeded. All the scientists preparing space experiments for the 1986 perihelion passage of Halley's Comet can breathe a sigh of relief too. It is where it was expected to be, coming towards us at a speed of about 11 km s^{-1}; they have just got 8.6 h less time to get ready. ☐

David W. Hughes is lecturer in Astronomy and Physics at the University of Sheffield, Sheffield S3 7RH.

Confident carbon calibrations

from D.D. Harkness

SEVERAL proposals of fundamental importance to the confident interpretation of ^{14}C data were put forward at the 11th International Radiocarbon Conference[*]. Of major consequence was a plan to revise the constants and format used in the calculation and reporting of conventional ^{14}C years BP. In the event, the plan was overwhelmingly rejected in favour of the *status quo* — definition of the time scale by use of a half life of 5,570 ± 30 yr and the setting of AD 1950 as the zero age. Similarly, it was accepted that the expression of analytical uncertainty should remain as the individual laboratory's best estimate of one sigma statistical confidence in age measurement. In contrast, no agreement could be reached on the question of a standard procedure for isotopic normalization in the calculation of marine shell ages.

Routine accuracy in ^{14}C measurement was recently assessed in various laboratories on the basis of tree-ring dating (International Study Group *Nature* **298**, 619; 1982) and a review of the results suggested the need for a more frequent exchange of samples between laboratories and the uninhibited publication of such results. Practicing laboratories also welcomed the opportunity for collective assessment of the new reference material (1980 oxalic acid) issued by the US National Bureau of Standards. Following appraisal and discussion of its isotopic ratios, as measured relative to the established (1957 NBS oxalic acid) standard, the issue of the replacement standard was endorsed but it was noted that an accompanying statement on the isotopic enrichment factors proposed for routine dating work was desirable.

Causal mechanisms for variations in natural ^{14}C concentration received considerable attention and a consensus emerged that the established long-term and high-frequency (wiggle) variations in ^{14}C production rate primarily reflect changes in geomagnetic field intensity. Solar and climatic effects cannot be entirely precluded from the available tree-ring/^{14}C record but they are certainly small — no clear correlation is evident, for example, between the existing carbon isotope (tree-ring) record and historically recorded climate (M. Stuiver, University of Washington). Nevertheless, a measurable impact on the atmospheric ^{14}C inventory could be expected from the marked changes in the dynamics of the global CO$_2$ system during the glacial to postglacial transition (H. Oeschger, University of Berne). Beyond the range of dendrochronological comparison, parallel ^{14}C and ^{230}Th ages from cave deposits, which are concordant during the Holocene, indicate a higher ^{14}C content in the Peniglacial atmosphere — a major ^{14}C

---

[*] The 11th International Radiocarbon Conference was held at the University of Washington under the sponsorship of the National Science Foundation, the Weyerhaeuser Company and the Quaternary Research Centre, Department of Geological Sciences and Department of Physics, University of Washington The conference proceedings will be published in *Radiocarbon* 25 (1983)

D.D. Harkness is at the NERC Radiocarbon Laboratory, Scottish Universities Research and Reactor Centre, East Kilbride.

0028-0836/82/470318-02$01.00

fluctuation at about 29,000–31,000 BP is again attributable to variations in global magnetic field strength (J. Vogel, University of Pretoria).

Ongoing attempts to determine the precise secular pattern of past ^{14}C variations mainly make use of the opportunity provided by tree-ring data for 'absolute' calibration of ^{14}C ages. Significant progress has been made in compiling continuous ($\sim$8,000 yr) chronologies from Irish and central European oak deposits with only a few gaps remaining to be bridged in each sequence (J. Pilcher, University of Belfast). Although numerous high-precision ^{14}C measurements with good agreement between laboratories are already completed from these oak deposits, an attitude of caution prevailed over early publication of the 'European oak calibration' as a more precise, but as yet partial, alternative to the re-evaluated Bristlecone pine record (Klein, J., Lerman, J.C., Damon, P.E. & Ralph, E.K. *Radiocarbon* **24**, 103; 1982).

Several papers *en bloc* served to confirm the continuing role of $^{14}C/^{12}C$ variations, both natural and man induced, in studies of the contemporary environment. Appreciable coverage was given to the use of ^{14}C measurements, in conjunction with allied geochemical data, to establish the recharge, transport and carbon exchange characteristics of regional groundwater systems. The continued interest in ^{14}C as a quantitative tracer for mass transfer highlighted the importance of the deep ocean as the ultimate sink for fossil CO_2; however, the net uptake of this anthropogenic excess must lead eventually to the increased dissolution of sedimentary calcite (T. Peng, Oak Ridge National Laboratory). Akin to its value in identifying urban sources of atmospheric and freshwater pollution, the sensitivity of ^{14}C measurement can contribute to the direct evaluation of localized gaseous dispersion patterns from nuclear installations (R. Otlet *et al.*, AERE, Harwell).

Awareness of intrinsic contamination in sample materials selected for conventional dating studies was a recurrent theme. Organic-poor sediments, often preferred for their more lucid geomagnetic signature, are particularly susceptible to the 'ageing' influence of allochthonous carbon (J. King, University of Minnesota). Similarly, while ^{14}C analysis of freshwater carbonates can provide interesting geochemical insights, the inferred dates are, in general, suspect (R. Pardi, Queen's College, CUNY).

A comprehensive review of technical progress in the application of accelerator mass spectrometry to natural ^{14}C measurement came from some eleven research groups active in the field. In essence, while the great promise of a revolutionary breakthrough in ^{14}C dating method seems ever closer, it has yet to be fulfilled. The routine preparation of suitable and isotopically homogeneous targets, together with the need to attain improved accelerator stability during and between sample runs, are outstanding constraints to the achievement of an analytical precision comparable with that established in radiometric counting. However, an incentive to continued development was the recent achievement of about 5 per cent analytical precision (equivalent to ± 400 yr dating uncertainty) in $^{14}C/^{13}C$ measurement using milligramme-sized carbon samples (D. Donahue, University of Arizona). By present comparison the proven, if less instrumentally demanding, application of this analytical approach in natural ^{10}Be measurement represents an immediate and exciting prospect for Quaternary research.

From shilling prisms to digitized images

from L.T. Sharpe

SELDOM has the field of colour vision been more stimulating than it is today when new techniques allow us to explore what for centuries has been mere matter for speculation. Modern methods and historical contributions were jointly emphasized at a recent international meeting* on colour vision held in Cambridge — a fitting place to bring together colour scientists because the problems of colour have exercised many of the university's most distinguished physicists and physiologists, including Newton, Young, Maxwell and Lord Rayleigh. Indeed, for many at the conference, the beginnings of modern colour science were betokened by a holograph notebook (lent for display by the Fitzwilliam Museum) in which Newton recorded his purchase in 1667 of three prisms for three shillings.

The meeting covered an unusually wide range of topics from microspectrophotometry of visual receptor cells to the phenomenological constancy of coloured surfaces illuminated by spectrally very different sources.

Perhaps the most impressive advances have been made at the very beginning of the visual pathway, in studies of visual transduction in single primate photoreceptors by Nunn and Baylor of Stanford University that have just been reported in *Nature* (**299**, 726; 1982). Individual outer segments of rods from cynomolgus monkeys (*Macaca fascicularis*) were sucked into micropipettes of small (2μm) orifice diameter so that the reduction in membrane current that occurs when light stimulates the outer segment could be measured. Transverse stimulation of the outer segments by spectral lights over the range 400–720 nm produces a spectral sensitivity curve with a peak at 491 ± 3 nm. An interesting discrepancy is thus revealed — the result agrees well with psychophysical measures of human scotopic sensitivity (if corrections are made for lens absorption and pigment self-screening) but not with microphotometric absorption measurements, where two independent groups find a peak value near to 500 nm. The difference recalls that seen between measurements of rhodopsin spectral sensitivity *in vivo* and in digitonin extract.

Only very preliminary results using the new technique are available for cones and for detailed information about their sensitivities we must rely mainly on microspectrophotometry. Recent technical refinements — transverse measurements that allow good optical isolation of the outer segment and yield reasonably high optical densities; digital computers that streamline data-gathering and analysis; and procedures for partial glutaraldehyde fixation of the retina that help maintain the structural integrity of the cone outer segments — have greatly increased the accuracy of microspectrophotometric data. Two separate groups, one in London (J. Bowmaker, H. Dartnall and J. Mollon), the other at Wood's Hole, Massachusetts (E. MacNichol Jr, J. Levine, R. Mansfield, L. Lipitz and B. Collins) are making precise measurements of the photopigments of individual rods and cones, using both fresh material and lightly fixed isolated retinae. The two groups substantially agree about the shapes and locations of the λ_{max} of the major classes of pigment in the Old World monkey species (rhesus and cynomolgus). But residual differences exist concerning the properties of the short-wavelength-sensitive cones. The Wood's Hole group finds a longer λ_{max} for the rare short-wave cones of the cynomolgus monkey (429 ± 4 nm; $n = 8$) than does the London group (415 nm; $n = 2$). (Neither group finds any short-wave cones in the rhesus monkey.)

A new question is whether, within the normal human population, there are slight

---

*An international conference on colour vision was held at the University fo Cambridge, 23–27 August 1982 The primary sponsor was the Scientific Affairs Division of NATO; additional support was provided by The Royal Society, The Welcome Trust and the US Army Research Institute for Behavioral and Social Science

L.T. Sharpe is in the Neurologische Universitatsklinik, 78, Freiburg im Breisgau, Hansastrasse, 9, FRG.

variations between observers in the spectral positions of their photopigments. Factor analysis of Stiles and Burch's 10-degree colour-matching data suggests that there are (D. MacLeod and M. Webster). The standard deviation of peak absorption wavelength (for a given receptor class) among individuals is estimated between 1 and 1.5 nm. Human microspectrophotometric data suggest a somewhat larger variance. For instance, the London group showed that two 'normal' clinical patients (normal with respect to Rayleigh anomaloscope and Farnsworth-Munsell 100-hue results) had an 8 nm (553 and 561 nm) difference in the $\lambda_{\max}$ of their long-wavelength pigment sensitivities. A similar difference in long-wavelength sensitivity was found between the patients' field sensitivity ratios calculated at 555 and 650 nm. Even larger variations in the $\lambda_{\max}$ of the middle- and long-wave cones are found for the squirrel monkey, *Saimiri sciureus*. These too are well correlated with differences in behaviourally measured colour vision (G. Jacobs, University of California).

A new research tool is provided by digital computers that can control the display of digitized images on a colour television monitor. The way in which a given digital value is translated into a particular colour can be controlled and rapidly altered so that a stimulus can be moved in any direction in colour space. Despite some technical problems arising from instability, non-uniformity and flicker (W. Cowan, National Research Council, Ottawa and R. Rodieck, University of Washington), raster-based colour stimulators can be impressively used (1) to simulate changes in the illumination of complex coloured scenes so that the visual computations underlying colour constancy may be analysed (J. McCann and K. Houston, Polaroid Corporation) and (2) to quantify the chromatic properties of neurones of the macaque lateral geniculate nucleus in terms of the secondary-stage processes or 'channels' of colour vision (A. Derrington, J. Krauskopf and P. Lennie, University of Sussex).

This last is very important because it is commonly assumed that visual information is transmitted centrally by two parallel and independent 'channels' — the achromatic and the chromatic. Although electrophysiology often appears to support this post-receptoral dichotomy, careful inspection of the properties of colour-coding retinal ganglion cells shows that their colour opponency is not a fixed characteristic, but rather varies with temporal (duration and frequency) and spatial (size and position) properties of the stimulus (E. Zrenner, Bad Nauheim). For instance, at low temporal frequencies (5 Hz), red-green colour opponent cells have two sensitivity maxima, one for excitation (say +R) and one for inhibition (say −G) with a broad neutral zone in between. At higher frequencies (30–33 Hz) colour opponency is lost; the spectral sensitivity function becomes broadband and single-peaked, resembling that of luminance-detecting cells. The increase in sensitivity in the midspectral region seems to be based on a phase shift between the centre and surround responses which turns an antagonism into a synergism.

100 years ago

Goolden's dip-circle, claimed to make readings correct to within 10 minutes of arc. From *Nature* 27, 128, 7 December 1882.

These results beg comparison with psychophysical experiments. Here too the simplistic view that it is possible to isolate 'channels' corresponding to two classes of neurone in the visual pathway is being challenged. The X-cells of the retina, whose small receptive fields predominate in the central fovea, are usually assumed both to code colour and to mediate resolution of acuity targets. When acuity is used as a criterion for equating the luminances of different colours, mixtures of such lights are photometrically additive. Additivity, in the conventional view, is a property of the luminance channel of psychophysics while the opponent chromatic channels are assumed to account for the nonadditivity of direct brightness matching and threshold measurements. How can the opponent red-green cells be nonadditive for threshold targets (detection of low spatial frequencies) and additive for acuity targets (detection of high spatial frequencies)?

All these complications suggest that colour and spatial vision may not be easily separable into discrete, processing channels. Indeed, even if separate channels exist for achromatic and chromatic vision, they may not be independent — luminance and chromaticity certainly interact in grating detection tasks. The interaction is not, however, symmetrical: colour masks luminance much more profoundly than luminance masks colour (K. De Valois and E. Switkes, University of California). The masking cannot be due purely to local (retinal) interactions because it is independent of relative test-mask phase. It must, therefore, occur at a level at which global chromatic and spatial frequency characteristics have been encoded.

Colour processing in the cortex is an area of hotly contested opinion. Two major controversies were discussed at the meeting. The first concerned whether particular parts of the primate prestriate cortex are specialized for colour analysis, as has been proposed by S. Zeki (*Nature* **284**, 412; 1980). Some researchers recording in anaesthetized and paralysed vervet monkeys find colour-coding cells dominating that part of area V4 lying on the lateral part of the anterior bank of the lunate sulcus (V. Andersen, C. Guld and O. Sjo, University of Copenhagen). Fewer are found in V2, almost none in V3. The colour-coding cells are often narrowly tuned for orientation (± 10 deg) and their spectral responses depend strongly on both the wavelengths of the adapting fields and the luminance of the stimulus. About half respond to white on a white background (usually a defining characteristic of luminance-coding cells). Other researchers, however, find few colour-coded cells in these areas when recording from alert, behaving rhesus monkeys (J. Krüger, B. Fischer and R. Boch, Freiburg I. Br.). Only about 10 per cent of the cells respond better to one or another colour. Rather they seem to have strong extraretinal inputs that are activated before and during visually guided eye movements. It may be, therefore, that in anaesthetized and paralysed animals extraretinal inputs cannot be activated and the excitability of the prelunate cortex depends only on cells with pure efferent sensory inputs originating from the retina. Thus for such 'unnatural' conditions the prelunate cells may merely appear to be colour biased.

The second controversy is whether colour cells in the primate striate cortex are confined to columns extending vertically from the cortical surface to the white matter (see also *News & Views* **300**, 220; 1982). In the rhesus monkey, the columns are identified as slabs or stripes which are 100–250 μm wide and of indeterminate length (C. Michael, Yale University). Within a column, all neurones respond exclusively to monochromatic stimuli but differ in their receptive field organization, axis orientation, or eye preference. In the vervet monkey, however, there is no evidence for such colour columns (J. Krüger and M. Bach). Experiments in which 0.8×0.64 mm^2 arrays of 30 parallel microelectrodes are used reveal non-colour-coding neighbouring sites in one cortical layer (say IVc) located directly above colour-coding sites in another layer (V). Such differences may be species dependent or may suggest that instead of colour columns encompassing the whole cortical thickness, independent columnar systems exist for the infra- and supragranular layers. Before any more progress can be made on this issue, a consensus is needed on how to classify cells as colour coding. Some researchers classify cells as colour coding if they respond to coloured, but not white, stimuli; others if they respond differently to two colours irrespective of other stimulus parameters; and still others if they show a large difference in response strength to two colours for at least one out of several stimulus configurations. □

REVIEW ARTICLE

Origin, nature and world climate effect of Arctic Ocean ice-cover

David L. Clark

Department of Geology and Geophysics, University of Wisconsin, Madison, Wisconsin 53706, USA

During the Cenozoic, an open water Arctic Ocean changed to the modern permanently ice-covered condition. Significant world climate modification accompanied this change but the precise role of the Arctic Ocean in major Pleistocene climate events is controversial. The present ice-cover averages 3 m thickness but there are theories that during the Pleistocene it was Antarctic-like, several thousand metres thick. The time of origin of the ice-cover is placed as young as 0.7 Myr ago and as old as the middle Miocene. Any theory concerned with origin, nature and climatic response of the Arctic ice-cover must consider the ocean's sediment record.

THE modern Arctic Ocean above 75° latitude has modest circulation with Pacific and Atlantic Oceans but is largely ice-covered during most of the year (Fig. 1). The detailed study necessary to understand Arctic Ocean history is not complete, in part, because of the logistical difficulties of working in an ice-covered ocean. Limited geophysical, oceanographic and biological studies have been accomplished even in the most inaccessible parts of the Ocean by use of the Arctic's ice as a platform from which to work. More than 500 short sediment cores that include the geological record of the central Arctic for parts of the Cretaceous to Holocene have been recovered from the ocean floor. Study of the sediment, its fauna and flora, provides data on sediment source, rate of sedimentation, water productivity, temperature and salinity and relationship of the Arctic water to the world ocean. In addition, aerial geophysical surveys have added to the Arctic Ocean data base[1]. The limited data assembled from this work is important for understanding elements of geological and climatic development of the present Ocean as well as its role in the tectonic evolution of the Northern Hemisphere[2]. Also, it is apparent that the Arctic Ocean has a significant role in the development of world climates during at least the past 75 Myr and may be an important factor in any future CO_2-induced climate change[3].

During the Cenozoic, world climate changed from one with a low thermal gradient, only about 50% of that of the present, to the modern condition of strong gradients[4]. The oldest known Arctic Ocean sediment is late Cretaceous and it accumulated in an ice-free environment[5]. The absence of an Arctic ice-cover was an important factor contributing to the lower atmospheric and oceanic thermal gradients that allowed temperate climates almost to reach the poles during the Cretaceous[4]. World-wide, these conditions changed sometime following the Cretaceous. The development of polar ice-covers probably dates from the Middle Cenozoic or late Neogene[6] (Fig. 2). The Arctic Ocean sediment record is not complete for this period of time but glacial–marine sediment was accumulating at least by the late Miocene in the central Arctic[7]. Together with Antarctic ice development, an Arctic ice-cover produced a profoundly steeper thermal gradient than had existed during the Mesozoic. This was a factor in the initiation of Pleistocene glaciation and modern climate.

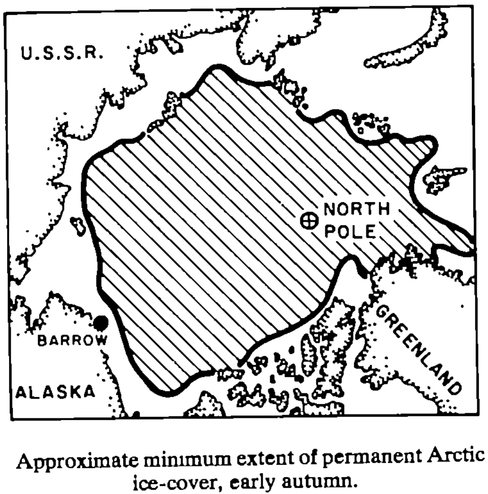

Fig. 1 Approximate minimum extent of permanent Arctic Ocean ice-cover, early autumn.

The evidence for the Arctic's role in the late Cretaceous to middle Cenozoic climate change is fairly well understood. The Arctic sediment record is one of biogenic silica, diatoms and silicoflagellates, probably representing relatively warm upwelling conditions during the late Cretaceous[5]. This was followed by a change to glacial–marine sedimentation for at least the late Miocene to Holocene[7]. The sediment record for the entire late Cenozoic Arctic Ocean indicates that more or less continuous glacial ice-rafting has been the principal sedimentation process. There were times when ice-rafting was very intense, alternating with time of less clastic sedimentation[7]. During these intervals of limited ice-rafting, increased biological productivity is suggested by increase in foraminifera, ostracodes and calcareous dinoflagellates. These data must be considered part of any theory that attempts to explain the nature of the Arctic ice-cover although it has not been used by those who have proposed fluctuating climatic regimes or giant ice-caps for the late Cenozoic central Arctic Ocean. Also while the data on sediment types are unequivocal, the timing of the development of the first Arctic ice-cover as well as the precise sequence of events leading to modern conditions are issues not fully resolved. The 'fine tuning' for resolution of time of initiation of the Arctic ice-cover may not be accomplished until a very complete central Arctic Ocean sediment core is recovered. Meanwhile based on short sediment core study, the discussion of the palaeoclimatologic changes that accompanied the development of the modern Arctic Ocean has produced diverse ideas.

Arctic role in the world climate

The importance of the Arctic Ocean for world climate was recognized by the 1956 Ewing–Donn theory[8]. In this early attempt at an unified explanation for Pleistocene glacial cycles, the Arctic Ocean had a central role. According to the theory, an open, ice-free ocean produced moisture to support the expansion of glaciers. Melting and retreat of glaciers in lower latitudes occurred when an Arctic Ocean ice-cover formed, sealing off the source of moisture and thus affecting glacier

0028–0836/82/470321—05$01.00

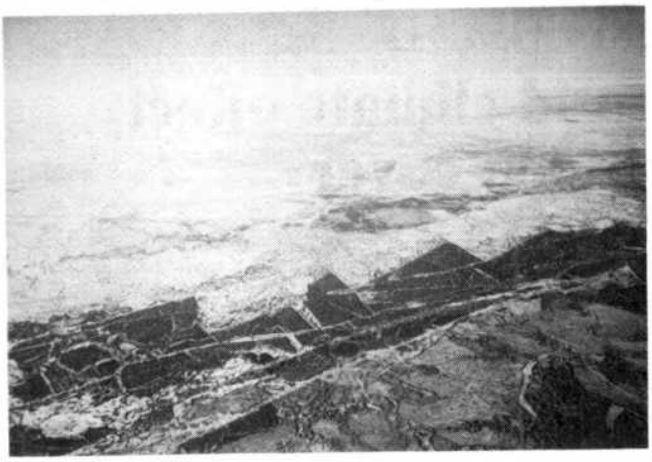

Fig. 2 The modern Arctic Ocean ice-cover. Aerial view showing dark, fine grained sediment laden pack-ice. Irregular pattern of sediment-rich ice and cleaner pack-ice due to fracturing of pack-ice during movement.

growth. In this ingenious theory, glacial and interglacial intervals of the Pleistocene were thought to be highly dependent on the condition of the Arctic Ocean surface.

Confirmation of the validity of the Ewing–Donn theory could be tested in various ways. In the years following its publication, palaeontologists, marine geologists and others gathered diverse data that questioned many of the theory's basic tenants. Using pollen data from the area around the Arctic basin, Colinvaux[9,10] summarized objections to the theory based on ecological constraints of demonstrated floral occurrences. Next, sediments and sedimentation rates in Arctic cores were found to be inconsistent with the theory[11–13]. Foraminifera abundance patterns for the central Arctic during the past 1.5 Myr showed no time of ice-free conditions that could be correlated with glacial or interglacial stages[14]. This raised additional objections to the theory and it was concluded that the Arctic must have remained frozen while lower latitude Pleistocene glacial advances and retreats were in progress[14]. Alternating thickening or thinning of the ice-cover may have occurred during the Pleistocene but the sediment, floral and faunal record seemed to confirm that there was no evidence for an open Arctic Ocean that could be correlated with Pleistocene glacier growth. Thus, the Ewing–Donn theory was untenable.

If the Arctic ice-cover was not cyclic in appearance and disappearance during the Pleistocene, (and it was ice-free in the earliest Cenozoic) the obvious question was the time when the Arctic Ocean first become ice-covered. Also, what were the changes that accompanied the great freeze and what was the condition of the Arctic Ocean throughout the Cenozoic? Although these questions could be answered by study of a continual sediment record for the Arctic Ocean, no DSDP Leg has been planned for the central Arctic and the ice problems are so profound that no similar drilling program is contemplated. However, extensive coring from floating ice-island T-3, produced several short sediment cores and their study produced good data. Most of the cores recovered during the T-3 years (1955–74), some 580 successful casts, were taken as part of heat flow studies by the US Geological Survey (A. Lachenbruch and V. Marshall). After conductivity measurements, sediment and faunal studies of the cores were undertaken at the University of Wisconsin-Madison. In addition several cores were taken by a group at Lamont-Doherty Laboratory (under K. Hunkins) and became the basis for work at Lamont as well as later work at Washington State University. The Arctic sediment cores yielded a wealth of data that were subsequently used in faunal analysis[12,14–24], sediment studies[7,25–28], and became the basis for diverse palaeoenvironmental interpretations[14,29–34]. These environmental interpretations have assumed new importance because of theoretical considerations related to a possible future CO_2 induced world climate change[3]. If a climate change occurs, one of the first effects may be the disappearance of at least the summer Arctic ice-cover[3]. In order to understand the environmental impact of such an event, climatologists have considered the possibility that there was a time in the recent geological past (past 3 Myr) when the Arctic had no ice-cover. If such a time occurred, it could provide an accurate analogue for understanding the change that might occur in the future[3].

There is no uniformity of thought concerning conditions of the Arctic ice-cover during the past 3 Myr. From the various data based interpretations as well as theoretical considerations, three different theories have been proposed to explain the evolution of the modern Arctic Ocean: the (1) fluctuating regime and (2) steady state theories are based on different interpretations of central Arctic sediment cores; the (3) ice-cap theory is based on data more theoretical, and from outside of the Arctic Ocean.

Formation of the modern Arctic Ocean

Each of the three theories, presumably includes an evolution of the present ice-cover, from similar beginnings but through quite different stages of development.

(1) The 'fluctuating regime' theory[35–37] proposes that the late Miocene to Holocene interval was represented by three different palaeoclimatologic regimes, only the most recent of which (I), occurring from approximately 0.7 Myr to Recent, was characterized by a perennial ice-cover. Of the three theories, this is the most elaborate and involved. This theory suggests that during palaeoclimatologic regime III (interpreted to be roughly from 4 or 5 Myr ago to 2.7 Myr ago), the Arctic Ocean was cold but not ice-covered. The ocean had productive waters, interpreted by the theory's proponents to be the highest productivity of any time during the past 4.5 Myr. The productivity of the surface waters affected deeper waters, as well, because of good vertical mixing. The next younger or palaeoclimatologic regime II, is interpreted to be characterized by stratified saline and fresh water with little vertical mixing, resulting in both little surface productivity as well as no bottom productivity. Coccoliths were reported to occur during this interval[36] and ice-free conditions are suggested, at least for part of the year. This regime extended from 2.7 to 0.7 Myr ago. Finally, the most recent climate regime, I, is interpreted to have been initiated at about the same time as the Brunhes–Matuyama boundary (0.7 Myr), and at this time permanent ice, similar to that of the present, formed. This time interval is interpreted to be characterized by sharp and frequent fluctuations in foraminifera abundance, and sparse coccoliths. Sparsity of coccoliths is suggested to be due to intense bioturbation.

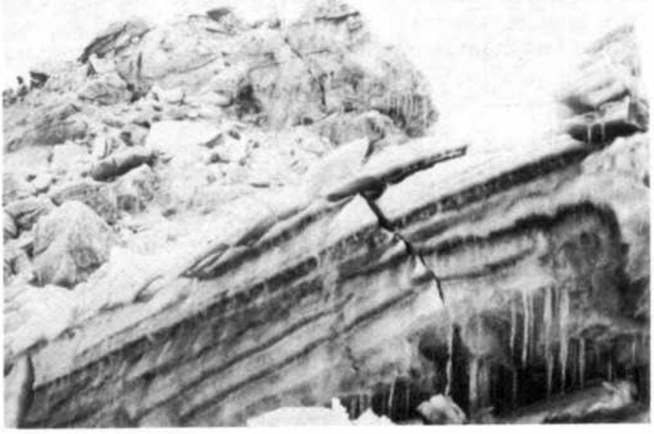

Fig. 3 Layers of fine silt and clay exposed in pack-ice that has been thrusted in a pressure ridge. Fine grained sediment is incorporated into newly forming ice during autumn storms in shallow shelf areas and then drifts seaward with surface currents. Pack-ice is a major source of fine grained sedimentation in the central Arctic Ocean.

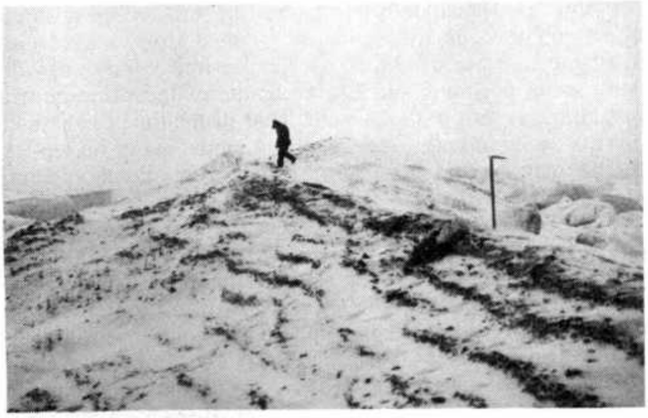

Fig. 4 Iceberg, moving with pack-ice of Arctic ice-cover, and showing glacial derived coarse grained sediment layers. Icebergs are the only source of coarse grained sedimentation in the central Arctic Ocean.

While, elaborate in design, many of the conditions interpreted to be necessary for this theory have a questionable basis. This may be due to the fact that fewer than a dozen dried-out and heavily sampled sediment cores from the limited Lamont collections were available for study. For example, strong vertical circulation and high productivity, interpreted for climate regime III, is based on abundance of Fe–Mn micronodules that are said to have foraminifera as nuclei. These micronodules, reported to characterize only regime III [35], actually occur in moderate abundance throughout the cores (sediment of regimes I and II, as well) and most do not have foraminifera as nuclei[7,19]. Regime II, said to have resulted from strongly stratified waters with little or not organic productivity, actually spans the time of the beginning of abundant foraminifera and, in general, the Arctic Ocean was more productive during this time than during time of regime III. O'Neill[19] studied 11 fresh sediment cores from along the flanks of the Alpha Cordillera and Canada Basin, some at 3–4 cm intervals. He recognized 75 benthic foraminifera species including 15 textulariid and miliolid species and 34 rotalid species, that range through the interval of regime II, said to be a time of nonproductive waters[35–37].

After comparing the fluctuating regime theory with the data of his cores, O'Neill concluded that the "high productivity model suggested by Herman and Hopkin[35], (for regime III) does not appear to be supported by the available data".

Inferences of red clay occurrence and bioturbation to depths of 30 cm during any of the regimes also cannot be verified[7,19]. Rather, glacial–marine sediment with erratics characterizes all sediment (from at least 5 Myr ago) and bioturbation cannot be interpreted to have affected more than 10 cm of sediment. Inconsistencies in the interpretation of coccolith data are also worrying. In July and August of 1980, Margolis and Herman[37] and Herman and Hopkins[35] reported that coccoliths occur in regime III sediment, but in October[36] no coccoliths nor discoasters were reported for regime III. In the final report[36], it turned out that 5 of the 6 samples said to have had nannofossils actually occurred in regime 1 sediment; the sixth sample (with two specimens) was from regime II. This was used as part of the evidence for ice-free condition. Ice-rafting of an occasional coccolith from marginal Arctic waters to the central Arctic may be a better explanation for all of the occurrences.

The fluctuating regime theory is difficult to verify because of inconsistencies in the reports as well as apparent misinterpretation of the sediment cores that form the basis for the theory.
(2) The 'steady state' theory[7,13,33,34] is also sediment based and argues that the same kind of glacial–marine sediment that accumulates today under an average of 3 m ice, has been accumulating for at least 5 Myr. Although there have been some changes in rate of sedimentation and in percentages of coarse material deposited, the changes have been of the same magnitude during most of the past 5 Myr and probably represent sedimentation in more or less similar conditions. The sediment record for several hundred cores has been organized into a lithostratigraphical sequence of 13 stratigraphical units[7]. The stratigraphical units consist of silty lutites reflecting lower sedimentation rates and corresponding to decreased ice-rafting, alternating with arenaceous lutites representing higher sedimentation rates and corresponding with increased time of ice-rafting. Clays and silts are transported both by pack-ice (frozen seawater) (Figs 2, 3) and glacial-ice (icebergs) but coarser sediment is only transported by icebergs[38] (Fig. 4). The lithostratigraphical sequence includes units that are fine-grained (probably principally rafted by pack-ice) and coarse-grained (rafted by glacial-ice). Because these units alternate throughout the 5 Myr for which the central Arctic record is more or less complete, both pack-ice and glacial-ice are considered to have been present since at least the Miocene. Older Cretaceous–Palaeocene material was recovered in two cores and their study was the basis for the interpretation that open water conditions existed during the late Mesozoic to early Cenozoic[5]. No sediment record has been recovered for the Eocene to late Miocene interval.

The steady state theory interprets the sediment record of the Arctic Ocean for the past 5 Myr to show little variation on a single theme, ice-rafting. Foraminifera and calcareous dinoflagellates show positive correlation during part of the Pleistocene (Fig. 5). Foraminifera abundance in the central Arctic Ocean and a percentage of coarse, glacial-ice-rafted material show inverse correlations throughout the interval when significant foraminifera have been present. Some effect of dilution by clastic influx is possible. Calcareous dinoflagellate occurrence also shows negative correlation with increased glacial ice-rafting[39] (Fig. 6). This is interpreted to indicate that during rapid ice decay and calving (inter-glacial intervals), surface waters may have been too low salinity to support foraminifera and dinoflagellates but that these organisms were relatively productive during stable glacial-growth (glacial intervals). The surface of the central Arctic Ocean could have been perennially ice-covered during the entire interval.

A fine tuning of this theory has resulted from the study of calcareous dinoflagellate fossils that show alternating times of abundance and rareness during the interval 2.0–0.7 Myr ago. Evidently, during this 1.3-Myr period, favourable conditions to encourage production of calcispheres occurred. Conditions before 2.0 Myr and after 0.7 Myr have been more like the present[39].
(3) The 'ice-cap' theory argues that Pleistocene sea level changes and oxygen isotope records from benthic foraminifera of the lower latitude oceans could be more easily explained if the Arctic Ocean had an Antarctic size ice-cap 1,000 m thick, during all or most of the Pleistocene[40–44]. This theory has evolved from ideas based on a West Antarctic analogy and explanations for displaced marine fossils in Alaska[40] and theoretical considerations suggesting that during the past 160,000 yr,

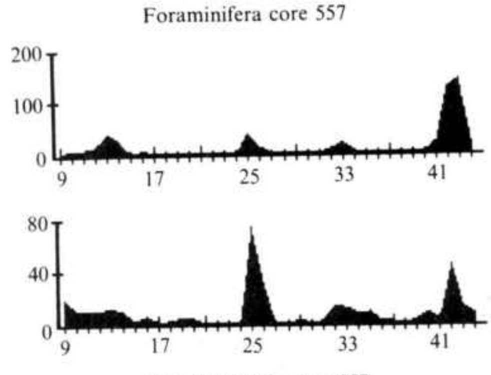

Fig. 5 Abundance of foraminifera and positive correlation with abundance of dinoflagellates for the interval 2.0–0.7 Myr ago in the central Arctic in core F1-557. Notice different vertical scales.

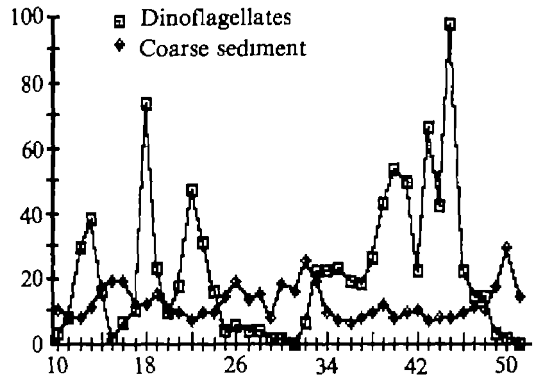

Fig. 6 Plot of abundance of dinoflagellates and percentage of coarse (glacially derived) sediment for core F1-301, central Arctic Ocean. General negative correlations seen in all cores studied, that is, time of occurrence of greatest percentage of coarse sediment (sample 50) correlates with time of lowest number of dinoflagellates and vice-versa (sample 45, 22 and so on).

the world benthic foraminifera ^{18}O record requires a larger ice volume than can be interpreted from sea level data[43,44]. The ice needed to explain the apparent discrepancy between sea level calculation and ^{18}O records of ice volume is interpreted to have been in the Arctic Ocean. A 50-m sea level difference, that would account for at least some of the discrepancy, would require a floating ice cap 1,300 m or more thick "close to the mean depth" of the Arctic Ocean[44]. Unfortunately, this theory ignores data from the Arctic Ocean. As pointed out earlier, during most of the 160,000 yr that a 1,000-m ice sheet is theorized to have been present, sedimentation similar to that of the modern Arctic ocean was in progress and various types of organisms lived, and at times, even flourished. It is difficult to understand phytoplankton and foraminifera thriving under >1,000 m of ice, as the ice cap theory demands. Clearly the evidence for relatively high organic productivity based on hundreds of short sediment cores that include the critical time interval, cannot be ignored[14,19]. Similarly, the mechanism that would permit accumulation of ice-rafted sediment beneath a >1,000 m ice-cap whose thickness is close to the mean depth of the ocean, is unknown.

This theory must accommodate the extensive data from Central Arctic Ocean sediment cores as well as theoretical considerations before it can be used to explain Pleistocene events.

Future CO_2-induced climate change and Arctic Ocean ice-cover

The three theories are concerned with the modern Arctic Ocean ice-cover and its geological history. Climatologists worried about the increasing atmospheric CO_2 are concerned about the melting of the Arctic ice cover[45-47] and future climatic effects. The early disappearance of the perennial Arctic ice-cover during a CO_2-induced climate change would produce a unipolar cryosphere, affecting sea surface temperature and producing a shift of climatic belts by several degrees latitude[3]. The climatic impact of an ice-free Arctic Ocean has received much consideration[48,49] although a sea level rise perhaps mostly related to Antarctic melting, may be in progress[50].

Flohn[3] has speculated that the best understanding of future effects on the climate could be obtained from a geological analogue; a time of Arctic Ocean ice-free conditions with continental positions and Earth climate of the same general magnitude as that of the present. That such a time did actually exist is disputed and it is argued that modelling of an ice-free Arctic may be the superior method of predicting climatic effects[51].

There is no widespread agreement that a realistic model of an ice-free Arctic Ocean has actually been produced, although there have been several interesting attempts[52-58]. Several of the models suggest that the ice could melt in the summer but even under considerable atmosphere CO_2 addition, winter ice would form, at least as long as the Earth's current orbital status persists. The climate change produced by an absence of summer ice and a reduced winter ice cover are matters for atmosphere modellers. No geological analogue with continents and climate patterns such as those of the present, has probably emerged for 5 Myr.

Conclusions

The role of the Arctic Ocean in Earth climate patterns has been significant, at least for the past 100 Myr. An open Arctic Ocean with extensive upwelling and free exchange with more southerly waters characterized the late Cretaceous–early Cenozoic. This is confirmed from central Arctic sediment[5,20,21] as well as from vertebrate and plant study in Arctic and sub-Arctic areas[59]. Formation of the Antarctic ice sheets along with development of glacial conditions in the Arctic were important factors for the general cooling of Earth during the Middle Cenozoic. Glacial–marine sediment was forming in the central Arctic at least 5 Myr ago. The first freezing of the Arctic surface waters may have been earlier than this but there is no direct sediment evidence to support this idea. This age probably is a minimum, as ice-rafted debris may have been accumulating in Svalbard as early as the Eocene[60].

From at least 5 Myr ago to the present, glacial–marine sediment, transported by ice-rafting of icebergs and pack-ice, has accumulated in the central Arctic Ocean. Generally, times of extensive ice calving are correlated with accumulation of coarser sediment and abundant erratics. These intervals of relatively rapid sedimentation (for the Arctic) alternated with times of accumulation of finer grained, predominantly ice-pack transported sediment and greater organic productivity. From ~2 to 0.7 Myr, calcareous dinoflagellates left a record of alternating abundances and rareness. Probably, during this time surface conditions permitted greater productivity than had been possible before 2 or since 0.7 Myr.

There is no evidence from the Arctic Ocean to support the idea of giant Ice Caps, 1,000 m thick, during any part of the Pleistocene. Evidence from modelling for future CO_2 induced climate changes predicts a reduced winter ice-cover and an absent summer ice-cover for the Arctic Ocean. If this occurs, significant climate changes are indicated. Unfortunately, no geological analogue is available. Rather, the only evidence from the central Arctic, suggests that conditions like those of the present, punctuated by times of greater iceberg activity, characterized the Arctic Ocean during most of the late Cenozoic.

A voltage-gated ion channel model inferred from the crystal structure of alamethicin at 1.5-Å resolution

Robert O. Fox Jr & Frederic M. Richards

Department of Molecular Biophysics and Biochemistry, Yale University, New Haven, Connecticut 06511, USA

The crystal structure of alamethicin in nonaqueous solvent has been determined, and refined at 1.5-Å resolution. The molecular conformation of the three crystallographically independent molecules is largely α-helical with a bend in the helix axis at an internal proline residue. The helix structure is highly amphipathic as most of the solvent-accessible polar atoms lie on a narrow strip of surface parallel to the helix axis. Molecular models for the voltage-gated ion channel, with n*-fold symmetry and based on the molecular conformations observed in the crystal, are characterized by strong surface complementarity, a hydrophilic interior and a hydrophobic exterior. The channel structures are stabilized by a hydrated annulus of hydrogen-bonded glutamine residues which produce the greatest restriction in the channel diameter.*

THE linear peptide antibiotic alamethicin spontaneously inserts into black lipid membranes producing voltage-gated ion channels[1]. While alamethicin isolated from *Trichoderma viride* is a mixture of several related chemical species[2,3], the sequences of the major (and minor) components have been identified as[4,5]:

$$\text{Ac-Aib-Pro-Aib-Ala-}\overset{5}{\text{Aib}}\text{-}\overset{\text{(Aib)}}{\text{Ala}}\text{-Gln-Aib-Val-}\overset{10}{\text{Aib}}\text{-}$$

$$\text{Gly-Leu-Aib-Pro-}\overset{15}{\text{Val}}\text{-Aib-Aib-Glu-Gln-}\overset{20}{\text{Phl}}$$

although cyclic[2,6] and branched[7] structures have been proposed. The N-terminal residue of alamethicin is acetylated (Ac^-). The peptide contains eight or nine α-aminoisobutyric acid (Aib) residues and has L-phenylalaninol (Phl) as its C-terminal residue. The conductance properties of alamethicin in black lipid membranes have been extensively investigated and recently reviewed[8]. The macroscopic conductance is strongly voltage-dependent, increasing *e*-fold for every 4–6 mV in applied voltage, and also exhibits a strong alamethicin concentration and ionic strength dependence[1,9–12]. The high power dependence of the conductance on alamethicin concentration suggests that the alamethicin ion channel consists of 6–11 or more molecules. An ionic strength-dependent partitioning of alamethicin into a lipid phase appears to explain the observed dependence of conductance on salt concentration[10].

At low alamethicin concentrations, conductance fluctuations are observed which have been attributed to single-channel gating events[9,13,14]. Single-channel current bursts fluctuate

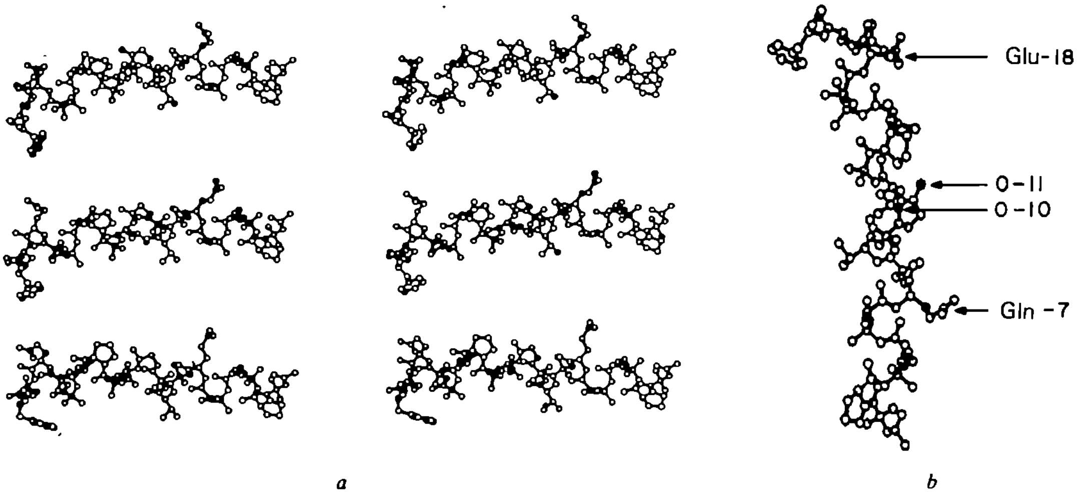

Fig. 1 *a*, The three alamethicin molecules present in the asymmetric unit are positioned in a similar orientation to the N-terminal segment. The N-terminus is to the right in each stereo diagram. The hydrophilic surface of each molecule projects towards the top of the figure. *b*, The solvent-accessible polar groups (see text) are labelled for molecule I. The hydrophilic surface of the molecule projects to the right.

among several discrete conductance levels which are not integral multiples of each other. The most probable conductance substate and the lifetime of the current burst are only moderately voltage-dependent. The strong voltage dependence of the macroscopic conductance has been attributed to a change in the number of gated channels rather than a significant change in the properties of a single channel. The alamethicin channel is only weakly cation-selective[13,15-17]. The higher conductance substates are less sensitive to cation radius[16], indicating that the increase in current is due to a change in the cross-section of the channel, rather than an increase in the number of parallel open channels of similar area. Kinetic measurements of alamethicin-induced current are well modelled by a single exponential time constant, which is only moderately dependent on the alamethicin concentration in phosphatidylcholine membranes[11] and independent of peptide concentration in glycerol monooleate membranes[12]. These observations suggest that alamethicin exists predominantly in a preformed oligomeric state before a voltage is applied to the membrane.

The voltage-gating event must represent the movement of a charged group in the electric field or the orientation of a molecular dipole. The latter mechanism has been accepted in most models of alamethicin channel voltage-gating. The 'barrel stave' model of alamethicin action[14,18] suggests that peptide monomers at the surface of the alkyl chain region of the bilayer, are oriented by the electric field via coupling to the molecular dipole, and aggregate to form an oligomer once aligned with the electric field. The conductance substates are explained by a change in the channel cross-section due to a fluctuation in the number of monomer units in the oligomer. Hall[19] has proposed a two-dimensional micelle of alamethicin at the surface of the membrane which is oriented in the electric field via the molecular dipole, forming an oligomeric structure having a constant number of monomers, which fluctuates in an undefined way to generate the conductance substates.

The conformation of alamethicin is partially α-helical in organic solvents, as determined by circular dichroism[20,21]. Crystal structures of small peptide fragments of alamethicin and poly(α-aminoisobutyric acid) are in a 3_{10} helical conformation[22,23], although a larger Aib-containing peptide adopts an α-helical conformation in crystals[24].

We performed a crystallographic analysis of alamethicin to define the detailed molecular conformation and packing involved in the ion channel, and to differentiate among the proposed chemical structures[2,4-7]. This structure analysis has defined the helix type (α or 3_{10}) and the deviations from those ideal geometries, and illustrated the packing of Aib-containing helices. Knowledge of the molecular structure in the crystal has allowed model-building studies to define the proposed channel structure.

Structure determination and refinement

Alamethicin was provided by the Upjohn Company and was used without further purification[25]. Crystals suitable for diffraction were prepared by 10-fold dilution with acetonitrile of a solution of alamethicin in methanol (100 mg ml^{-1}). Integrated X-ray diffraction intensities were collected to 1.5 Å resolution by diffractometry using a modified Wyckoff scan[26]. An isomorphous heavy-atom derivative was prepared by diffusion of dimethyl mercury into the crystal from a mother liquor solution. Heavy-atom parameters and protein phase angles were refined[27] at 3.0 Å resolution. An atomic interpretation of the electron density map was constructed and refined using the distance-restrained least-squares procedure of Konnert and Hendrickson[28]. Calculated phases from the refined model were used to extend the resolution from 3.0 Å to 1.5 Å.

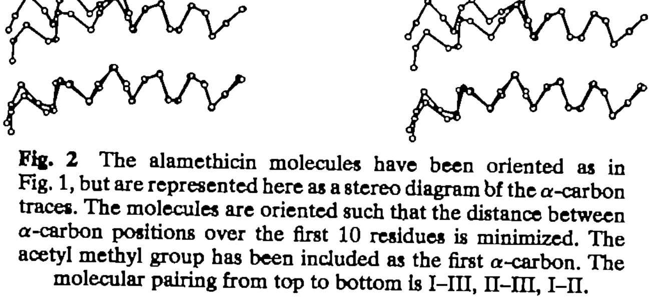

Fig. 2 The alamethicin molecules have been oriented as in Fig. 1, but are represented here as a stereo diagram of the α-carbon traces. The molecules are oriented such that the distance between α-carbon positions over the first 10 residues is minimized. The acetyl methyl group has been included as the first α-carbon. The molecular pairing from top to bottom is I–III, II–III, I–II.

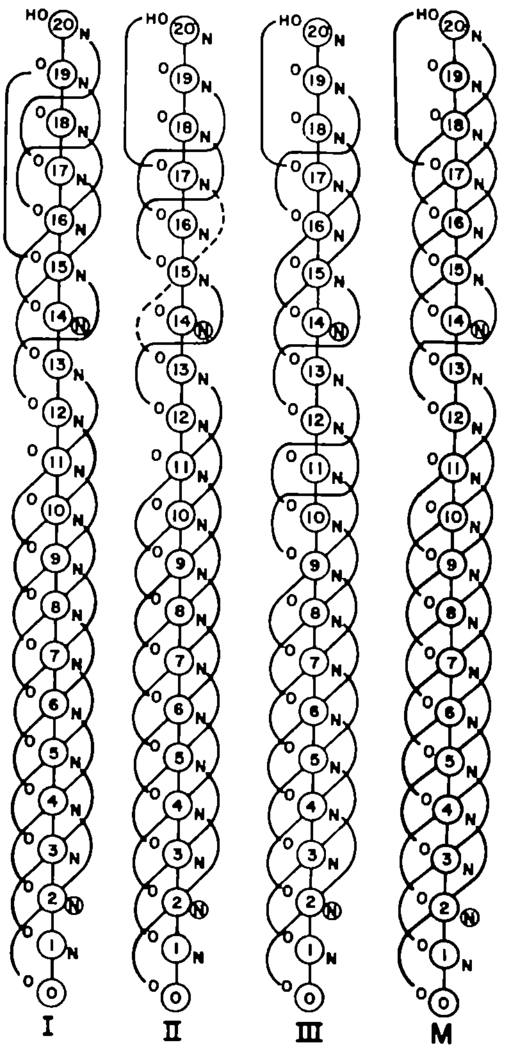

Fig. 3 The intramolecular hydrogen-bonding pattern for each of the three independent alamethicin molecules (I, II, III) is indicated together with the connections used in the channel model building (M) as described in the text. Residue 0 represents the acetyl group; circled N symbols, proline residues. The broken lines indicate an unusually long interaction. Hydrogen bonds of the 5→1 type (α-helix) cross the vertical diagonally while 4→1 hydrogen bonds (3_{10} helix) are represented by lines crossing the vertical axis horizontally.

Molecular models of the proposed channel structures were constructed with Corey–Pauling–Koltun (CPK) units and by a molecular graphics program using an Evans and Sutherland PSII display system. Space-filling drawings were generated on a colour raster graphics unit (Advanced Electronics Design, Inc.) using the program of Connolly[29].

Crystals of alamethicin are of space group $P2_1$, $a = 33.33$, $b = 29.62$, $c = 23.20$ Å, $\beta = 120.4°$ and contain three molecules per asymmetric unit. The solvent content of the crystals is 30%. The present analysis was carried out at 1.5 Å resolution although diffraction maxima have been observed to 1.0 Å. The distance-restrained least-square refinement converged with a crystallographic residual of 15.5% and a r.m.s. deviation from ideal bond lengths of 0.04 Å. Details of the crystal structure determination and refinement will be presented elsewhere.

Molecular structure and crystal packing

The crystal structure of alamethicin is consistent with the linear backbone structure[4,5], and excludes the cyclic[2,6] and branched[7] structures from further consideration. The side chain density of the final $(2F_0-F_c)$, model-phased, electron density map, calculated from the complete molecular model, reveals no deviation from the chemical sequence proposed for the major component of alamethicin[5]. It is unlikely that side chain heterogeneity due to minor components, if they were in fact present in the crystals, would be observed in the electron density map described above.

In general, all three alamethicin molecules in the asymmetric unit exist in an α-helical conformation over their entire lengths. There are, however, small deviations from a continuous α-helical conformation in the form of short (one to two residues) 3_{10} helical regions in the C-terminal domain. Figure 1 shows a stereo diagram of the three independent molecules. Each helix axis is bent slightly and to a different extent near the Pro-14 residues. The angular variability of the bend and the variations in helix parameters seem to be due to the differences in intermolecular polar interactions among the three independent alamethicin molecules. Figure 2 illustrates the difference in bend angles among the three molecules (I, II, III), and Fig. 3 gives the intramolecular hydrogen-bonding pattern for each molecule.

The accommodation of the Pro 14 residue into the α-helical backbone is accomplished by the introduction of a 4 → 1 hydrogen bond (N-15 to O-12) which shifts the proline imino ring from a position directly above the carbonyl of Aib 10 to one between the carbonyls of Aib 10 and Gly 11. The Pro 14 imino ring is further accommodated by the bend in the helix axis away from the Pro 14 ring direction. In Fig. 2 the molecules have been superposed such that the overlap of like α-carbons for the first 10 residues is maximized between each pair of molecules. Molecules I and II display a similar bend angle, deviating significantly only at the C-terminal residues where the hydrogen-bonding pattern differs. Molecule III displays a much smaller bend in the helix at the Pro 14 residue, which is accommodated in part by a displacement of the Gly 11 carbonyl away from the helix axis.

The solvent accessibility[30] was calculated for each isolated alamethicin molecule without neighbouring peptide or solvent molecules. The solvent-accessible surface area is generally less than 5 Å for carbonyl oxygen atoms participating in backbone hydrogen bonds. The carbonyls of Aib 10 and Gly 11 do not participate in backbone hydrogen bonds and have solvent accessibilities between 5 Å^2 and 17 Å^2. The carbonyl oxygen atoms fully exposed at the C-terminus of the molecules have calculated areas of 18–30 Å^2. The carbonyl groups of Aib 10 and Gly 11 of molecule I are hydrogen-bonded to methanol solvent molecules, while the carbonyl of Gly 11 of molecule III is hydrogen-bonded to the amide side chain of Gln 7 from molecule II. The carbonyls of residues 10 and 11 of molecule II and 10 of molecule III do not form hydrogen bonds with the solvent structure as it is presently modelled.

The alamethicin sequence contains four residues having polar side chain groups: Gln 7, Glu 18, Gln 19 and Phl 20. The Phl 20 hydroxyl group hydrogen bonds to the backbone in two of the three independent molecules. The carbonyl oxygen atoms of Aib 10 and Gly 11 are solvent-accessible and must also be considered as polar regions on the alamethicin molecular surface. Although the backbone structure differs among the three independent molecules in the C-terminal region, the distribution of polar groups on the surface of each molecule is very similar. The Gln 7 and Glu 18 side chains and the carbonyl oxygen atoms of Aib 10 and Gly 11 all lie on a narrow strip on the surface of each molecule parallel to the helix axis. The polar strip lies on the convex surface of the bent helices. The

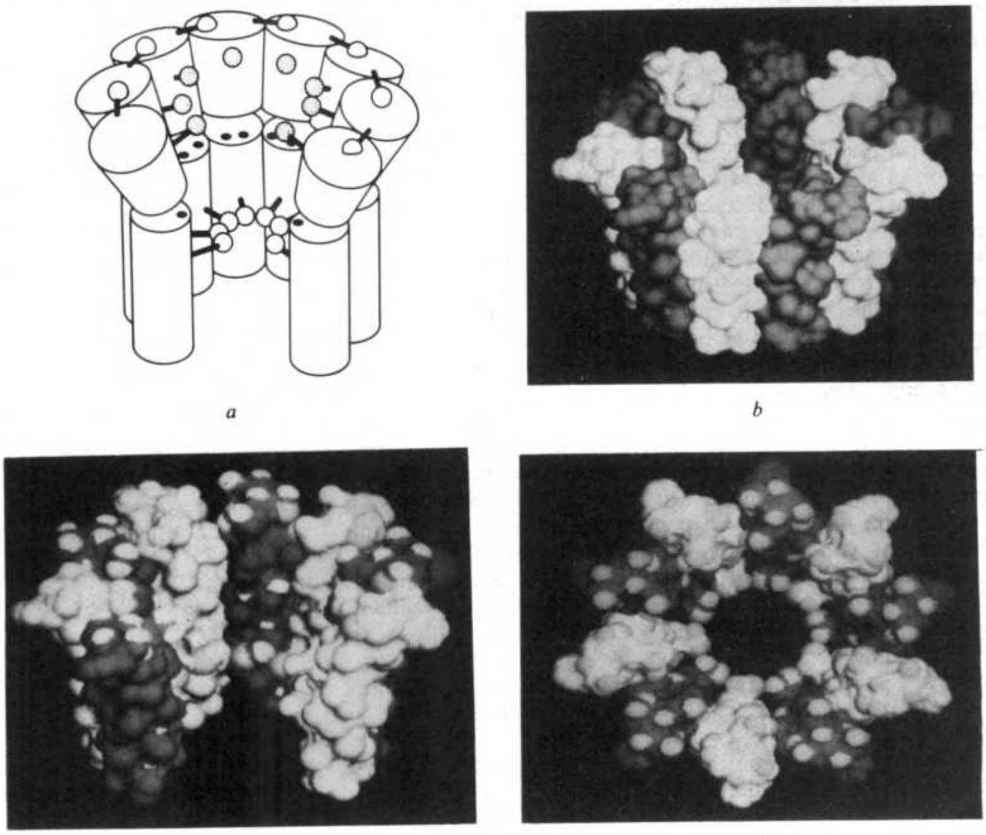

Fig. 4 *a*, Schematic and computer graphics representations of the proposed pore. The alamethicin monomer as seen in the crystal is shown as two cylindrical segments signifying the interruption of the α-helical hydrogen bonding introduced by the Pro 14 residue. The stippled spheres at the mouth of the channel represent the Glu 18 residues while the open spheres at the centre and top of the channel structure indicate the hydrogen-bonded annulus of Gln 7 and Gln 19 residues, respectively. The parallel cylinders represent the N-terminal domain of the alamethicin molecules. The black dots on the face of each cylinder represent the solvent-accessible carbonyl groups of Aib 10 and Gly 11. The upper cork-shaped elements represent the C-terminal domains, and are tipped away from the channel *n*-fold axis, illustrating the bend imposed by the Pro 14 residue. The C-terminal elements are flaired to indicate the increasing bulk of the side chains in this region, maintaining van der Waals' contact even as the helix axes diverge. The stippled spheres represent the Glu 18 side chains, which are removed from direct contact due to the flair of the C-terminal region. The Gln 19 side chains are represented by the spheres at the top of the C-terminal segments illustrating the hydrogen bond interactions with the carbonyl oxygen atoms of a neighbouring molecule. *b*, A solvent-accessible surface representation of the complete alamethicin channel exterior, illustrating the strong surface complementarity of the hydrophobic exterior surface of the N-terminal region. *c*, A cutaway view of the alamethicin channel as in *a*, representing the solvent-accessible surface of each molecule. Alternate molecules are shaded light and dark to illustrate the intermolecular packing: the lighter shading represents solvent-accessible oxygen and nigrogen atoms of the backbone and side chains. Molecule I was used to form the channel structure without modification, thus modifications to the C-terminal regions of the molecule which would allow Gln 19 hydrogen bonding to neighbouring molecules have not been made. Also, the Gln 7 annulus does not seem as restricted as was observed in the CPK modelling, as the side chain geometry has not been altered to agree with the physical model. *d*, A view down the oligomer axis from the C-terminal surface.

Gln 19 side chain does not lie on this polar strip. Thus, the alamethicin structure is amphiphilic in two respects, as most of the polar groups are segregated in the C-terminal region of the primary structure, and lie along a narrow polar strip parallel to the helix axis in the tertiary structure.

The orientation of the three independent alamethicin molecules does not result in a symmetric trimer structure, but the independent molecules pack with each other and with molecules related by 2_1-symmetry operations and translations to form a complex array of irregular channels, parallel to the x-axis of the unit cell. Although the alamethicin molecules pack to form solvent-filled channels, the polar residues do not segregate towards the centre of the channel as might be expected for a membrane ion channel. In any single solvent channel, both faces of a single molecule type contribute to the channel surface. The three independent molecules, identified as the asymmetric unit, are oriented in parallel with their C-termini close to the origin and their N-termini directed in the $+x$ direction, perpendicular to the 2_1-symmetry axis. Molecules of the asymmetric unit pack in an antiparallel arrangement with symmetry-related molecules.

Construction of alamethicin channel models

For the construction of models of the alamethicin pore, a 'mean' monomer unit was used, representing essentially an average of the three peptide conformations observed in the crystal structure. The alamethicin conformation was idealized as two regular α-helical segments (1–13 and 14–20) with an angle of 20° between the two helix axes. A single $4\rightarrow1$ hydrogen bond (Val 15 to Leu 12) was introduced as seen in each of the monomers in the crystal. Such monomer units were assembled into oligomers using the following rules: (1) n-fold symmetry around the membrane plane normal, (2) asymmetric distribution between the two sides of the membrane, (3) optimization of side-chain packing between monomer units, (4) maximization of intermolecular hydrogen bonding. Two alamethicin CPK models were docked by hand in various orientations and the fit was assessed subjectively. One set of orientations resulted in a particularly favourable packing of side chains in the N-terminal domain; in this orientation the helix axis of the N-terminal segments is parallel to the oligomer axis. The relative rotation about the helix axis is such that the Gln 7 amide groups from neighbouring molecules form hydrogen bonds with good geometry. When such interactions are propagated, complete channels containing 8–12 molecules are generated. The most favourable oligomer size cannot be determined from these model-building studies, however the hydration structure described below favours an octameric channel structure.

The side chains of the N-terminal domains interdigitate to form a zipper-like structure. All side chains participating in this interface are short (Ala or Aib), consisting of only β-carbon atoms. The Pro 14 residue is directed towards the centre of the channel, causing the helix axis of each molecule to bend away from the oligomer symmetry axis (Fig. 4). The molecules still maintain van der Waals' contact in the C-terminal domain interface but with less favourable surface complementarity, as the side chains in this region are bulkier. The channel model has a funnel-like appearance with a flair at the C-terminal domain region, due to the bend in the helix axis induced by the Pro 14 side chain.

The interior of the channel contains three bands of polar groups capable of hydrogen bonding to water. Each Gln 7 residue donates and receives a Gln 7 hydrogen bond involving residues of each neighbouring molecule, forming a hydrogen-bonded annulus within the channel (Fig. 4). The amide plane of each Gln 7 side chain is tipped out of the mean plane of the Gln 7 residues; each amide is tipped in a direction opposite to that of its neighbours, resulting in a zig-zag pattern. The resulting structure projects amide hydrogen bond donors from each Gln 7 side chain towards the oligomer symmetry axis such that the amide protons are alternately directed above and below the mean Gln 7 plane.

The Gln 7 side chains are in a relatively low energy conformation while making two hydrogen bonds with good geometry. Such considerations indicate that the hydrogen-bonded annular structure will be relatively stable even in the presence of channel water. The unhydrated Gln 7 annulus produces a 7 Å diameter constriction in the octameric channel.

The carbonyl groups of Aib 10 and Gly 11 are solvent-accessible in the model as found for isolated molecules in the crystal. Such hydrogen bond acceptors will provide a further means of solvating the channel interior.

The Glu 18 side chains are also directed towards the oligomer symmetry axis, but because the helix axes of the monomers are directed away from the oligomer axis in this region of the molecule, they do not make direct contact. Indeed, the oxygen atoms of neighbouring carboxyl groups are separated by a minimum distance of ~3.6 Å. The Glu 18 carboxyl groups can be further separated if strict n-fold symmetry is not obeyed. In an aqueous salt solution at neutral pH, the Glu 18 side chain carboxyl groups would be ionized but would be sufficiently shielded from each other by a cloud of condensed counterions so that they would not greatly destabilize the channel structure.

The Gln 19 side chain is tangential to the C-terminal rim of the oligomer, such that the carbonyl is directed towards the oligomer axis while the two amide protons hydrogen bond to oxygen atoms of a neighbouring molecule. The hydrogen bonds are made to the hydroxyl of Phl 20 (which in turn is hydrogen-bonded to the carbonyl oxygen of Aib 17 and to the carbonyl oxygen of Glu 18). This hydrogen-bonding system continues throughout the oligomer structure, stabilizing the C-terminal domains and in part counteracting the residual electrostatic repulsion of the Glu 18 residues. The stabilization realized from the Gln 19 interactions will depend on the hydrophobicity of that region of the membrane.

The exterior of the ion channel is highly hydrophobic, containing many small alkyl side chains and no polar side chains.

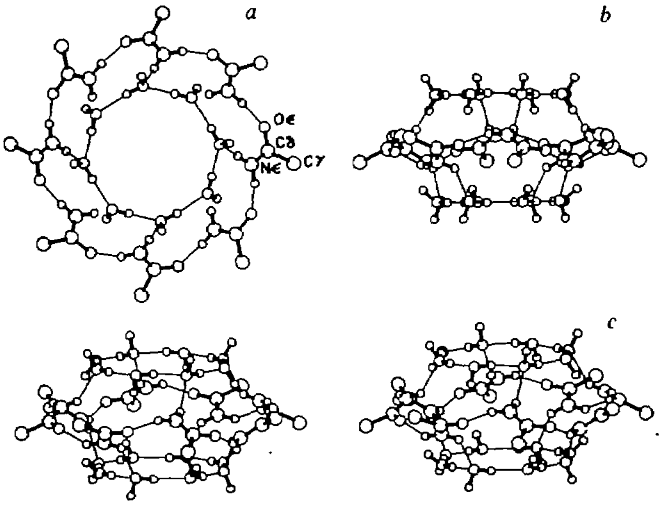

Fig. 5 Ball-and-stick drawings of one possible structure of the solvent near the Gln 7 annulus. *a*, The hydrated Gln 7 annulus viewed along the axis of the octomeric channel model. The atoms of one side chain are labelled. Only atoms beyond C^β are shown. The outer ring hydrogen bonds connect amide and carbonyl groups in adjacent Gln residues; the inner ring of hydrogen bonds connects eight water molecules to each other. The roughly radial bonds connect the unused proton of alternating amide groups to four of the water oxygen atoms. For clarity, the lower ring and interstitial water molecules are not shown. *b*, The hydration structure of the Gln 7 annulus perpendicular to the oligomer axis. The alternating orientation of the Gln 7 side chains can be seen together with the hydrogen bonding to both rings of water. *c*, A stereo diagram of the hydrated Gln 7 annulus. Four additional water molecules can easily be added inside the cage with many hydrogen-bonding possibilities. The mass density of such a 14-molecule hydration complex would be close to that of bulk water.

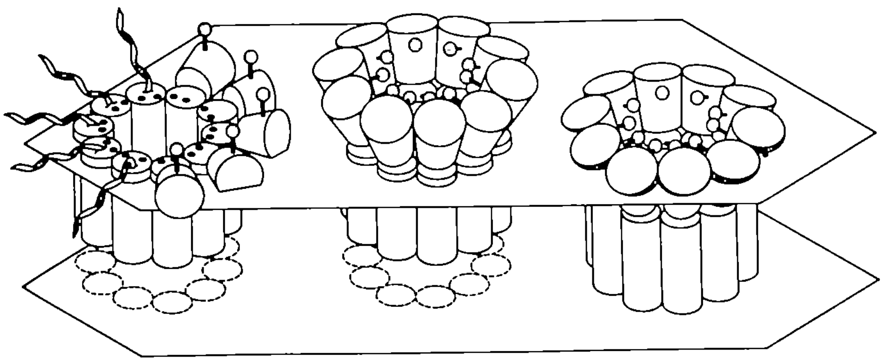

Fig. 6 Voltage-gating channel model. The parallel planes specify the boundary of the alkyl chain region of a lipid bilayer. Elements of the channel model which are in common with Fig. 4*a* are as described in legend. The left-hand channel illustrates the structures proposed for the alamethicin oligomer in the absence of an applied voltage. The helical ribbons signify an extended random coil structure. The cork-shaped elements represent the C-terminal region of each molecule, bent away from the channel *n*-fold axis and partially buried in the alkyl chain region. The channel model in the centre represents a hypothetical intermediate produced by an applied voltage. The model on the right is proposed as the open form of the ion channel.

The conformation of the model used in the construction of the oligomer contains only one non-hydrogen-bonded amide within the central region of the α-helix; this amide is located on the exterior of the channel.

The length of the channel along the oligomer axis is 32 Å, which is about the thickness of the alkyl chain region of biological and black lipid membranes. Thus, each end of the alamethicin molecule will be at the interface of the head group and alkyl chain regions of the lipid bilayer.

The distribution of polar groups in the alamethicin channel is much more regular than that found in globular proteins, as the polar groups within the channel occur in bands at different elevations. The first hydration layer within the channel must interact with this regular array of polar groups in a limited number of orientations, leading to a hydration structure which may be much more regular and extensive than that normally found surrounding globular proteins in crystals or in solution.

Ordered water structure may be of functional significance in the region occupied by the Gln 7 residues. The Gln 7 annulus is the most restricted region of the channel and contains a regular array of hydrogen bond donors directed towards the oligomer axis. The details of the hydration structure will depend on the number of monomers in the alamethicin oligomer. In general, each Gln 7 side chain amide proton will donate a hydrogen bond to a water oxygen atom, causing a further constriction in the ion channel. Such hydrogen-bonded water molecules would be further stabilized by a second set of water molecules bridging the first hydration layer, resulting in a hydrogen-bonded ring of water above and below the Gln-7 annulus. The hydrated Gln 7 annulus for an octameric channel is illustrated in Fig. 5. The diameter of the hydrated annulus region accessible to bulk solvent molecules or ions is ~4.5 Å for the octamer.

Functional implications of the channel model

We suggest that changes in the size or geometry of the Gln-7 annulus are responsible for the conductance substates observed in single alamethicin channels, as this structure provides the greatest restriction to the alamethicin channel cross-section. The model-building studies have not led to a unique channel structure, but to a family of oligomer models containing 8–12 monomers. Thus, the barrel-stave model[14,18] cannot be excluded by model-building studies alone. A channel oligomer of fixed composition could give rise to the conductance substate fluctuations if the stability of the Gln 7 annulus is altered by the applied voltage. The dipole moment of each Gln 7 side chain amide group is oriented almost perpendicular to the electric field in the channel model presented above. If the electric field is sufficient, the amide group will reorient such that the carbonyl is directed towards the C-terminus of the channel. Such a reorientation would result in an enlargement of the channel diameter while exposing a Gln 7 carbonyl group which could interact favourably with a hydrated cation, thus providing a path for cation movement through the channel. Such a reorientation would disrupt the hydration structure, which would also lead to an increase in the channel cross-section. The involvement of different numbers of amide groups in such reorientation might explain the fluctuating conductance substates, although persistence for milliseconds implies the existence of activation barrieo iation whose structural origin is not yet clear.

A molecular explanation of the voltage-gating event requires an understanding of the alamethicin molecular structure in the resting membrane and the physical basis for the voltage-driven structural change. A physical model for the voltage-gating process is presented in Fig. 6. We suggest that the hydrophobic N-terminal segment of alamethicin (residues 1–10) inserts into the alkyl chain region of the lipid bilayer without the aid of an applied voltage, forming a solvent-filled channel traversing one-half of the alkyl chain region. This preferential insertion is expected because of the small number of solvent-accessible polar backbone and side chain atoms present in that segment relative to the more hydrophilic C-terminal region. The insertion of the N-terminus of the alamethicin α-helix into the lipid bilayer results in a favourable orientation of the molecular dipole moment in the electric field generated when that side of the membrane is at a positive potential. The C-terminal portion of the molecule is modelled either as a random coil, associating with the head group region of the bilayer or projecting into the solvent, or as an α-helical segment bent away from the channel *n*-fold axis. The lack of hydrogen bonds to the carbonyl groups of residues 10 and 11 (Fig. 3) which project towards the channel *n*-fold axis, would allow such a hinge motion without disrupting any hydrogen bonds observed in the crystal conformers or as proposed in the model, and would allow the hydrophobic exterior surface of the C-terminal segment to partition into the alkyl chain region of the bilayer. The dipole moment of the C-terminal helical segment would be perpendicular to the electric field direction in the bent helix model, while the dipole moments of the individual peptide groups would be randomly oriented if the C-terminal segment were in a random coil conformation.

An electric field applied to the alamethicin molecules in the sense used in conductance experiments would favour either a coil–helix transition or a reorientation of the C-terminal helical segment, both resulting in the intermediate shown in the centre of Fig. 6. This C-terminal exterior surface now presents a larger hydrophobic surface to the head group and aqueous phase region of the membrane. The burial of this surface in the alkyl chain region of the bilayer would thus serve as the driving force for the voltage-gating event. The inserted alamethicin channel is of sufficient length to span the alkyl chain region of the bilayer but would not extend significantly into the head group region.

Recently, two results have been published which are consistent with the proposed structure of the ungated alamethicin oligomer illustrated in Fig. 6: (1) cross-linking of a lipid photolabel to alamethicin in liposomes results in labelling of only the N-terminal segment (residues 1–13), indicating that this portion of the peptide is accessible to the alkyl chain region of the bilayer[31]; and (2) electron micrographs of negatively-stained liposomes containing alamethicin reveal a circular stain-excluding structure which is stained at its centre[32].

This study was supported by the National Institute of General Medical Sciences grant GM-21714 (G. Palade, principal investigator), and by a research trainee fellowship awarded to R.O.F. under grant GM-07223-05. This paper is adapted from a dissertation submitted by R.O.F. to Yale University in partial fulfillment of the PhD degree requirements. We thank the Upjohn Co. for the gift of alamethicin. We also thank J. Mouning and J. Simpson for assistance in preparation of the manuscript and S. Anderson, J. Johnson, P. Pepin and A. Perlo for technical assistance. The computer-generated space-filling drawings of the alamethicin channel model were produced by M. Connolly.

The sequences of an expressed rat α-tubulin gene and a pseudogene with an inserted repetitive element

Ihor Lemischka & Phillip A. Sharp

Center for Cancer Research and Department of Biology, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139, USA

The rat genome contains two segments closely related to a rat α-tubulin mRNA. Both have been cloned and complete nucleotide sequences are presented. Analysis of the structure and sequence of one of these establishes it as a functional α-tubulin gene. The second segment is a processed α-tubulin pseudogene. Comparison of this pseudogene to the mRNA and gene coding for α-tubulin strongly suggests that a mature mRNA was involved in its origin. Features of the pseudogene and a dispersed repetitive element inserted within it possibly reflect a common RNA-mediated process of insertion.

MICROTUBULES are ubiquitous cellular structures found in eukaryotic organisms and responsible for a variety of functions. The basic subunit of the microtubule is a heterodimer composed of two proteins, the α- and β-tubulins. The amino acid sequence of each of these proteins is conserved and their gene sequences cross-hybridize among distantly related organisms[1]. The multiple functions of microtubules might reflect multiple tubulin proteins with different amino acid sequences and thus multiple genes. Amino acid sequence[2] and nucleotide sequence data[3,4] have shown that mammalian α-tubulin protein is microheterogeneous within species. Whether this microheterogeneity reflects functionally specific α-tubulin proteins is not known.

All tubulin genes are probably derived from a common ancestral sequence. Analysis of the number of α- and β-tubulin genes in mammals using cDNA sequences as probes has detected 10–20 copies of each per genome[5–7]. These segments could either represent functional genes or nonfunctional pseudogenes. On the basis of their sequence organization, pseudogenes can be divided into two classes: simple duplications of the expressed loci with subsequent divergence of nucleotide sequences, or copying of sequences present in RNAs and integration of these cDNA-like segments. The latter type has been referred to as processed pseudogenes[8].

It has been proposed that pseudogenes of small nuclear RNAs were created through RNA intermediates[9]. These pseudogenes are typically flanked by short direct repeats ,that are thought to have been generated during integration of the pseudogenes. Many dispersed repetitive elements in mammalian DNA, such as human Alu elements, are also flanked by short direct repeats, perhaps also created by their insertion (reviewed in ref. 10).

The similarity in structure among processed pseudogenes, pseudogenes of small nuclear RNA and Alu dispersed repetitive elements suggests that these all could result from a common process involving RNA. We report the sequence of an expressed rat α-tubulin gene, a processed pseudogene derived from it and a rat dispersed repetitive element inserted into this pseudogene. The structures of these elements are consistent with the hypothesis that the pseudogene and the dispersed repetitive element were created through RNA intermediates.

Cloning of rat DNA segments closely related to rat α-tubulin mRNA

The sequence of a cDNA clone of rat brain α-tubulin mRNA has been described previously[4]. The cDNA clone pILαT1 is 1,617 nucleotides in length and possesses sequences from the 3′ poly(A) tract, through the coding sequences to within approximately 33 nucleotides of the 5′ terminus of an abundant α-tubulin mRNA. Twenty-nine of these 33 nucleotides were determined by sequencing primer extension products[4]; the total sequence is shown in Fig. 3.

Others have detected multiple copies of genomic α-tubulin sequences in a variety of species[11–14]. To determine the number of α-tubulin genes in rat, three probes were prepared from the α-tubulin cDNA clone; probes I and II encompass sequences of the amino and carboxyl terminal portion of α-tubulin, respectively, while probe III contains sequences totally included within the 3′-untranslated portion of the mRNA. As α-tubulin is a highly conserved protein, probes I and II should hybridize to most of the α-tubulin related sequences in the rat genome.

0028-0836/82/470330—06$01 00

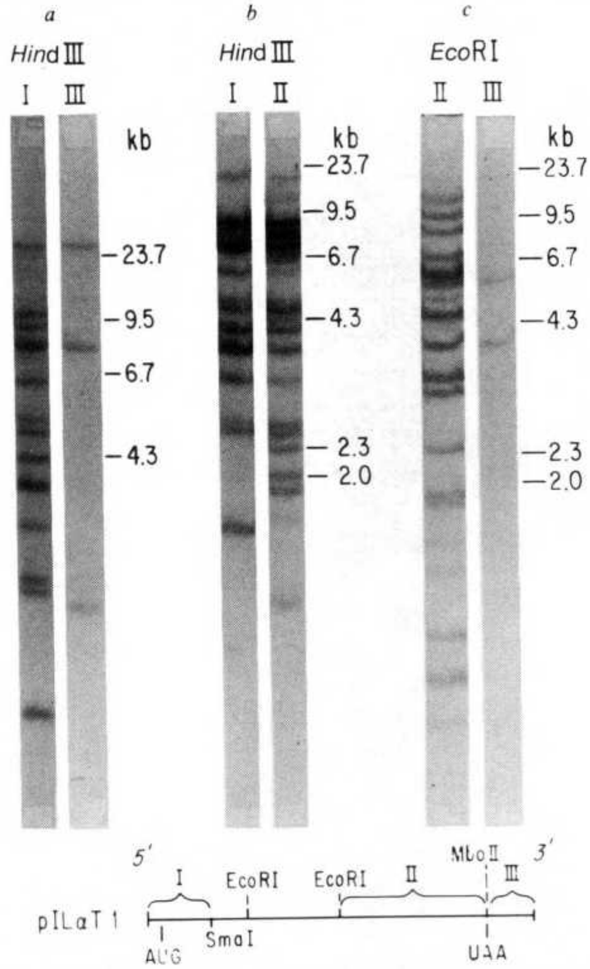

Fig. 1 Genomic representation of different portions of α-tubulin cDNA. Sprague–Dawley rat liver genomic DNA was extracted[37] and cleaved to completion by either *Hin*dIII or *Eco*RI endonucleases, as indicated above each set of lanes. *Hin*dIII does not cleave the cDNA pILαT1, while *Eco*RI cleaves the cDNA at two positions. The spectrum of fragments was resolved by electrophoresis (10 μg per lane) and transferred to nitrocellulose[38]. cDNA probes were prepared by digestion of pILαT1[4] with the indicated restriction endonucleases and isolation of appropriate fragments from preparative agarose gels by the sodium iodide-glass bead method[39]. ^{32}P-labelling was performed by nick-translation[40]. Hybridization and washing (see below) of blots was done essentially as described previously[4]. Three different probes were used: probe I encompassing 66 nucleotides of the 5′ untranslated (UT) and 190 nucleotides of the amino-terminus portion of α-tubulin mRNA, probe II consisting of 590 nucleotides of COOH-terminal information and ending 5 nucleotides before the termination codon and probe III, totally contained in the 3′-UT portion of the mRNA. *a*, probe I hybridizes to 16 fragments. All of the 16 bands persist through stringent washes (0.5–2 × SSC, 65 °C). Hybridization of genomic blots with probe II (*b* and *c*) allows an estimate of 14 copies of sequences homologous to the carboxyl-terminal portion of α-tubulin mRNA. In total, 10 fragments hybridize to both probes I and II (part B). The lane in *a* probed with III and washed at a moderate stringency (2 × SSC, 65 °C) contains four different fragments homologous to the 3′-UT portion of α-tubulin mRNA. However, in *c* only two fragments in an *Eco*RI digest remain hybridized after a high stringency wash (0.2 × SSC, 65 °C). Therefore, the rat genome contains only two copies of α-tubulin 3′-untranslated sequences closely related to the mRNA represented in pILαT1.

Sequences in the 3′-untranslated region of the mRNA should be less constrained and could perhaps be used to distinguish between rat genomic sequences closely related to the cDNA clone and those more distantly related. This is in fact the case. The amino-terminal and carboxyl-terminal probes hybridize to 16 and 14 *Hin*dIII fragments of rat DNA, respectively (see Fig. 1*a*, *b*). Ten of these bands hybridize to both probes, suggesting that these fragments contain the entire α-tubulin coding sequence. However, only two *Eco*RI bands hybridize in stringent conditions to the probe from the 3′-untranslated portion of the mRNA, suggesting that there are only two genes closely related to the cDNA clone (see Fig. 1*c*).

λ-Phage libraries of rat liver DNA sequences were screened by the method of Benton and Davis[15] with radioactive probes from both the 5′- and 3′-untranslated (UT) portion of the cDNA clone pILαT1. We had shown previously that these two probes hybridize in stringent conditions to the same set of genomic bands in a Southern blot. Seven phage plaques detected as positive with both probes in the first screen yielded positive hybridization signals in subsequent screening and these independent phages were selected for further study. Southern blotting of restriction endonuclease digests of the phage DNAs distinguished two phages, λαT15 and λαT14, that hybridized to the probes under high stringency. These two phages clearly had different restriction cleavage patterns.

Mapping of α-tubulin sequences within recombinant phages

Electron microscopy was used to map sequences complementary to α-tubulin mRNA in both λαT15 and λαT14. First, hybridization and R-loop mapping showed that both phage

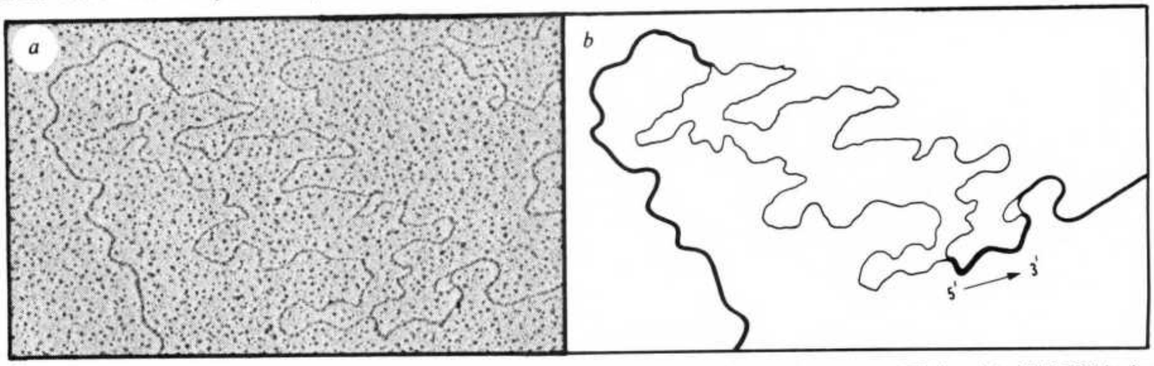

Fig. 2 Electron microscopic analysis of recombinant phage DNA. A heteroduplex formed between λαT14 and λαT15 DNAs is shown in *a* and represented diagrammatically in *b*. Hybrids were formed and mounted as described[41] with minor modifications. A several-hundred-nucleotide region of non-homology separates a 1,590 ± 110-nucleotide duplex segment from the long arm of the Charon 4A vector DNA. The position of this double-stranded region with respect to the positions of R-loops (formed by hybridization of mRNA and phage DNA; not shown) and with respect to restriction and blotting data established this as the segment homologous to α-tubulin cDNA. This combination of data also allowed the assignment of the designated polarity with respect to α-tubulin mRNA sequences.

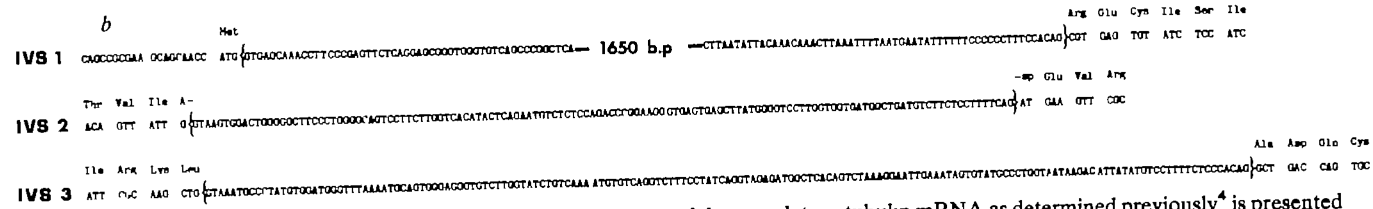

Fig. 3 Sequence of α-tubulin gene and pseudogene. *a*, The sequence of the complete α-tubulin mRNA as determined previously[4] is presented along with the sequence of the α-tubulin gene ($\lambda\alpha$T14) in the correct alignment above the mRNA. Sequences upstream of the mRNA initiation nucleotide (+1) are numbered beginning at −1. Putative transcriptional regulatory regions, GTATATAAGG at −31 and GGACCAA at −77 are boxed. The ATG initiation codon is underlined. Positions of intervening sequences are denoted (IVS1–3). The α-tubulin mRNA is polyadenylated at one of four terminal residues (overlined and labelled poly A). Note that the coding sequence of the gene is identical to that of the mRNA. The sequence of the α-tubulin processed pseudogene ($\lambda\alpha$T15) is aligned below the sequence of the mRNA. Comparison with the gene reveals close homology up to the mRNA initiation nucleotide (+1) and no significant homology further upstream (mismatches are indicated by asterisks). Several small deletions and two single base insertions into the α-tubulin mRNA homologous sequences in $\lambda\alpha$T15 are represented by underlined gaps or arrows, respectively. All three intervening sequences are precisely absent. The $\lambda\alpha$T15 sequences homologous to α-tubulin mRNA are immediately flanked by short 14-nucleotide direct repeats of AAAAAGAGATTTTT (underlined and labelled 5′ or 3′ D.R.). Note that comparison of 3′-flanking sequences in $\lambda\alpha$T14 and $\lambda\alpha$T15 reveals no significant homology. The position of the inserted repetitive element (R.dre.1) found in the pseudogene is shown by an arrow. This element is flanked by direct repeats of 15 nucleotides which occur once in α-tubulin mRNA. These 15 nucleotides are underlined. The sequence of this inserted element and direct repeats is shown in Fig. 4. *b*, Positions and sequences of introns found in the α-tubulin gene ($\lambda\alpha$T14). Sequences of introns are presented with surrounding coding regions. The introns are bracketed. Approximately 60% of the large intron IVS1 sequence has been determined.

DNAs contained sequences complementary to mRNA extracted from rat neuroblastoma cells (line B50; not shown). The RNA/DNA duplex arm of the R-loop measured 1,510 ± 130 nucleotides in length, the same approximate length as the α-tubulin mRNA. Second, the R-loop structures did not reveal the presence of long introns in either duplex. However, in $\lambda\alpha$T14 we frequently observed a cross-over of the two arms of the R-loop at a site ~540 nucleotides from one end. This would be consistent with the presence of a short intron.

Heteroduplex analysis of $\lambda\alpha$T14 and $\lambda\alpha$T15 showed that the two inserted rat DNA segments contained 1,590 ± 110 nucleotides of sequence homology, just sufficient to encompass the total α-tubulin mRNA sequences (Fig. 2*a*). The homologous sequences were not interrupted by long segments of nonhomologous DNA and were flanked by single-stranded loops which did not hybridize to one another in these mounting conditions. In the heteroduplexes of $\lambda\alpha$T14 and $\lambda\alpha$T15 two small knobs were observed at reproducible positions along the duplex segments. Similar knobs have previously been observed for small deletions or insertions in heteroduplexes and suggest that the region of homology is interrupted by a few short segments of nonhomologous sequence. In 5% of the heteroduplexes a single-strand loop of about 1,500 nucleotides was formed at one end of the duplex, suggesting the presence of a larger intron.

Restriction endonuclease cleavage maps were prepared for both $\lambda\alpha$T14 and $\lambda\alpha$T15 phage DNAs by Southern blot analysis using probes similar to those described for Fig. 1. This mapped the α-tubulin related sequences in the phage DNAs to positions adjacent to the longer arm of the Charon 4A vector, and oriented these sequences as indicated in Fig. 2*b*.

DNA sequence of a rat α-tubulin gene

The nucleotide sequence of the α-tubulin related portion of both $\lambda\alpha$T14 and $\lambda\alpha$T15 recombinants was determined by the chemical cleavage method of Maxam and Gilbert[16]. Initially DNA sequencing was done by directly labelling termini in recombinant phage DNA. Subsequently, portions of the α-tubulin related sequences in both $\lambda\alpha$T14 and $\lambda\alpha$T15 DNA were subcloned into the plasmid pBR325 for further sequencing. In total, ~6,000 nucleotides of sequence were determined and over 80% was read from either both strands or from one strand terminally labelled at different cleavage sites.

Recombinant $\lambda\alpha$T14 probably contains sequences specifying an expressed α-tubulin gene of the rat. The nucleotide sequence of this gene is compared with that of the previously sequenced rat α-tubulin cDNA, pILαT1, in Fig. 3*a*. All of the rat α-tubulin mRNA sequence is found in $\lambda\alpha$T14 but is interrupted by three introns. In Fig. 3*a* the positions of the introns are denoted and the sequence of part or all of each intron is given in Fig. 3*b*. All three introns have consensus splicing sequences at their 5′ and 3′ boundaries, permitting assignment of their position in the coding sequence of α-tubulin[17]. Twenty-eight nucleotides upstream from sequences complementary to the suggested 5′ end of the α-tubulin mRNA, is the sequence TATAA-, the expected TATA or Goldberg–Hogness sequence[18]. In preliminary experiments, this DNA segment has been tested for transcription template activity in the whole cell extract system[19]. The length of RNA polymerase II runoff transcripts suggests that the *in vitro* system initiates RNA at a position near or identical to that of the 5′ end of the mRNA, consistent with this being the initiation site of α-tubulin mRNA synthesis.

DNA sequence of a rat α-tubulin pseudogene

Recombinant $\lambda\alpha$T15 contains an interesting α-tubulin pseudogene. First, the α-tubulin related sequences in this phage are remarkably similar to those of the cDNA clone, pILαT1 (see Fig. 3*a*) and therefore to the α-tubulin mRNA. As in the mRNA, sequences corresponding to all three introns in the expressed gene have been precisely excised from the α-tubulin related sequences in $\lambda\alpha$T15. In addition, this gene is homologous to sequences at the 5′ and 3′ termini of the α-tubulin mRNA but the homology to the expressed gene ends precisely at the limits of the mRNA. For example, sequences complementary to the suggested 5′ end of α-tubulin mRNA are present in $\lambda\alpha$ T15 and $\lambda\alpha$ T14 but sequences immediately upstream from this site are totally different (shown in Fig. 3*a*). In the $\lambda\alpha$T15 case, 14 nucleotides of sequence immediately 5′ to the mRNA-related sequences are directly duplicated at the 3′ boundary of the mRNA-related sequences. A short poly (dA) tract is present at the 3′ terminus of the mRNA related sequences in $\lambda\alpha$T15, immediately preceding and included in the second copy of the 14-nucleotide direct repeat. There is no significant homology between $\lambda\alpha$T15 and $\lambda\alpha$T14 DNAs downstream from this position. Some 140 and 540 nucleotides of sequence have been determined 5′ and 3′, respectively, of the α-tubulin related sequences in $\lambda\alpha$T15 DNA.

DNA sequence of a rat dispersed repetitive element interrupting the rat α-tubulin pseudogene

The α-tubulin related sequences in the pseudogene are not completely colinear with α-tubulin cDNA; they are interrupted by a 110-nucleotide segment and a duplication of 15 nucleotides of tubulin sequence at position 1,119 (denoted in Fig. 3*a*). Figure 4 shows the sequence of the 110-nucleotide segment, and the flanking 15-nucleotide direct repeats. This sequence has several features common among dispersed repetitive elements, particularly the Alu-like elements of human, mouse and

Fig. 4 Relationship of repetitive element (termed R.dre.1) contained in the α-tubulin pseudogene. Two-dimensional matrices were used to align the sequence of R.dre.1 with sequences of a closely related element found as the third member of a tandem array of three repetitive sequences located in an intron of rat growth hormone[21]. A second such element (not shown), found several kilobase pairs upstream from the α-tubulin pseudogene, shows a comparable relatedness to R.dre.1. Similar alignments were attempted with consensus sequences for human Alu-like elements, rat 4.5S RNA and rat 7S RNA[42] with only marginal success. These elements are not closely related to R.dre.1. The top line of the figure shows the consensus RNA polIII promoter elements[20] derived from a compilation of tRNA sequences and present in all DNAs thought to be transcribed by this polymerase. In all the comparisons mismatches are underlined, deletions are represented by (−) and insertions are designated.

Chinese hamster DNAs[10]. The 5′ portion of the 110-nucleotide segment contains a consensus RNA polymerase III initiation sequence[20] while the 3′ portion has the customary A-rich sequence. A specific probe for this 110-nucleotide segment hybridizes as a smear to a Southern blot of an *Eco*RI digest of rat DNA. In addition, partial sequence data have revealed the presence of another such element upstream from the pseudogene in λαT15. Barta *et al.*[21] have reported the sequence of an array of repetitive elements in an intron of a rat growth hormone gene. These repetitive elements occur as a tandem array of three related segments. The sequence of one component of this array is also shown in Fig. 4 and only differs in three positions from the element in the rat α-tubulin pseudogene. Clearly, the 110-nucleotide segment, designated R.dre.1 (rat dispersed repetitive element 1), is a member of a rat dispersed repetitive element family and is structurally related to the Alu-like elements.

Discussion

The sequence reported here from λαT14 is the only example of a fully characterized α-tubulin gene which is expressed. We propose that this is a functional gene because: (1) its exon sequences are identical to those of the previously reported α-tubulin cDNA and (2) the only other closely homologous 3′-untranslated sequence in rat is part of an α-tubulin pseudogene. It is likely that there are at least two α-tubulin genes expressed in rat cells, as a second partial cDNA sequence has been reported[3]. However, S_1 nuclease digestions of RNA/DNA hybrids have shown that the α-tubulin gene described here accounts for a large fraction of the α-tubulin mRNA in rat brain as well as in neuroblastoma, fibroblast and glioma cells in culture (I.L. and P.A.S., unpublished observations).

The active rat α-tubulin gene contains three introns, all begin and end in the consensus splicing sequences[17] GT------CAG. The first intron of ~1,770 nucleotides interrupts the coding sequence after the initiation codon ATG, is a class 0 intron[17] and delineates a protein domain of one amino acid. The second intron of 130 nucleotides interrupts codon 76 after the first nucleotide and is thus a class 1 intron. The third intron of 165 nucleotides falls between codons 125 and 126 and is thus another class 0 intron. In view of the limited information about the tertiary structure of tubulin, it is not possible to relate gene structure with protein structure.

Two human DNA segments containing α-tubulin related sequences have been characterized by electron microscopy[5]. It is not clear whether these human DNA segments are expressed α-tubulin genes. These segments hybridize to a chicken cDNA segment but not to human cellular mRNA; both segments have two introns in roughly the same positions as those of the first two introns in the rat gene. However, one segment clearly has a third long intron in the carboxyl-terminal portion of the cDNA which is not present in this rat gene.

Tubulin is a ubiquitous eukaryotic protein and comparison of the number and positions of α-tubulin gene introns in species from different kingdoms might suggest when introns and RNA splicing developed during evolution. A similar comparison has been partially made for actin genes with bewildering results. Intron positions in yeast and *Drosophila* actin genes are unique, while intron positions in sea urchin and vertebrates (both deuterostomes) are frequently conserved[22]. Interestingly, actin genes of vertebrates and soybean have an intron position in common, suggesting that the primordial gene contained this intron[22]. Whether the highly conserved α-tubulin genes will have a similar diversity of intron positions remains to be determined.

As α-tubulin is a major cellular protein, its transcription initiation site should be a strong constitutive promoter. The sequence around the promoter site conforms well with consensus sequences derived from comparison of other sites[23]: GTATATAAGG is found at −31 and GGACCAA is positioned at −77. This DNA segment is active when added as template to a whole cell extract (I.L., unpublished results) but not very active. At the 3′ end of the gene, polyadenylation occurs somewhere in a tract of 3A residues following the customary AATAAA[24].

The intracellular level of α-tubulin mRNA is apparently regulated by the concentration of free tubulin protein[25,26]. The mechanism of this regulation whether transcription, RNA stability or RNA processing is not known. It should be possible to investigate this autoregulation of α-tubulin protein synthesis with probes prepared from the sequenced expressed gene. In addition, sequences responsible for α-tubulin mRNA synthesis and regulation can be defined by *in vitro* modification of the α-tubulin gene and transfection of cells.

The only other cellular DNA sequence highly homologous to the rat α-tubulin cDNA is a pseudogene. This pseudogene was undoubtedly formed by copying of a mature mRNA transcribed from the expressed α-tubulin gene. All sequences corresponding to introns have been precisely deleted, the pseudogene sequences commence at the 5′ end of the mRNA and terminate at or in the poly(A) tract forming the 3′ end of the mRNA. In addition, a direct repeat of 14 nucleotides flanks the precise 3′ and 5′ ends of the pseudogene. This structure strongly suggests that an α-tubulin mRNA was copied into DNA sequence and inserted into a cellular sequence creating the 14 nucleotide direct repeat. Since the pseudogene should be neutral in terms of genetic selection, and differs from the expressed gene by 38 point substitutions in 1,646 positions, the time of its creation can be estimated[27]. Neutral mutations are fixed in the germ line of mammals at a rate of 0.7% per million years. Thus the 2.3% divergence of the pseudogene suggests that it arose $3\text{-}5\times10^6$ yr ago in the germ line of rat. This is well after rat and mouse diverged (30×10^6 yr)[28] and suggests that species even more closely related to rat may not contain this pseudogene.

Evidence for RNA intermediates in the generation of a subclass of pseudogenes has been previously obtained. Pseudogenes related to small nuclear RNAs are characterized by direct repeats that immediately bracket RNA related sequences[9]. Pseudogenes of α-globin of mouse[29] and human λ immunoglobulin[8] are also thought to be RNA derived as they lack introns and the latter terminates in a poly(A) tract. In these two cases, pseudogene sequences related to the expressed loci extend beyond the 5′ terminus of the differentiated cell mRNA. This predicts that an aberrant transcript was used as template in generating these pseudogenes. Two (human) β-tubulin processed pseudogene sequences have also been described[30,31]; each seems to span the amino acid coding sequences and terminates in a poly(A) tract. However, the structures of expressed β-tubulin genes are not known and limit further comparison. In all four cases, the pseudogene sequences are flanked by direct repeats.

A rat dispersed repetitive element is present in the α-tubulin pseudogene sequences. This element (R.dre.1) could have been inserted either in an expressed locus or after the RNA intermediate was used in the creation of the characterized pseudogene. In either case, it is likely that insertion of the repetitive element inactivated the gene and the total began evolving as a neutral sequence. Thus, R.dre.1 should have diverged from its progenitor sequences by less than 2.3%, the divergence of the pseudogene sequence in which it is found. Dispersed repetitive elements almost identical to R.dre.1 have been sequenced by others. An intron of rat growth hormone gene contains a 104-nucleotide segment which only differs in three positions from the repetitive element in the pseudogene (see Fig. 4)[21]. More interestingly, five members of a rat repetitive element family that hybridize to a brain-specific RNA of 160 nucleotides are similarly related to the R.dre.1 element[32]. The function of the 160-nucleotide brain-specific RNA is not known. Sequences related to R.dre.1 are also found in brain-specific hnRNA suggesting that their expression may be specific for certain differentiated cells. This has led to the proposal that these elements be called 'identifier sequences (ID)'[32]. Since the repetitive element in the pseudogene is mobile, any differentiated cell-specific transcription would suggest specific insertion into transcription units only expressed in that cell type. How this specificity could be recorded in germ cells is unclear. The fact that seven rat elements related to R.dre.1 are almost identical in sequence implies that this family of 100,000 dispersed elements is more highly conserved than most families of dispersed repetitive elements. Whether this reflects their recent creation or a high frequency of gene conversion remains to be determined. Given the short period of time that R.dre.1 has had to diverge in sequence, it is likely that these elements are very similar in sequence to that of the hypothetical template RNA. Identification of this template RNA is critical in advancing our understanding of these processes.

Dispersed repetitive elements have been most extensively studied in human DNA where 500,000 copies of a family of related sequences, 300 nucleotides in length, are found, the Alu family of dispersed repetitive elements[10]. About 80% of the members of this family are bracketed by direct repeats of 7–20 nucleotides. The hallmarks of Alu-like elements are nucleotide sequences characteristic of the RNA polymerase III consensus promoter in the 5′ portion and sequences rich in poly(A) tracts in the 3′ portion of the element[10]. Many of these elements are templates for *in vitro* transcription by RNA polymerase III[33]. The RNA product is typically initiated at the 5′ boundary of the repetitive element immediately down stream from the direct repeat. RNA polymerase III consensus sequences are clearly present in the repetitive element (R.dre.1) in the rat α-tubulin pseudogene (Fig. 4). A duplication of 15-nucleotides flanks R.dre.1 in the pseudogene. This duplication probably occurred during insertion of the repetitive element. A similar argument has previously been made for a direct repeat flanking a repetitive element in a monkey satellite sequence[34]. Direct repeats at the site of insertion are characteristic of mobile elements such as transposons in bacteria, ty elements in yeast, *copia* elements in *Drosophila* and retroviruses in mammals[35]. Generation of direct repeats of 7–20 nucleotides is not characteristic of integration of DNA fragments during DNA transformation of mammalian cells[36]. This argues strongly for an active integration process in the mobility of Alu-like repetitive elements.

The striking parallels in the structure of the α-tubulin pseudogene and the rat repetitive element inserted within it, suggest that the two sequences were generated by the same process, a process that (1) copies RNA sequences into DNA sequences, (2) creates direct repeats on insertion, (3) retains the colinearity of inserted sequence and RNA intermediate, and (4) perhaps creates or requires an adenine-rich tract at the 3′ terminus of the RNA or DNA intermediate. Given that there are 500,000 dispersed repetitive elements in human DNA, insertion of small repetitive elements in the germ line of mammals must not be uncommon. It seems reasonable to propose that pseudogenes of mRNAs are generated by the occasional utilization of mRNA substrates by the process which disperses Alu-like elements. Several β-tubulin pseudogenes in man and probably at least three of the α-tubulin related segments in rat (I.L. and P.A.S. unpublished observations) are processed pseudogenes. Whether tubulin mRNAs are special in their propensity to be duplicated and inserted by this mechanism is not clear. However, if they are typical of mRNAs in general, account for 1% of the total mRNA in a given tissue and are converted into processed pseudogenes at a rate of 1 per 3×10^6 yr, it would appear that the germ line of mammals might be increased by 100 such pseudogenes in this period, not a negligible process when considering alterations in the genetic composition of a species.

The peculiar galaxy NGC1275 = Per A = 3C84 remains a problem in the classification of extragalactic sources despite intensive study in all available wavebands. Included in Seyfert's original list[1], it was described as a Seyfert 2 by Khachikian and Weedman[2] on the basis of observed emission line profiles. Later Weedman[3], however, declined to classify NGC1275 and most recently Véron[4] has suggested that on the basis of its emission line spectrum, variability and radio and polarimetric properties we should regard NGC1275 as a (rather anomalous) BL Lac object. We present here results of IUE spectrophotometry of NGC1275 which show an absorption feature identified with Lyα at a velocity of 8,200 km s^{-1}. We attribute the origin of this feature to the intervening galaxy responsible for the high velocity emission filaments seen around NGC1275. Profile fitting yields a neutral hydrogen column density in the absorbing medium $N_{\mathrm{H}} \sim 1.8 \times 10^{20}$ atoms cm^{-2}. Combining this result with available 21-cm absorption data yields a spin temperature $T_s \sim$ 52 K for the absorbing gas, typical of that in interstellar H I clouds seen in our Galaxy. The implications of these results are discussed.

In addition to the nuclear emission line spectrum Minkowski[5] discovered two discrete emission line systems at 5,300 km s^{-1} and 8,200 km s^{-1} in the network of filaments surrounding NGC1275. The low velocity (LV) system, at the intrinsic redshift of NGC1275 itself, is roughly symmetrically distributed about the galaxy, while the high velocity (HV) filaments are seen only to the north and west of the nucleus[6-10]. The LV system is thought to arise in condensations in an accretion flow of intracluster gas onto NGC1275 [6], excited either by collisional ionization from shocks generated by colliding clouds or by photoionization by the Seyfert nucleus. Observations of the core of the Perseus cluster with the High Resolution Imager on the Einstein Observatory in an effective range 0.7–3 keV also show evidence for a cooling intracluster flow[11], although the relation between the optical and X-ray emission is not fully understood. In contrast to the origin of the LV system, a substantial body of evidence now exists which supports the suggestion that the HV system arises in an infalling late spiral seen along the line of sight to NGC1275 itself[7]. Observations in favour of this hypothesis include: (1) A velocity pattern over the system of HV filaments indicative of a rotating spiral seen almost edge-on[8]. (2) Obscuration of the underlying LV continuum and emission in the HV system are highly spatially correlated. In addition, the Balmer decrement seen in the LV system is much steeper than that seen in the HV system, implying that the latter is intervening[7]. (3) Line strengths in the HV system are typical of those seen in low density, high excitation H II regions excited by stars in the outer regions of late-type galaxies, namely H $\gg$[N II], [O III]$>$Hβ, [N II]$\sim$[S II], [O II]λ3,729$>$[O II]λ3,726. In particular, the low [N II]:[S II] ratio implies a low mass of gas recycled by nucleogenesis in the intervening galaxy[7]. (4) The velocity width of the lines, the Hβ luminosity and the spatial distribution of excitation level in the HV system are consistent with those seen in spirals[6]. (5) 21-cm radio observations show narrow absorption typical of galactic clouds against the nuclear radio source in NGC1275 at a velocity of 8,200 km s^{-1} (refs 12–14).

We have studied three spectra of NGC1275 obtained with the SWP camera aboard the IUE satellite[15]. The wavelength range covered by these spectra is 1,150–1,950 Å; details of the individual integrations are given in Table 1. The absorption feature identified with Lyα at 8,200 km s^{-1} was clearly seen in all three spectra, but only SWP 3452 and SWP 4658 were included in the subsequent analysis due to the poor signal-to-noise ratio in SWP 3430. This was due not only to the shorter integration time but also to the intrinsic weakness of the continuum source in NGC1275 at the epoch of this image (see Table 1). Variability in both the continuum and nuclear emission line spectrum in NGC1275 is rapid and complex, and will be discussed elsewhere (S.A.B. *et al.* in preparation).

The spectra were extracted from the geometrically and photometrically corrected (second file) image using the high resolution package developed by Snijders and Adams[16]. The wavelength scales in individual spectra differed by $<$1 Å and after averaging, the resulting absorption profile was modelled using a curve of growth analysis code developed for use in modelling interstellar line profiles[17]. Only data points to the red of the central absorption velocity were used as the blue wing of the absorption feature was heavily contaminated by Lyα emission at 5,200 km s^{-1} associated with the non-thermal Seyfert nucleus. To facilitate comparison with the model profiles the red wing data were reflected about the central absorption velocity (see Fig. 1). Profiles were generated for a range of H I column densities 0.4–4$\times 10^{20}$ atoms cm^{-2}, that is well on the damping part of the curve of growth, and were convolved with the IUE instrumental profile at 1,240 Å, which is approximated by a gaussian of FWHM 1,000 km s^{-1}, before comparison with the observed profile.

Figure 1 shows the optimum model profile together with the observed data. The data were normalized to the observed continuum and the abscissa shows velocity in the observer's frame. The feature at $v \sim 11{,}500$ km s^{-1} (and reflected at $v \sim$ 4,900 km s^{-1}) is due to Si II $\lambda\lambda$1,260, 1,264 Å galactic absorption.

The optimal fit was found to correspond to a H I column density of $N_{\mathrm{H\,I}} = 1.8\ (+1.0, -0.8) \times 10^{20}$ atoms cm^{-2}. De Young *et al.*[14] have derived $N_{\mathrm{H\,I}} = 3.5 \times 10^{18}\ T_s$ atoms cm^{-2} K, where T_s is the spin temperature of the absorbing material, by study of the 21-cm absorption in the intervening galaxy and combining this with our result we find $T_s = 52\ (+28, -24)$ K. If we assume for the absorbing cloud a gas kinetic pressure $NkT = 2 \times 10^3\ k$ cm^{-3} K as determined for interstellar clouds in the Galaxy[18], then the implied density is $n_{\mathrm{H}} \sim 35$ cm^{-3}. These values for both spin temperature and gas density lie within the limits $T_s < 300$ K and $10 < n_{\mathrm{H}} < 100$ cm^{-3} set by Romney[12] for the 21-cm absorbing medium using 21-cm techniques.

Comparing the observed column density with the derived particle density in the cloud, we can estimate a value for the

Table 1 Short wavelength IUE spectra of NGC1275

Image No.	Date year/day	Exposure time (min)	F_λ(1,500 Å) ($\times 10^{-14}$ erg cm^{-2} s^{-1} Å^{-1})
SWP 3430	1978/328	185	0.48 ± 0.07
SWP 3452	1978/329	345	0.81 ± 0.06
SWP 4658	1979/075	250	0.94 ± 0.06

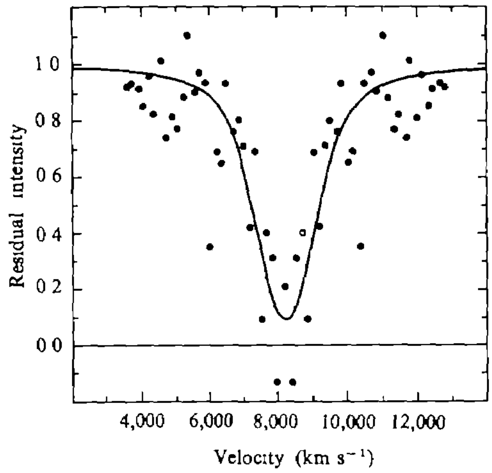

Fig. 1 Absorption due to Lyα at a velocity of 8,200 km s^{-1} in the UV spectrum of NGC1275. The solid line shows the best fit model profile, corresponding to a neutral hydrogen column density $N(\mathrm{H\,I}) = 1.8 \times 10^{20}$ atoms cm^{-2}. Intensity is normalized to the observed continuum and the abscissa shows velocity in the observer's frame. Possible error in centring the absorption feature in velocity space is included in the total error on column density given in the text.

linear dimension of the cloud, $d \sim 2$ pc, consistent with the dimensions of interstellar clouds in our Galaxy. The mean thermal velocity in the cloud is of the order of 1 km s^{-1}, which suggests that the velocity width of 6 km s^{-1} seen in the 21-cm absorption feature arises as a result of turbulent motion within the cloud. This velocity width is again similar to that seen in clouds in the Galaxy.

The position of the cloud in the intervening galaxy can be estimated from the published map of the high velocity filaments[8]. This suggests that the visible galaxy is of the order of 26 kpc in diameter and is inclined at $I \sim 70°$ to the plane of the sky. The nuclear source in NGC1275 lies at the south-east margin of the HV emission, and our line of sight thus passes through the intervening galaxy at angle of about 20° to the disk at a radial distance of ~13 kpc.

The derived density and temperature for the cloud strengthen the conclusion of Kent and Sargent[6] that the cloud must be distant from the nucleus of NGC1275. Scaling their model by our results shows that the cloud would be destroyed by the nuclear X-ray source in NGC1275 unless it were at least 50 kpc from the source, provided the cloud is not heavily shielded against the X-radiation.

The above results thus confirm the hypothesis that the high velocity system of filaments seen about NGC1275 arises in an intervening galaxy distant from and in line of sight to NGC1275 itself.

SAGE—European ozonesonde comparison

R. Reiter

Fraunhofer Institute for Atmospheric Environmental Research,
Garmisch-Partenkirchen, FRG

M. P. McCormick

Atmospheric Sciences Division, NASA Langley Research Center,
Hampton, Virginia 23665, USA

Between February and December 1979, 30 correlative or 'ground-truth' comparisons were conducted of ozone profiles derived from the satellite sensor SAGE (stratospheric aerosol and gas experiment) and those derived from balloon-borne ozonesondes launched in Europe[1]. The ozonesonde launches took place at Biscarrosse (44.3° N, 1.2° W), Garmisch-Partenkirchen (47.5° N, 11.0° E), Hohenpeissenberg (47.8° N, 11.0° E), and Lindenberg (52.2° N, 14.1° E). Data comparisons were made when the distance between the SAGE profile and ozonesonde launch location was <1,500 km and the time interval between the measurements ≤24 h. This is not an ideal situation but is necessary to accomplish many comparisons without a significant perturbation to the schedules of the ozondesonde launch stations. Even with these large differences in time and space, the comparisons are very good with an average difference between 18 and 28 km of 8.8%. One comparison, however, was within 1 h and a 13 km spatial distance. This was carried out from the 2 April 1979 launch from the ozone station at Garmisch-Partenkirchen. The results are remarkable and together with the general results from the other comparisons are described below.

SAGE uses the technique of limb extinction or solar occultation to infer the vertical distribution of stratospheric ozone. At

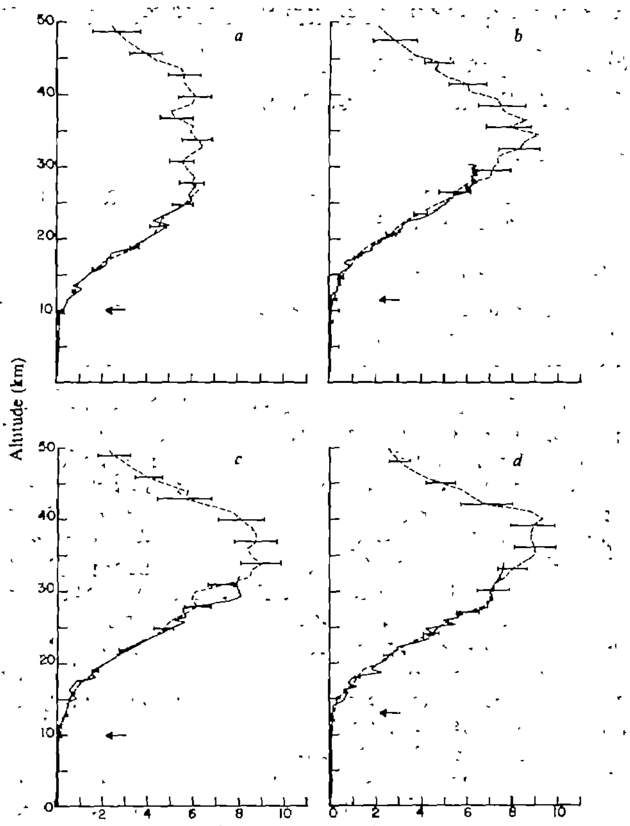

Fig. 1 Ozone comparisons made at four stations in Europe plotted as ozone mixing ratio versus altitude. SAGE data are plotted as the dashed lines and the ozonesonde data as the solid lines. The horizontal lines on the SAGE data indicate the 1σ uncertainties in the SAGE measurements. The horizontal arrow in each comparison plot indicates the altitude of the tropopause. *a*, Lindenberg, 28 February 1979. The separation (Δ*X*) at 20 km altitude between soundings is 828 km. The ECC sonde launch time (T_{ecc}) was 1100 GMT while the SAGE measurement time (T_s) was 0643 GMT. *b*, Garmisch-Partenkirchen, 10 June 1979, $\Delta X = 703$ km; $T_{ecc} = 1716$ GMT; $T_s = 1949$ GMT. *c*, Biscarrosse, 29 October 1979, $\Delta X = 683$ km; $T_{ecc} = 1331$ GMT; $T_s = 1620$ GMT. *d*, Hohenpeissenberg, 31 October 1979; $\Delta X = 871$ km; $T_{ecc} = 0706$ GMT; $T_s = 1638$ GMT.

each spacecraft sunrise or sunset, SAGE acquires the Sun and measures its brightness in four spectral bands in the region 0.385–1.0 μm. The radiances are mathematically inverted as shown by Chu and McCormick[2] to yield profiles of ozone and NO_2 concentration and aerosol extinction with a 1 km vertical resolution on the Earth's horizon. The instrument and experiment are described elsewhere[3]. The ozonesondes used for these comparisons are variations of the two basic sondes, the Brewer–Mast and Komhyr–ECC sonde[4]. They have been shown to operate well to ~30–35 km with an accuracy of 10% (ref. 5).

Table 1 lists the mean absolute differences between SAGE and the European ozonesondes when ozone mixing ratio (p.p.m.v.) is used as the basis for comparison. The mean absolute difference *M* was calculated by

$$M=\frac{1}{N}\sum_{i=1}^{N}\frac{|R_i-r_i|}{(R_i+r_i)/2}$$

where R_i and r_i are the *N* mixing ratios of SAGE and the European ozonesondes at the SAGE altitudes between 18 and 28 km. Figure 1 shows a composite of profiles typical for each station. The horizontal bars on the SAGE data indicate the expected 1σ uncertainties. The tropopause is indicated by an arrow. The comparisons are quite reasonable, especially considering the large differences in time and space. Figure 2*a* shows the 2 April 1979 Garmisch comparison where the time and space differences were very small. Two altitude regions show

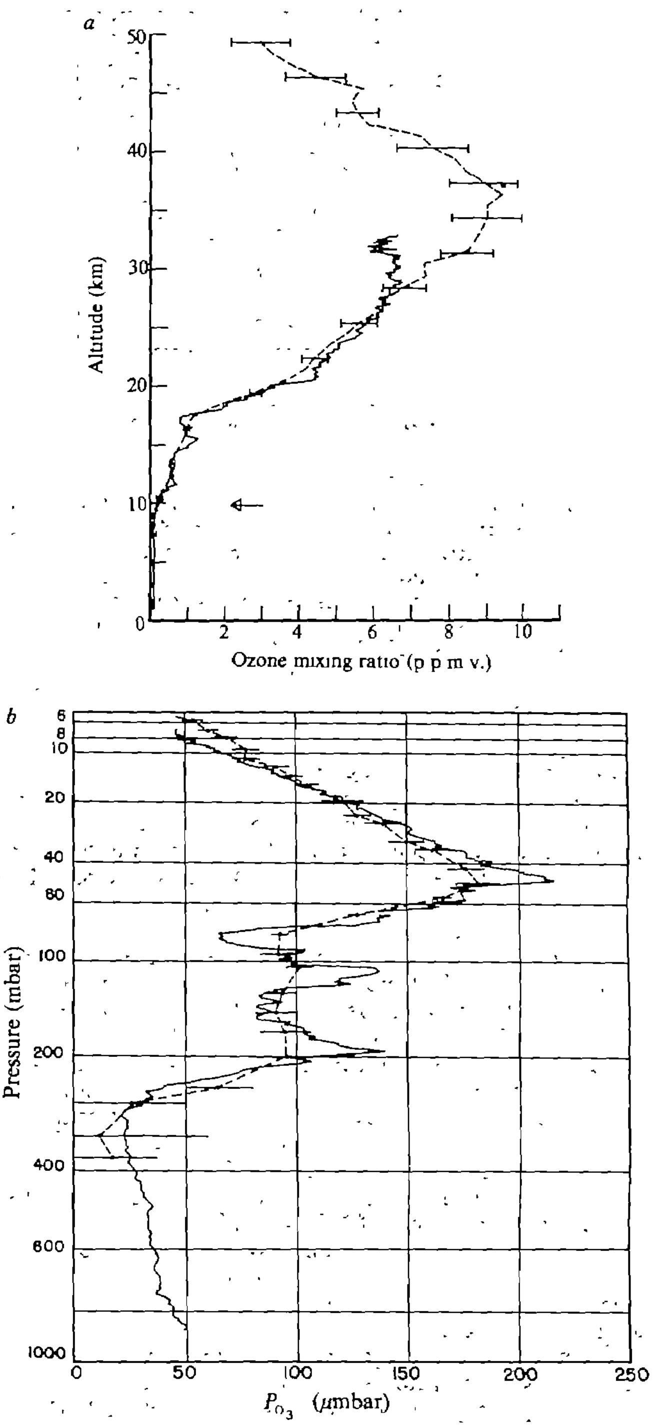

Fig. 2 *a*, Comparison on 2 April 1979, of ozone volume mixing ratio profiles derived from SAGE and an ozonesonde launched from Garmisch–Partenkirchen (47.5° N, 11.0° E). The ECC sonde was launched at 1645 GMT and reached an altitude of 20 km at 1745 GMT. The SAGE measurement was made at 1743 GMT. The horizontal distance between the limb-centroid of the SAGE measurement at 20 km altitude and Garmisch was 13 km. *b*, Comparison as in *a* except ozone is plotted as partial pressure versus pressure altitude.

differences beyond the 1σ expected limits. The fall-off of the ozonesonde data near 30 km is probably due to pump inefficiencies at these altitudes and is characteristic of several ozonesonde soundings. Differences near the tropopause are typical of limb measurement comparisons. Whereas the balloon device samples air as it rises, SAGE integrates its signal over the Earth's limb between the satellite and the Sun. The effective stratospheric pathlength is ~200 km. Over these distances the tropopause and, therefore, the tops of clouds (cirrus and subvisible cirrus) are variable, affecting the measured extinction. In addition, clouds have occasionally been seen to penetrate the local tropopause. Therefore, we feel that SAGE data should not be compared with *in situ* measurements for the first 1 or 2 km above the indicated tropopause. The mean absolute difference over the 18–28 km range of comparison is only 6.5%. Figure 3 repeats this Garmisch comparison in terms of ozone partial pressure versus pressure altitude to >30 km. The effect of horizontal and vertical integration by SAGE is quite evident, but the agreement is remarkable. For example, the ratio of SAGE to ozonesonde values at 13 out of 17 levels between 12.5 and 28.5 km, lies in the range 0.92–1.06. Allowing for uncertainties in the ozone measurements, differences in vertical resolution, time, and space gradients, this agreement is encouraging.

The SAGE ozone data will be archived beginning in summer 1982 at the United States National Space Science Data Center, Greenbelt, Maryland and the World Ozone Data Center, Toronto, Canada.

We thank the staffs at Biscarrosse, Hohenpeissenberg and Lindenberg for providing ozonesonde data, T. J. Swissler and M. T. Osborn for assistance, and Mr D. E. Miller for organizational work in the coordination of the European joint measurements and for scientific advice.

Effects of γ radiation on the leaching kinetics of various nuclear waste-form materials

Aaron Barkatt, Alisa Barkatt & William Sousanpour

Vitreous State Laboratory, The Catholic University of America,
Washington DC 20064, USA

When a solid used to immobilize high-level nuclear wastes is evaluated with respect to its long-term durability and effectiveness as a barrier against radio-isotope release, the massive doses of ionizing radiation to which the solid will be exposed during storage have to be taken into account. Unlike particle radiation, which can give rise to considerable damage even in dry conditions[1], γ irradiation seems to enhance leachability significantly only when the solid is in contact with an aqueous medium while being irradiated[2]. Even in these conditions studies of the effect of γ irradiation at dose rates similar to those expected in repository conditions show only a modest radiation-induced enhancement in leach rates. This enhancement, expressed in terms of the ratio $R_{irr} = L_I/L_0$ between the leach rates measured in irradiated and non-irradiated conditions, respectively, is typically of the order of 1–4 in the case of borosilicate glasses containing typical commericial as well as defence waste stream compositions[2–4]. We show here that the radiation-induced enhancement of leach rates can be ascribed primarily to radiolytic acidification of the aqueous medium and secondarily to radiolytic formation of complexing species. As a result, wasteforms based on major components such as alumina, which are more susceptible to acid dissolution and to attack by complexing agents than silica, show much larger radiation-induced enhancements of their leach rates than silicate glasses.

A series of waste-form materials including PNL 76–68 borosilicate glass[3], SRL TDS-131 borosilicate glass[4], CU PGM high-silica glass[2] and Synroc-D [5] were leached inside the cavity of a ^{137}Cs γ source. In each case, a sample with a surface area of 2.5×10^{-4} m^2 was placed in a volume of 0.025 l contained in a 0.030-l polypropylene centrifuge tube closed with a screw cap. The γ dose rate was 8.6×10^4 rad h^{-1}, of the same order of magnitude expected at the surface of a waste-form fully loaded with defense waste[4]. Leachants included de-ionized water and a pH 6 0.05 M phosphate buffer. For each combination of solid and leachant two identical experiments were carried out inside the radiation chamber and two outside the chamber in order to evaluate R_{irr}. The temperature in all cases was 25 ± 1 °C. In each case, the leaching period was 3 days, and at the end of this period the leachate was completely removed, analysed and replaced with fresh leachant. This procedure was repeated until five 3-day leaching periods were completed. The experimental error (2σ) in the measurement of leach rates based on Si was up to ±5%, and in the case of other elements up to ±20%. The results showed that the leach rates usually dropped slightly (by <30%) during the first two intervals and became constant throughout the last three intervals. However, R_{irr} did not show significant dependence on time in any of the experiments.

The results of the leach experiments in the cases of the four waste-form materials in water and in a pH 6 phosphate buffer are shown in Table 1. The first part of Table 1, which summarizes the observed radiation-induced leach rate enhancements in water, shows that the enhancements observed in the cases of the three glasses, which range between 1 and 4, are much smaller than those observed in the case of Synroc-D. This is particularly noticeable when one considers the major structure elements, silica in the case of the glasses and alumina in the case of Synroc-D, which determine the long-term corrosion rate of the bulk material. (In the case of the glasses, the small concentration of alumina in the leachates and the relatively high detection limit (0.05 mg l^{-1} Al as compared with 0.005 mg l^{-1} in the cases of the other elements) did not permit an accurate evaluation of R_{irr}). The moderate enhancements found in the case of the glasses agree with previous findings[2–4]. In all cases, the final pH of the irradiated leachates was found to be between 4.0 and 4.3. On the other hand, the pH of the unirradiated leachates remained at the level of 5.7–5.8 corresponding to pure water in equilibrium with atmospheric CO_2.

The second part of Table 1 shows that the enhancements in leach rate become much smaller when the radiation-induced pH decrease is eliminated as a result of buffering the medium at pH 6 using a 0.05 M phosphate buffer. In this case all the enhancements are <2. This is a very strong and direct indication that the radiation-induced acidification of the aqueous medium is the primary cause of the enhancement of leach rates in γ radiation fields.

Based on this conclusion, the large enhancement in leach rates observed in the case of Synroc-D indicates that this material is much less durable in weakly acid media than the glasses. This is directly confirmed by the findings summarized in the third part of Table 1, which show the ratio R_{ac} between the leach rates obtained in high-dilution non-irradiated leach tests carried on the four materials detailed above in solutions buffered at pH 4 and 6, respectively. (The buffer strength in each case was 0.01 M, and the surface-to-volume ratio was 10 m^{-1}; to obtain high accuracy, the tests were carried out at 90 °C with the data corresponding to the period between the second and the fourth days used in Table 1.) The relative sensitivity of the materials to leaching in a weakly acidified medium agrees very well with their sensitivity to leaching in irradiated pure water as documented in the first part of Table 1.

The different alumina content of the four tested materials is probably the reason for the large differences observed in the sensitivity of their leach rates to pH decrease, whether as the result of irradiation or due to the introduction of acid. The solubility of silica is almost completely independent of the pH in the range 2–7 (ref. 6) and is little affected even in more concentrated acids (except HF, H_3PO_4 and their derivatives)[7].

0028–0836/82/470339—03$01.00

Table 1 Radiation effects on leaching and related enhancements

	PNL 76–68 ($<0.1\%$ Al_2O_3, 40.0% SiO_2)	SRL TDS-131 (3.7% Al_2O_3, 43.9% SiO_2)	CU PGM (8.1% Al_2O_3, 57.3% SiO_2, 4.4% P_2O_5)	SYNROC-D (19.0% Al_2O_3, 6.75% SiO_2)
R_{irr} (water)				
Si	1.35	3.9	3.5	25
Sr	1.0	1.5		15
Ca	2.3	1.7		36
Na	2.8	1.2	4.2	9
Al				113
R_{irr} (pH 6 buffer)				
Si	1.15	1.2	1.45	1.4
Sr	1.5	1.0		1.0
Ca	0.7	1.2		1.1
Al				1.75
R_{ac} (pH 4/pH 6)				
Si	2.2	11.0	6.5	2553
Sr	12.4	3.9	30	235
Ca	5.6	6.7	7.7	194
Al				66
R_{oxal} (0.05 M/0 01 M)				
Si	2.0	6.9	0.7	3.4
Ca	2.0	7.5	0.7	0.9
Al		6.6	0.9	3.5
Ti	2.3	6.9		11

On the other hand, the solubility of alumina rises very sharply when the pH decreases (by factors of 3, 26 and 1,800 at pH levels of 6, 5 and 4, respectively, relative to the solubility at pH 7)[8]. The sensitivity of silicate solids and glasses[7] to acid dissolution grows rapidly and progressively[9] with the introduction of alumina, and aluminosilicate minerals display a pH dependence almost as sharp as the one observed with pure gibbsite[10].

In the present case, the rise of R_{irr} and R_{ac} with alumina content is roughly exponential, showing a similarity to the data in ref. 9. Focusing again on data based on the major structure elements, it can be seen that in the case of PNL glass, which contains only traces of alumina, the dissolution rate (based on Si) increases only by a factor of 1.35 when leaching is carried out in a radiation field. For SRL and CU glasses, which have an Al_2O_3 content of 4–8%, the corresponding R_{irr} ratios are between 3 and 4, and in the case of Synroc-D (19% alumina) R_{irr} based on Si is 25 but R_{irr} based on Al, the major matrix element in the latter case, is as high as 113. A minor discrepancy is shown by the finding that CU glass is not more sensitive to the presence of acid (as indicated both by R_{irr} and by R_{ac}) than SRL glass despite the higher alumina content of the former. This can be attributed to the presence of a relatively high concentration of P_2O_5 in the case of CU glass alone, as $AlPO_4$ is much less soluble than Al_2O_3 in moderately acidic media[11]. In addition, the high silica content of CU glass is likely to strengthen the matrix against acid attack.

The formation of acidic species on irradiation of aerated water has been observed earlier[3,4], and the pH decrease appears to be larger the higher the radiation dose. Earlier work showed that both nitric acid[3,4] and hydrogen peroxide[3] appear in the irradiated medium. Present findings show the presence of HNO_3, HCOOH, $(COOH)_2$ and H_2O_2 at concentrations of 78, 46, 30 and 16 μmol l^{-1}, respectively, at the end of a 3-day irradiation period in the conditions detailed above. In addition, small amounts of higher organic acids have been detected. The formation of organic acids in aqueous carbon dioxide solutions previously reported[12,13] is likely to result in the present case from reduction of dissolved atmospheric CO_2 by hydrated electrons, which are highly reactive towards CO_2 (ref. 14). The mechanism of HNO_3 formation from dissolved atmospheric N_2 and, possibly, O_2 is less clear, but preliminary doping experiments with alcohols and the observation that hydrated electrons are not reactive towards N_2 (ref. 15) indicate that hydroxyl radicals may be involved.

In any case, the formation of nitric acid may not be very significant in repository conditions in the event that the replenishment of atmospheric gases, after the chamber which contains the waste packages has been sealed, proves to be slow. On the other hand, the fact that at least one half of the total acid content in irradiated water is due to the formation of carboxylic acids from dissolved CO_2 implies that enhanced leaching due to radiolysis may prove to be a persistent effect due to the presence of significant levels of CO_2 and carbonate species in ground-water in general[16]. The extent of carboxylic acid formation in a particular ground-water composition is likely to depend on the concentration of carbonate species as well as on the pH.

Furthermore, the radiation-induced formation of oxalic acd and of other organic acids, as well as the possible formation of aldehyde and glycol[13], raises the possibility that the radiation-induced increase in leach rate is due in part to specific effects of complexing species such as oxalate. It is well-known that glasses undergo accelerated attack in the presence of complexing agents[17].

As the data in the second part of Table 1 demonstrate, leach rates are enhanced by factors ranging up to almost 2 even when the pH decrease is suppressed by means of a buffer. This residual enhancement probably reflects the effect of the formation of oxalate and other complexing species. The fourth part of Table 1 shows the results of measurements of R_{oxal}, the enhancement of leach rates in the presence of oxalate. The measurements were carried out using the same procedure as that used in the non-irradiated leach experiments used in the determination of R_{irr} (25 °C, surface-to-volume ratio $= 10\ m^{-1}$, five 3-day leach periods). R_{oxal} represents the ratio between the leach rates obtained in a 0.05 M pH 5 Na oxalate–oxalic acid buffer and in the same buffer diluted by a factor of 5 with de-ionized water, respectively. The results show significant enhancements in leach rates in all cases, except CU glass, when the samples are exposed to the more concentrated oxalate buffer. The lack of effect in the case of CU glass may be related to the high concentration of silica, which forms a dense network insensitive to complexants. On the other hand, SRL glass and Synroc-D, which exhibit high values of R_{oxal}, have high concentrations of complexable species such as Al and Ti. The build-up of radiation-produced complexing species, in particular oxalate, in ground-water is probably most significant with respect to the leaching of actinides, lanthanides and transition metal ions which are strongly complexed by oxalate.

The hydrophobic interaction is long range, decaying exponentially with distance

Jacob Israelachvili & Richard Pashley

Department of Applied Mathematics,
Institute of Advanced Studies, Australian National University,
Canberra, ACT, 2600 Australia

The attractive interaction between organic nonpolar molecules, such as hydrocarbons, in water is unusually strong. This 'hydrophobic interaction'[1] is responsible for the very low solubility of hydrophobic molecules in water, and has a central role in micelle formation, biological membrane structure, and in determining the conformations of proteins[2,3]. It was once believed that because the interaction is so strong there is a 'hydrophobic bond' associated with it[2,4]; but it is now recognized that the interaction involves the configurational rearrangement of water molecules as two hydrophobic species come together[5–9] and is therefore of longer range than a typical covalent bond. However, there has been no experimental information available concerning the distance dependence and effective range of this interaction. From measurements of the total force as a function of distance between two hydrophobic surfaces immersed in aqueous electrolyte solutions we have determined accurately the attractive component due to the hydrophobic interaction and found that the hydrophobic interaction has the same range as, but is about an order of magnitude stronger than, the van der Waals-dispersion force; and that in the range 0–10 nm it decays exponentially with distance with a decay length of ~1 nm. The results can be roughly extrapolated to molecular interactions and show that the interaction free energy of two hydrophobic solute molecules of radius *R* (nm) in water at 21 °C is approximately given by $\Delta G_H = -40R$ kJ mol^{-1}, which is in agreement with previous estimates. However, the hydrophobic interaction is not due to a 'hydrophobic bond', and its long-range nature has obvious implications for the mechanism and rates of folding as well as the equilibrium conformations of proteins and other macromolecules.

We have measured the forces between two hydrophobic surfaces in aqueous solutions in the distance range $D = 0$ (contact) to $D > 50$ nm.The experimental techniques used were similar to those used previously for measuring the forces between mica surfaces in liquids[10–14], which allow for the force F between two crossed cylinders of mica of radius R to be measured with a distance resolution of about 0.2 nm. In the present experiments the mica surfaces were rendered hydrophobic by the adsorption of a monolayer of the cationic surfactant hexadecyltrimethylammonium bromide, $CH_3\text{-}(CH_2)_{15}\text{-}N(CH_3)_3^{\oplus}Br^{\ominus}$ or CTAB, from solution. At concentrations just below the CMC (10^{-3} M) the positive CTA$^{\oplus}$ group adsorbs onto the negatively charged mica surface as a compact monolayer exposing a hydrophobic surface composed of CH_3 and CH_2 groups[12]. In this range of concentrations the net surface charge on the mica$^{\ominus}$–CTA$^{\oplus}$ surface goes from being negative to positive, passing through its point of zero charge (PZC). Thus in addition to any attractive force between two such monolayer-covered surfaces there is a repulsive electric 'double-layer' force arising from the incomplete charge neutralization at the mica$^{\ominus}$–CTA$^{\oplus}$ interface. We have measured how these forces vary with distance for a range of CTAB concentrations in both distilled water and in NaCl and KBr solutions up to 0.1 M and at various *p*H values in the range 5.4–10.4.

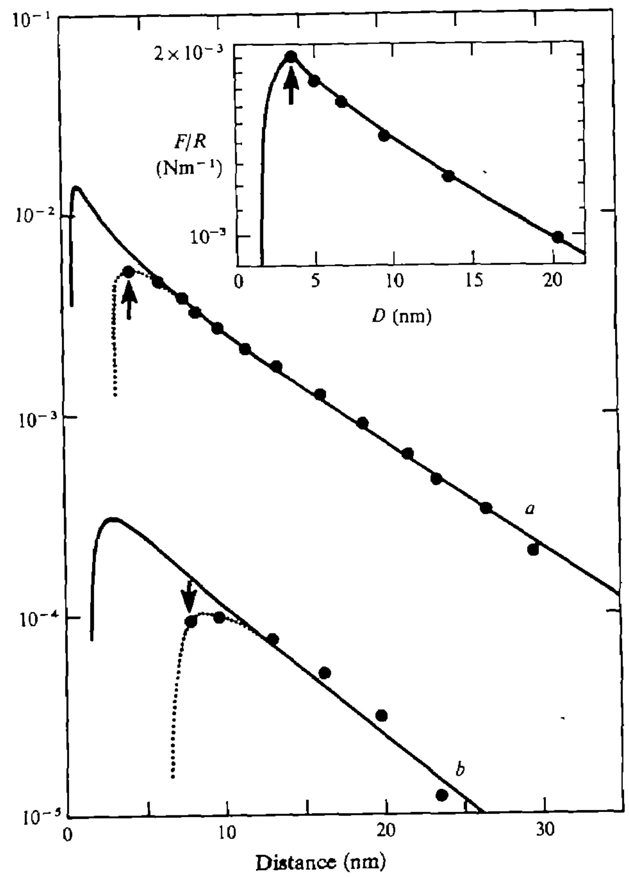

Fig. 1 Measured repulsive force F between two cylindrically curved hydrophobic surfaces (of radii R) as a function of distance D in $\sim10^{-3}$ M NaCl and KBr solutions at 21 °C (plotted as normalized force F/R). The effective surface charge density corresponding to the observed double-layer forces are 1*e* per 5 nm^2 (*a*), and 1*e* per 95 nm^2 (*b*). The solid lines are the theoretical force laws expected from the classical DLVO theory[15,16]. Dotted lines, experiment force laws. Inset: measured force law between uncoated mica surfaces where excellent agreement with the DLVO theory is obtained. Errors in distance measurements are negligible (±0.2 nm); errors in the force are roughly equal to the size of the experimental points, except at smaller distances where the errors are smaller.

0028–0836/82/470341—02$01 00

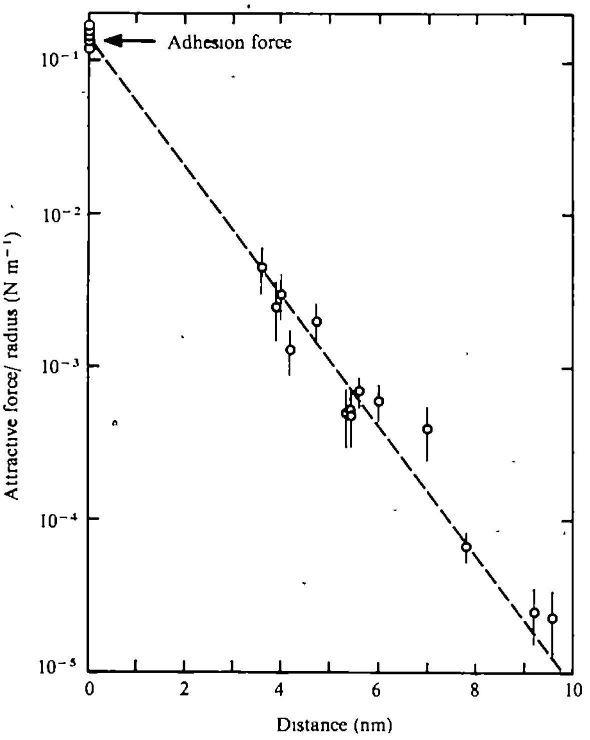

Fig. 2 Attractive force law F_H as a function of distance D as deduced from a wide range of force curves such as those shown in Fig. 1 (and for different values of R between 0.75 and 2.0 cm). Experimental points are obtained from the differences between the measured and theoretical forces in the regions of the observed maxima (arrows in Fig. 1). The hydrophobic interaction decays exponentially out to a separation of about 10 nm, and is given by $F_H/R = 0.14\,e^{-D/1.0}\,N\,m^{-1}$.

Figure 1 shows the measured forces in two instances: high surface charge, and very low surface charge (near the PZC). In each case (and in many others, not shown) the attractive component of the interaction greatly exceeds that expected from the normal van der Waals-dispersion contribution to the total van der Waals + double layer (DLVO) interaction[15,16], which is shown as the solid curves in Fig. 1. This is in marked contrast to similar measurements of forces between uncoated mica surfaces in dilute electrolyte solutions[11,14] where the agreement with the DLVO theory is excellent (Fig. 1 inset).

By subtracting the measured forces from the theoretical curves one can deduce the additional attractive force between the hydrophobic surfaces at different values of D down to the 'force barriers' (arrows in Fig. 1), below which the net force becomes rapidly attractive and the two surfaces jump into monolayer contact at $D = 0$.

The additional attractive (hydrophobic) force is plotted as F_H/R against D in Fig. 2, where we have also included the adhesion or 'pull-off' force at $D = 0$, given by the force needed to separate the two surfaces from adhesive contact. It is apparent that over the distance range 0–10 nm the hydrophobic force-law is well described by an exponential function given by

$$F_H/R = C\,e^{-D/D_0}$$

where $C = 0.14 \pm 0.02\,Nm^{-1}$, and decay length $D_0 = 1.0 \pm 0.1$ nm.

We found that the strength of this interaction is not sensitive to the type and concentration of the electrolyte present, nor to the *p*H. The adhesion force F_H/R at $D = 0$ did, however, increase slightly when the repulsive double-layer forces were weaker, as might be expected. Experiments were also performed with the surfactant concentration progressively diluted to 1/100 of the CMC with no resulting change in the attractive force-law, thus ruling out the possibility that the presence of surfactants is responsible for the extra attraction (through some bridging mechanism involving premicellar aggregates, for example).

The measured attractive force-law is about an order of magnitude larger than the maximum possible van der Waals-dispersion force; and since it decays exponentially with distance rather than as a power law it cannot be attributed to a 'modified' dispersion interaction. It is most likely that this force is the 'hydrophobic interaction'. Although we cannot discuss here all the implications arising from this work or correlate our results with previous experimental and theoretical studies the following three points are notable:

(1) The hydrophobic interaction acts over long-range and cannot be considered as arising from any bond-like association. For two surfaces 50% of the total interaction free energy occurs at distances beyond about two water molecule diameters. The exponential dependence of the interaction has been predicted in recent theories of solvation forces[7,8].

(2) The measured force law given above corresponds to a pair interaction free energy of

$$\begin{aligned}\Delta G_H &= -CRD_0\,e^{-D/D_0}\\ &\approx -84R\,e^{-D/D_0}\,kJ\,mol^{-1}\ (R \text{ in nm})\end{aligned}$$

for two crossed cylinders or for a sphere of radius R near a flat surface, while more generally the value of R above should be replaced by $R_1R_2/(R_1+R_2)$ for two interacting spheres of radii R_1 and R_2. Although there are obvious objections to extrapolating this expression down to molecular radii, it does give surprisingly good values when used to estimate the hydrophobic interaction of small solute molecules in water. Thus for two dissolved methane molecules (hard sphere radius $R = 0.18$ nm)[17–19], two benzene molecules ($R = 0.25$ nm)[17,18], and two cyclohexane molecules ($R = 0.28$ nm)[17,18], the values obtained for the free energy of dimerization ($\Delta G_H \approx -42R$ kJ mol^{-1} at $D = 0$) in each case are $\Delta G_H \approx 7.6$, 10.5 and 11.8 kJ mol^{-1}, respectively, which compare surprisingly well with the various theoretical and experimentally determined values of 7.5–8.8 (refs 5, 6), 8.5–9.6 (refs 9, 20) and 11.3 (ref. 20) kJ mol^{-1}.

(3) The long-range attractive forces measured between surfactant[12] and lipid bilayers[21,22], where both hydrophilic and hydrophobic groups are present at these interfaces, appear to be well described by the van der Waals-dispersion force, suggesting that the hydrophobic interaction is neutralized when the local structure of water molecules is dominated by their interaction with nearby hydrophilic groups.

Oscillatory spreading explanation of anomalously old uplifted crust near oceanic transforms

Enrico Bonatti & Kathleen Crane

Lamont-Doherty Geological Observatory, Columbia University, Palisades, New York 10964, USA

Rocks significantly older than their theoretically predicted age have been recovered in the vicinity of some Atlantic Transform Zones. Rocks of Palaeocene (55–58 Myr) and possibly even of Cretaceous age are found near the Vema Transform, on tectonically uplifted crust which should not be older than 30 Myr. We present here a model which might explain the presence of uplifted, anomalously old crust near the Vema Transform Zone (TZ). The proposed model involves axial rift propagation and reorientation and migration of the transform as a result of a change in the regional stress field. During transform migration a crustal wedge, formerly part of the African plate, is transferred to the South American plate. The ensuing oscillatory spreading can explain the anomalous age of the uplifted crustal block. Compression resulting from rift propagation and transform migration provides a mechanism for crustal uplift.

Two fundamental tenets of the theory of plate tectonics are: (1) the age of the oceanic crust increases with distance from the axis of crustal accretion (the axis of mid-oceanic ridges) where the age is close to zero; and (2) the depth below sea level of the oceanic basement increases proportionally to the square root of the age of the crust, due to cooling and thermal contraction of the oceanic lithosphere during its motion away from the axis of accretion. These two tenets are supported by a wealth of observations obtained from the three major ocean basins. However, exceptions exist. In particular, crustal blocks which have been subjected to intense vertical tectonic movements and reach anomalously shallow depths have been observed in the vicinity of large offset ridge–ridge transform zones in the Atlantic and Indian Oceans[1-3]. Moreover, rocks significantly older than their theoretically predicted age have been reported from the vicinity of some Atlantic transform zones, namely the Atlantis TZ at 29° N (ref. 4), the St Paul TZ to 1° N (ref. 5) and the Vema TZ at 11° N (refs 6–8). No satisfactory explanation has been presented to date, which would reconcile seafloor spreading with the occurrence of old material close to the axis of lithospheric accretion.

The Vema TZ offsets the axis of crustal accretion by ~300 km (Fig. 1). The transform valley is filled with nearly 1 km of sediment; the recent strike-slip transform motion can be traced in the sediment close to the axis of the transform valley[9]. To the south of the transform valley and parallel to it, lies a narrow ridge (transverse ridge) whose summit is shallower than 600 m below sea level[10,11]. The ridge constitutes a major topographic anomaly relative to the predicted depth–age relationship (Fig. 2), and is probably a tectonically uplifted sliver of crust and upper mantle[11,12].

The summit of the uplifted ridge is capped by shallow-water reef limestones, some of which have undergone sub-aereal diagenesis. Palaeofacies studies and age determinations of these limestones indicate that the summit of the uplifted block was above sea level from late Miocene up to middle Pliocene time (from ~10 to 3 Myr BP). It subsequently subsided at an average rate of 0.3 mm yr^{-1}, a rate one order of magnitude faster than predicted by thermal contraction of the plate[8].

Although equatorial magnetic anomalies are not very well developed, they are good enough to estimate spreading rates. Values ranging from 1.1 to 1.4 cm yr^{-1} have been determined from profiles located immediately north of the transform[11,13,14]. Assuming this spreading rate is correct, and that the uplifted crust on the southern side of the transform valley was originally created at the southeastern axial segment of the Mid-Atlantic Ridge, an age of 30–35 Myr can be estimated for the area of maximum uplift on the transverse ridge (Fig. 3). However, deep-sea limestones were recovered from the uplifted block (in addition to the shallow water samples), which have been dated as early Palaeocene (~55–58 Myr BP) on the basis of their fossil plantonic foraminiferal fauna[8]. This anomalously old age is consistent with ages determined from other limestone samples bearing pre-Tertiary fossil crab coprolites of the genus *Parafavreina*[6,7].

It is possible that the anomalously old crust is related to reorientation and migration of the transform in the past. A set of sediment-filled valleys south of, and striking 10°–15° oblique to the Vema Transform (Fig. 1) were identified and interpreted as traces of former transforms by Van Andel *et al.*[11,13]. These fossil transform traces are present only in crust older than ~10 Myr. The different orientation of the former transforms relative to the presently active Vema TZ suggests that a reorientation by 10°–15° of the direction of spreading occurred

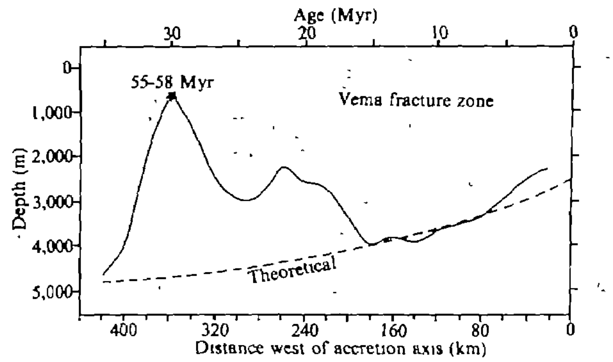

Fig. 2 Topography versus age on a profile immediately south of the Vema Transform valley, compared with the theoretical curve[23] predicted for thermal contraction of the lithosphere. A spreading rate of 1.2 cm yr^{-1} is assumed.

in this area $\sim$10 Myr BP (ref. 13). This reorientation is also suggested by both a change in the trend of the western extension of the Vema fracture zone, and by a corresponding change in strike of the 10-Myr old magnetic anomalies[13].

Based on this information, we propose the following sequence of events to explain the existence of anomalously old and tectonically uplifted crustal blocks along the transform (Fig. 3).

(*a*) Before $\sim$10 Myr ago a ridge–ridge transform zone was active to the south of the present Vema TZ. The strike of the former transform was 10°–15° NW of the present transform strike.

(*b*) A change in spreading direction of 10°–15° occurred, probably related to a reorientation of the lithospheric regional stress field. In response to the changing stress field, the south-east segment of the accretion axis gradually propagated northward. This northward propagation of the axis of spreading might have taken place in a manner similar to that suggested for the Juan de Fuca ridge, the Galapagos rift and the East Pacific Rise[15–18]. According to Fujita and Sleep[19] and Crane and Gallo[20] the magnitude and direction of intraplate stress acting on the ridge–transform system may be the primary cause for the readjustment of a transform and the reorientation of the zone of extension.

(*c*) A new ridge–transform–ridge geometry, similar to that of the present Vema TZ became established $\sim$10 Myr BP.

(*d*) Spreading in an east–west direction has occurred for $\sim$10 Myr. The fossil transform valley can be traced south of the presently active Vema TZ.

We stress that the geometry outlined in the evolutionary scheme of Fig. 3 can be modified without changing the substance of the model. For instance, we have assumed that the change in orientation of the axis of spreading and of the transform pivots around a fixed point at the southern tip of western axis of spreading. This assumption may not be strictly true.

One consequence of the model illustrated by Fig. 3 is that a portion of crust close to the northern side of the former transform boundary moved east-south-east before the reorientation of spreading direction (Fig. 3*a*). After the migration of the transform to the north, this wedge of crust was transferred from the African to the South American plate and thus began to move to the west (Fig. 3*c*, *d*). We refer to this reversal of spreading direction as 'oscillatory spreading', and we suggest that this might explain the presence of anomalously old crust on the southern side of the Vema TZ.

Considering the location and age of the anomalously old rocks, assuming an average spreading rate of 1 cm yr^{-1} or more, and assuming that the present spreading direction became established roughly 10 Myr ago, it follows that the 55–58-Myr old crust cannot be explained simply by one cycle of instantaneous transform reorientation and migration, as depicted in Fig. 3. The simple model of Fig. 3 can explain the 55–58-Myr old crust if there was a transitional period of reorientation and migration of the transform lasting several million years, during which the wedge of crust between the old and the new transform would remain more or less stationary. Alternatively, the anomalous 55–58-Myr old crust might have been involved in more than one stage of migration of the transform by rift propagation. The presence of crust as old as Cretaceous, if confirmed, would support the idea that several transform migration steps have occurred. The existence of at least three fossil transform valleys to the south of the presently active Vema TZ (Fig. 1) suggests indeed that the northward transform migration by rift propagation occurred in more than one step.

The observation that the presently active transform valley is filled by sediments younger than a few million years[11,21] supports a young age for the Vema Transform Valley and is consistent with the suggested model.

Transform reorientation and migration might be responsible also for the vertical tectonic motions which gave rise to the uplifted crust at the Vema TZ. Vertical tectonic movements of crustal blocks can occur in the vicinity of a transform zone due to several distinct processes[12,18,22]. One process would involve small changes in spreading direction, which result either in

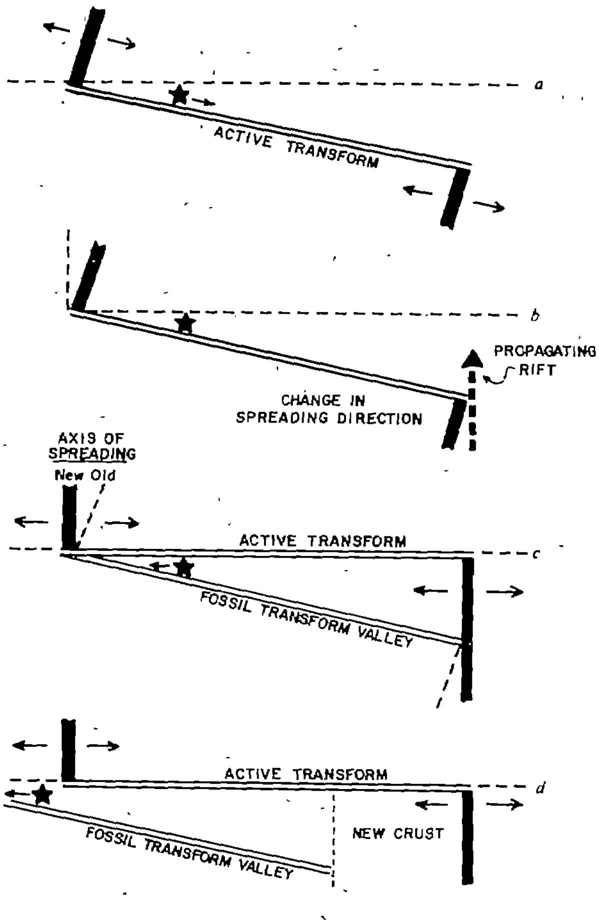

Fig. 3 Proposed model on transform migration and oscillatory spreading. *a*, Former ridge–transform–ridge geometry. Crust at site ★ is part of African plate and moves east-southeast. *b*, A change of 10°–15° in spreading direction occurs. Southern ridge axis starts propagating northward. *c*, Situation 10 Myr ago. Migration and reorientation of transform has taken place. Site ★, now part of South American plate, reverses its motion and starts to move to the west giving rise to oscillatory spreading. *d*, Present situation, site ★ continues to move westward. Fossil transform valley present south of the present transform. To explain the ages obtained from the summit of the uplifted crustal sliver, more than one cycle of transform migration is required. Alternatively a long (several million years) period of transition between stages *a* and *c* is necessary.

compression or extension along the fracture zone. Within our proposed model of rift propagation and transform reorientation and migration, compressional regimes are likely to occur in portions of the crustal wedge situated between the old and the new transform. The wedge should be subjected to maximum compression during the time of transition from the old to the new ridge–transform–ridge geometry (stage *b* in Fig. 3). Crustal uplift might have occurred in response to the compressional regime. Note that the summit of the uplifted block stayed above sea level from at least mid-Miocene (~10 Myr BP) to mid-Pliocene (3 Myr BP) time[8]. These ages are consistent with a model which predicts the subsidence of the block after the present ridge–transform–ridge configuration became established, ~10 Myr BP. Uplift took place before 10 Myr ago.

A possibility to be considered is that a compressional regime develops in front of a propagating rift. In cases where the rift is unable to advance, compressional stresses at its tip may induce vertical movements of the crust. It is possible that during the reorientation of the Vema ridge–transform system, while the south-east axis of accretion was able to propagate northwards, the north-west axis did not propagate to the south but created compression and crustal uplift on its front across the transform. In fact, we note that the uplifted crustal block is located roughly across the transform from the north-west axis of spreading.

A more precise assessment of the processes which led to crustal uplift and presence of anomalously old crust at the Vema TZ may allow us to use the proposed model to explain transform related anomalous ages and vertical tectonics in other areas.

Fault location by radon and mercury detection at an active volcano in Nicaragua

William B. Crenshaw*, Stanley N. Williams† & Richard E. Stoiber

Department of Earth Sciences, Dartmouth College Hanover,
New Hampshire 03755, USA

The Masaya Caldera Complex, Nicaragua, with the active crater, Santiago (Fig. 1), is the site of present-day basaltic volcanism[1,2]. Some of the faults that bound the caldera and lie within it can be located geologically; others are postulated. A possible older caldera rim lies to the south of the present margin. To investigate whether one can identify faults in this environment of active volcanism, concentrations of radon and mercury in the regolith were determined at 232 selected points in and adjacent to the caldera. Higher concentrations of Hg^0 or Rn or both occurred over 75% of the known structures studied. Some hitherto suspected structures were confirmed while others were not. Lack of a chemical signature may be ascribed to the absence of a structure, inappropriate sampling sites, post-fault lava cover or other sealing of the structure. We show here how the use of Rn and Hg^0 determinations has helped in structural analysis at this active volcano.

Radon was detected using α sensitive film enclosed in Track Etch Detector Cups which were buried at 40-cm depth for ~30 days. Analyses of the tracks on the film were performed by the manufacturer. Radon is reported as tracks per mm^2 per 30 days (0.91 tracks per mm^2 per 30 days = 1 pCi l^{-1} for the allyl deglyol carbonate detector used)[3]. Replicate radon analyses indicated a deviation of 10%, similar to the deviation reported by others[4–6].

Mercury was determined, using a gold film mercury detector (Jerome Instrument Corp., Model 301), in the $<0.5\,\phi$ (0.17 mm) size fraction of the regolith collected from 40 cm depth at each of the Rn locations. The 5% deviation indicated by replicate analyses agrees with that of Cox and Cuff[4].

Traverses (Fig. 1) were made[7] approximately perpendicular to known or suspected faults or fissures, and were usually 150–300 m long with 6 or 7 samples per traverse. Seventeen traverses crossed structures for which geological evidence was strong. Sixteen other traverses crossed postulated structures.

In a previous study[5] Rn was successfully used to delineate fault zones in a known geothermal area, but was of different scale (60–150 m cup spacing) and in different terrain than the one described here. A geothermal resources survey on the north rift zone of Haleakala volcano, Hawaii used a 1–1.5 km sample spacing[4]. Significantly elevated Hg^0 and Rn values marked the

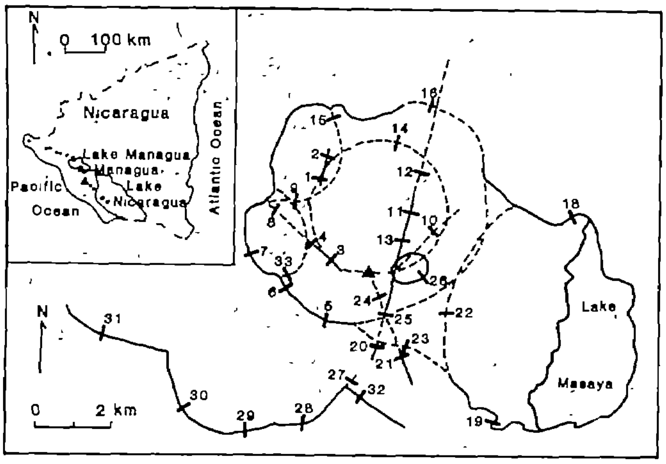

Fig. 1 Partial and simplified map of structures of Masaya Caldera Complex. Solid lines indicate location of faults or fissures known on basis of geology; dashed lines indicate location of postulated faults or fissures; bars indicate location of traverses (not to scale). Numbers of traverses are referred to in text (traverse 17, not shown, lies to north on regional fault). ▲, Location of Santiago crater, site of present-day activity. Inset shows location of Quaternary volcanoes (●) and study area (▲) in Nicaragua.

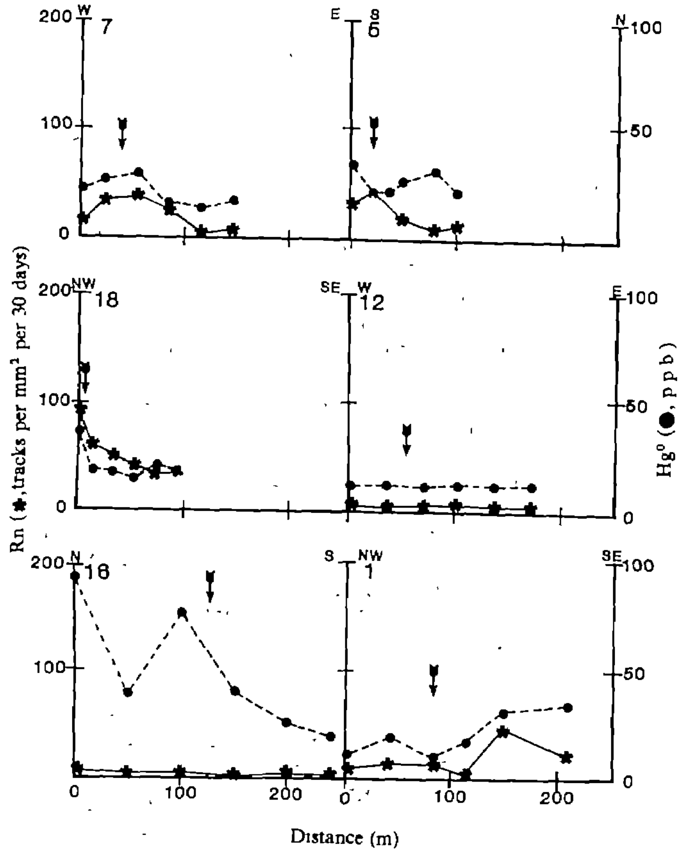

Fig. 2 Rn and Hg^0 signatures from selected traverses (numbers in upper left of each example as in Fig. 1). Arrow indicates location of fault or fissure based on field geology. Individual traverses: 7, Hg^0 and Rn peaks coincide with each other and with projected fault location (caldera fault scarp); 5, Rn and Hg^0 peaks separated by 60 m (caldera fault scarp). 18, Fault probably on the extension of the traverse (caldera fault scarp). 12, Neither Rn or Hg^0 show significant change along traverse (an attempt to locate position of fissure). 16, Hg^0 signature 2 peaks, but no significant Rn peak (hidden caldera fault scarp). 1, Hg^0 peaks and a less marked Rn peak separated by 50 m (an attempt to locate portion of a fissure).

rift zone. The survey reported here examined narrower fault zones and in much greater detail.

Data have been selected from this study to show the variation in Hg^0 and Rn signatures (Fig. 2). Radon and mercury signatures marked the caldera-bounding fault on all traverses across it (5, 6, 7, 16, 18, 19, 23) although detection of two segments where visual expression was lacking (16, 23) was uncertain. The scalloped caldera boundary suggests coalescing collapses rather than a single engulfment[1]. Both Rn and Hg^0 analyses on four of the five traverses crossing presumed locations of such structures (4, 8, 9, 15, 33) indicate that these circular features may exist beneath the covering of recent basaltic lava flows. Circular distribution of active vents in the caldera may outline the trace of a collapse crater[1] but Rn and Hg^0 analyses (3, 14) do not support its existence. A third hypothesis suggests that there may be two overlapping caldera collapse features (J. Garayar, personal communication). The traverse (22) designed to test such a hypothesis did not support its presence. A proto-caldera rim, outside the present scarp, may be represented by a deeply eroded fault scarp. Rn analyses from samples on traverses across this fault (27–32) confirm its presence. Hg^0 analyses were less conclusive. Linear features cross the caldera floor, but prediction of their location, despite surface expression in some instances, met with mixed success. Of 11 traverses across faults or fissures, one (11) failed to indicate a fault, two (4, 25) indicated possible faults and the others (2, 3, 8, 10, 12, 13, 20, and 24) indicated faults in the predicted location. For the 16 traverses over known faults or fissures Rn and Hg^0 both successfully predicted 75% and for the 17 traverses over possible faults Rn successfully predicted 65% and Hg^0 76%.

Radon values (Table 1) are very much larger in areas of well developed soil, as in Hawaii[8], but the ratio of peak to background values is greater in most localities outside the area of well-developed soil. Factors affecting radon concentration include recent lava flows acting as effective barriers to ground gas migration and the fact that the radon content in the tholeiitic lavas is lower than in the more siliceous volcanics in the areas of best soil developed outside the caldera. The high porosity of soils compared with the sparse regolith developed over recent flows allows more effective radon migration and the greater surface area enhances radon emanation. At Masaya Caldera Complex, meaningful measurement of radon in areas of fresh lava flows is feasible, despite the very low peak values.

The Hg^0 content of the fresh lava sampling sites (2, 3, 9, 11–16, 22, 23, 25) (geometric mean of 21.8 p.p.b. (part per 10^9)) is much greater than reported[9] from Icelandic lava, 2–9 p.p.b. Hg^0 data (Table 1) indicate less distinctive populations in the three areas defined by the type of regolith. The ratio of peak to background values is usually smaller in areas of well-developed soil than elsewhere. Secondary soil processes may be important in determining the background variation of Hg^0, as at Long Valley California[10].

Hidden cues in random-line stereograms

H. K. Nishihara & T. Poggio

Artificial Intelligence Laboratory and Department of Psychology,
Massachusetts Institute of Technology,
Cambridge, Massachusetts 02139, USA

Vernier acuity shows that the human visual system can interpolate the relative position of a feature with astonishing precision, of the order of a fraction of the distance between neighbouring photoreceptors in the fovea. The remarkable properties of this interpolation process have been the subject of many recent studies[1–9]. A major question that is still unanswered is whether the process is parallel—operating automatically at all times over a large part of the visual field—or serial—operating selectively at isolated locations only when judgments in the hyperacuity range are required (as in a forced choice task). Successful fusion of random-line stereograms having breaks in the vernier acuity range has been previously interpreted[10] to suggest that the interpolation process underlying hyperacuity is parallel and preliminary to stereomatching. Here we demonstrate with computer experiments that vernier cues are not needed to solve the stereomatching problem posed by these stereograms, and we provide psychophysical evidence that human stereopsis probably does not use vernier cues alone to achieve fusion of these random-line stereograms.

Julesz and Spivack's[10] claim that stereo fusion of their random-line stereograms is based on vernier cues alone is apparently the best evidence for the interpolation process being parallel; Fig. 1*a* shows an example of their random-line stereograms. Figure 2 illustrates by a small 4 × 5 array of picture elements, the way in which Fig. 1*a* was generated. Each picture element contains a thin vertical line segment at one of two possible horizontal positions, separated by one-fifth of the picture element diameter. The random selection of the two positions to make the 4×5 array produces five vertical lines through the array with frequent small horizontal breaks. Once the left array is generated in this way, it is copied into the right array where a rectangular region of picture elements at the centre (dotted lines) is shifted horizontally by an integral number of picture element diameters (here the shift is one picture element). Thus the pattern of breaks is correlated in the left and right arrays with zero disparity around the borders and a fixed horizontal disparity in the central region. Figure 1*a* is the same except that the array has 100 × 100 picture elements and the horizontal shift is two picture elements. Similar patterns can also be made with horizontal line grids. The only obvious monocular information is the pattern of minute horizontal breaks occurring randomly in the thin vertical line grids. The stereograms clearly yield stereopsis—the centre square is seen in front of the surround—even with monocular breaks of as little as 16 arc s, which is below the threshold for resolving two lines. Note that the stereomatching problem posed by this type of stereogram is not solvable by simply measuring the position disparity between nearest line segments in the two arrays of the stereo pair. The correct matches in the central region are shifted horizontally by one or more picture elements so the nearest matches are all false targets. Thus, the matching problem can only be solved by taking into account, in some manner, the pattern of breaks in an area. For this reason Julesz and Spivack[10] argued that it is necessary to detect the vernier breaks and match corresponding ones before stereo fusion.

The key question is whether vernier cues are indeed the only monocular information present in this type of stereogram. It has been suggested to us (H. Barlow and W. Richards, personal communications) that receptive fields—for example, centre-surround ganglion cells—each integrating over angular extents of several arc min might detect coarse monocular structures in such stereograms. If so, this structure alone may be sufficient to drive binocular stereomatching without need of vernier precision. Indeed, a recent theory of human stereo vision[11–14] (see also ref. 15) proposes that the two images are filtered through several, roughly bandpass, channels, each with a different centre-surround receptive field size, and that stereomatching is based mainly on zero-crossings (boundaries between regions of positive and negative response) in each of these channels. Essentially all images (for example, random-dot stereograms) when processed in this way, reveal a clear coarse structure (see for example Fig. 3.6 of ref. 13). When the random-line stereogram of Fig. 1*a* is filtered in the same way, coarse monocular features do appear (Fig. 1*b*). The underlying cause of this coarse structure is the variation in spacing between neighbouring lines. While the absolute changes in spacing are small, the percentage change in the line spacing is appreciable. For the patterns described by Julesz and Spivack, the ratio of smallest to largest line spacing is 2:3. Figure 1*b* shows the locations where a centre-surround operator would give positive (white) and negative (black) responses to the random-line pattern shown in Fig. 1*a*. The coarse structure here is well preserved by the photoreceptor sampling at intervals of 30 arc s. Interpolation between these points to increase spatial precision is unnecessary.

Many matching algorithms can successfully use the monocular features provided by the larger operators to solve the stereo correspondence problem. As an example, Fig. 1*c* shows the output obtained with the cooperative algorithm of Marr and Poggio[16,17] when applied to the binary array shown in Fig. 1*b*. It identifies correctly the different disparities of the centre square and the surrounding background. Essentially the same results are obtained with the other stereomatching algorithms developed in our laboratory, when applied to the same filtered images. Thus these random-line stereograms can be solved without need of vernier precision.

At this point, our computer demonstration shows only that non-vernier, monocular cues are present and could be used for successful stereomatching, but the question remains of whether our visual system actually uses them instead of the vernier cues. Psychophysical experiments can be used to test these hypotheses. We have examined the differences expected between systems relying entirely on one or the other approach. As noted above, the coarse structure shown in Fig. 1*b* is due to the large line spacing variation in the patterns. Increasing the line spacing while maintaining a fixed break size reduces the detectability of coarse structure present in the patterns but does not affect the detectability of the vernier breaks (larger spacings should actually improve vernier acuity[6]).

Figure 3 shows a random-line stereogram having twice the line spacing as shown in Fig. 1, but with the same break size and disparity for the central region. This stereo pair is difficult to fuse when viewed at a distance which gives a vernier break size of about 15 arc s while the pair of Fig. 1*a* can be fused easily at that distance. These patterns were computer-generated on a high-resolution cathode ray tube and viewed stereoscopically from a distance of 4 m at which the size of the vernier breaks was ~15 arc s. We tested four subjects in these conditions and for all of them the stereogram of Fig. 3*a* was much more difficult to fuse than Fig. 1*a*; this is consistent with the computer simulations (compare Fig. 1*c* with Fig. 3*c*).

Other psychophysical observations, though less critical, are also consistent with the large channel hypothesis. For example, we expect that (1) random-line stereograms could be fused for very small break sizes if line spacings were made proportionally smaller—fusion would eventually be limited by the loss of contrast as the receptive field extends across more than several

0028–0836/82/470347—03$01 00

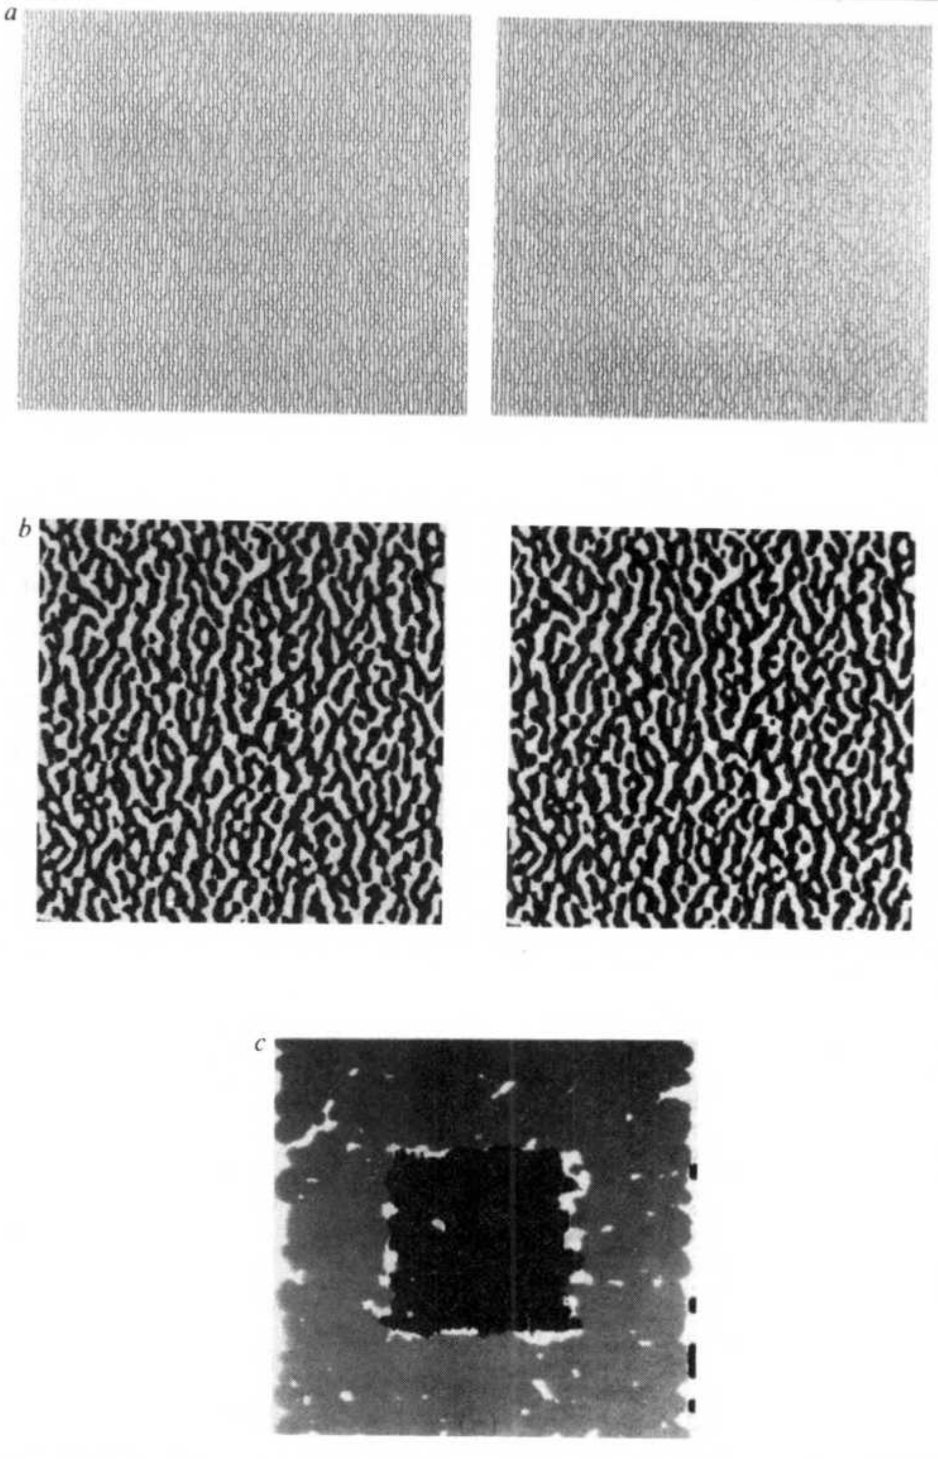

Fig. 1 *a*, Random-line stereograms of thin vertical line segments with small breaks, portraying a centre square in front of the surround. When the patterns as printed here are viewed at 1.4 m, the vernier breaks are ~15 arc s and the minimum line spacing is 1 arc min (the spacing and the diameter of the cones in the human fovea is ~30 arc s). The central square has a disparity relative to the background of 10 times the break size. *b*, The stereogram of *a* filtered through a centre-surround operator consisting of the difference of two gaussians (DOG)[19]. The width of the operator's centre is 16 times the break size in *a*. When *a* is viewed from a distance making the break size 15 arc s, this corresponds to what a filter with a 4-arc min centre would compute—a medium-sized channel as revealed by psychophysical experiments[11,20,21]. Positive values are shown as white and negative as black; white (black) values would then represent the activity of the corresponding ON (OFF) centre-surround ganglion cells. The patterns in *a* were first convolved with a gaussian ($\sigma = 20$ arc s) to simulate the optics of the eye; this result was then sampled at intervals of 30 arc s before convolution with the DOG operator. *c*, The result of applying the stereomatching algorithm of Marr and Poggio[16] (see legend of Fig. 3*c*) to the (binary) array shown in *b*. The grey levels here indicate the disparity of the matches obtained by the algorithm after five iterations, black corresponding to +6 pixels disparity (+3 arc min), and zero disparity appears as grey. White indicates non-matched pixels. The algorithm successfully extracts the correct disparity information without need of vernier interpolation.

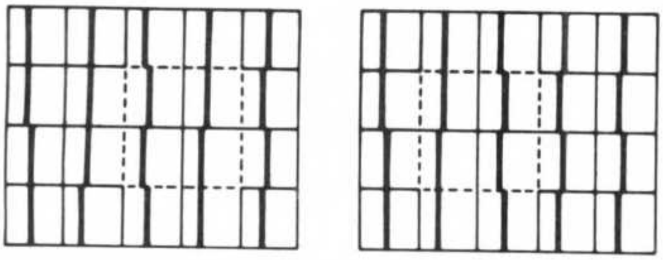

Fig. 2 Method by which the stereogram of Fig. 1*a* was generated (from Julesz and Spivack[10]).

lines; and (2) the disparity limit should be larger for horizontal random-line patterns. The regions of positive response in Fig. 1*b* are elongated slightly in the direction of the lines. This gives a larger average horizontal distance between vertical zero-crossings for the case of horizontal random-line patterns, and thus larger disparities can be viewed without confusion from false targets. Julesz and Spivack[10] report both phenomena: fusion continuing weakly with break sizes beyond the threshold for vernier acuity, and larger disparity range for horizontal patterns.

Thus, our computational experiments establish that the stereomatching problem posed by the random-line stereograms can be solved without vernier interpolation, while the psychophysical data suggest that human perception of these

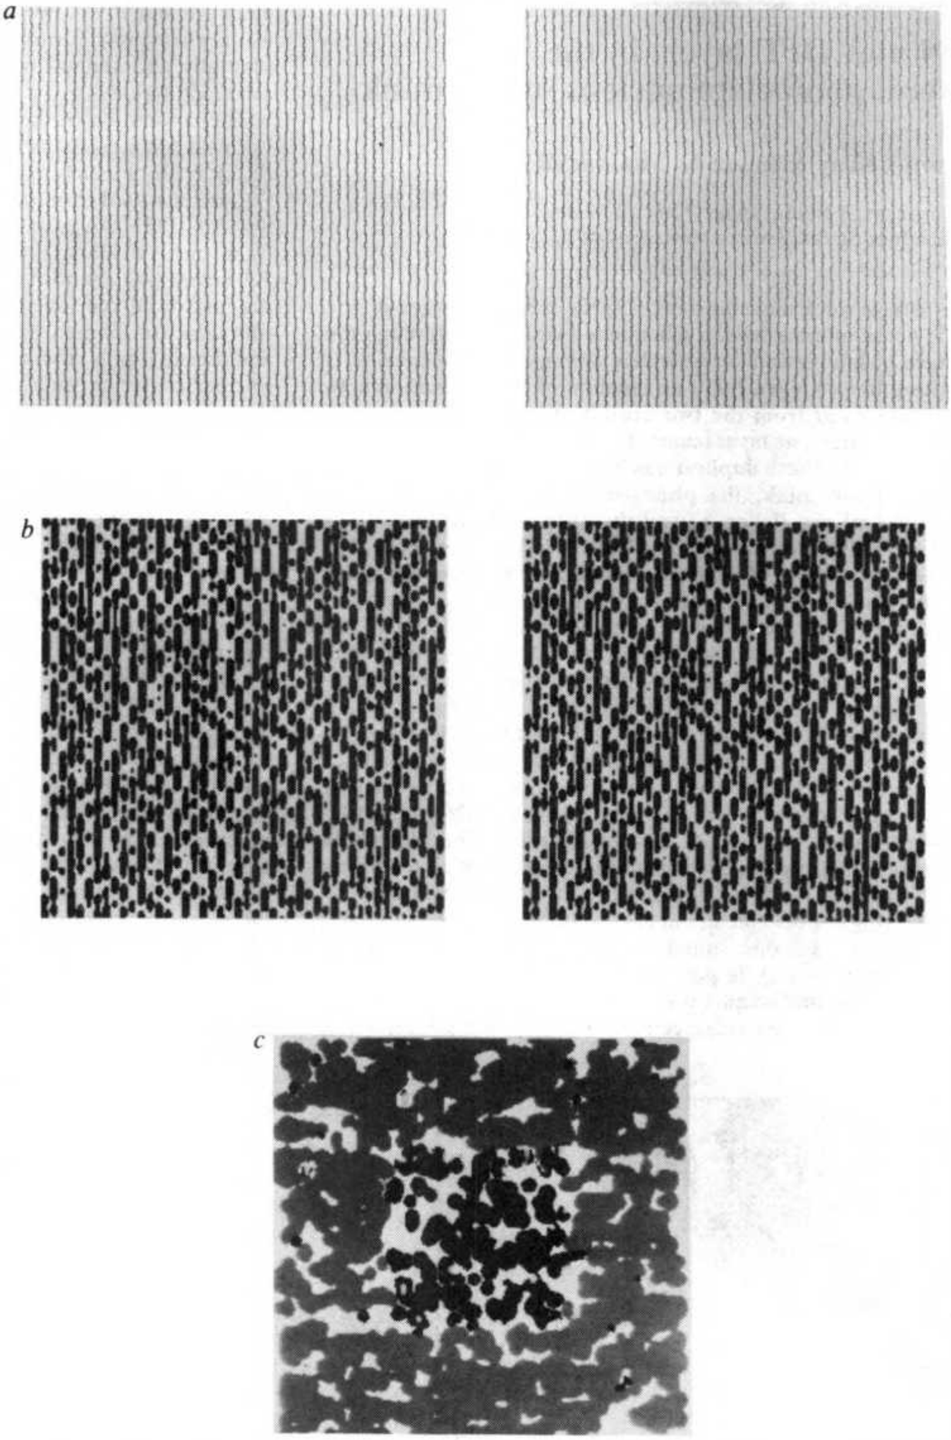

Fig. 3 *a*, A random-line stereogram with the same break size as in Fig. 1*a* but twice the line spacing. The disparity of the central square is the same as in fig. 1. *b*, The sign of the convolution of *a* with a centre-surround operator as in Fig. 1*b*. The vertical line grid in *a* dominates the coarse structure shown here; there is much less effect from the variation in line spacing due to the pattern of breaks. *c*, The result of applying the stereomatching algorithm to the array of 3*b* after five iterations. No match is obtained (white regions) over a larger portion of the array compared with Fig. 1*c*. The algorithm used here, as in Fig. 1*c*, is the cooperative algorithm of Marr and Poggio[16,17] operating on the sign of the stereo images after convolution with a DOG mask. Parameters are the same as described in ref. 16. The network corresponding to the algorithm is loaded by an 'and' operation on the 'binarized' convolved images. In this way the cooperative algorithm originally described for random-dot stereograms can be successfully used on stereo pairs of natural images, at several different resolutions (set by the size of the DOG mask). In Fig. 1*c* and 3*c* we have used seven disparity layers covering a total disparity range of ±7 pixels. We have run the algorithm with different disparity ranges and also with rather different parameters, obtaining similar results.

stereograms does not rely on vernier acuity cues. The reason for this is that the elegant random-dot and random-line stereograms of Julesz[18] and Julesz and Spivack[10], when appropriately processed, exhibit otherwise hidden cues that simplify the stereomatching problem. (The same cues may have a significant role in human stereo vision of natural images.) The stereograms therefore cannot be used to support the hypothesis that the detection of vernier breaks is computed in parallel and made available to other later processes.

ON and OFF layers in the lateral geniculate nucleus of the mink

Simon LeVay & Susan K. McConnell

Department of Neurobiology, Harvard Medical School,
25 Shattuck Street, Boston, Massachusetts 02115, USA

The lateral geniculate nucleus (LGN), a major target of the optic nerve in mammals, is a laminated structure, although the pattern of lamination varies widely among different species. It has long been known that one function of the lamination is to segregate input from the two eyes. Many animals, however, have more than one layer innervated by each eye; the functional significance of these duplications has been only partially elucidated. In the mink, the principal layers innervated by the contralateral eye (layer A) and the ipsilateral eye (layer A1) are each split into two adjacent leaflets[1]. We report here that the anterior leaflet of each pair contains ON-centre neurones and the posterior leaflets OFF-centre neurones.

Extracellular recordings were made from the LGN of six adult male minks (*Mustela vison*) of the brown-eyed pastel variety. The minks were anaesthetized with pentobarbital, paralysed with galamine triethiodide and mechanically respirated. The corneas were protected either with 84-D contact lenses or with silicone fluid. Standard electrophysiological techniques were used[2]. Tungsten electrodes (tip impedance 10 MΩ at 1 kHz) were lowered vertically through the LGN, and visual responses were assessed at 50-μm intervals. The electrodes permitted the isolation of single units (at ~40% of all recording sites) and also recorded rich multi-unit activity. Stimuli consisted of light spots and annuli for the study of centre-surround organization. In one animal, counterphased square wave gratings (0.5 or 1 cycle per deg) were also used to assess the linearity of spatial summation within receptive fields. Points of interest were marked with electrolytic lesions (3–5 μA for 3–5 s, electrode negative). At the end of the experiment, the animal was perfused with formol–saline. The LGN was sectioned parasagittally and stained with cresyl violet for reconstruction of electrode tracks.

The lamination of the mink LGN is illustrated in Fig. 1*a*, *b*. Its most striking feature is the pair of A laminae (A_{ant} and A_{post}), both of which receive input from the contralateral eye[1]. A_{ant} is separated from the optic radiation by the perigeniculate nucleus (PGN). A_{ant} and A_{post} are separated from each other by a thin cell-sparse zone. Behind the A laminae lie the two A1 layers ($A1_{ant}$ and $A1_{post}$), both of which are innervated by the ipsilateral eye. The A1 laminae differ from the A layers in that they are thinner, less clearly separated from one another, and occupy only the ventromedial portion of the nucleus. Further posterior are a thin magnocellular layer innervated by the contralateral eye (C_m), and at least two parvocellular C layers (C_p). Aside from the sublamination of the A and A1 layers and the large size of the monocular segment, the mink LGN resembles that of the cat[3].

Because of the curvature of the layers, an electrode driven vertically through the LGN will pass obliquely or tangentially through several or all of the layers. One such penetration is illustrated in Fig. 1*a*, *b*. In the C layers, mixed ON- and OFF-centre responses were obtained on stimulation of the contralateral eye. In the A sublaminae, cells were also driven by the contralateral eye, but ON-centre responses were confined to A_{ant} and OFF-centre to A_{post}. The transitions between ON- and OFF-centre responses were quite abrupt: one point of transition from ON- to OFF-centre activity was marked by a lesion (L1 in Fig. 1*b*). The lesion was centred on the cell-sparse zone between A_{ant} and A_{post}. A similar functional pattern was revealed in the A1 sublaminae, with the difference that the cells were driven by the ipsilateral eye. Again, ON-centre activity was confined to the anterior leaflet of the pair and OFF-centre responses to the posterior leaflet. A lesion was placed at the ON/OFF transition point (L2 in Fig. 1*b*). Histologically, the subdivision of layer A1 was not as distinct as that of layer A; nevertheless, the lesion lay squarely in the middle of the layer.

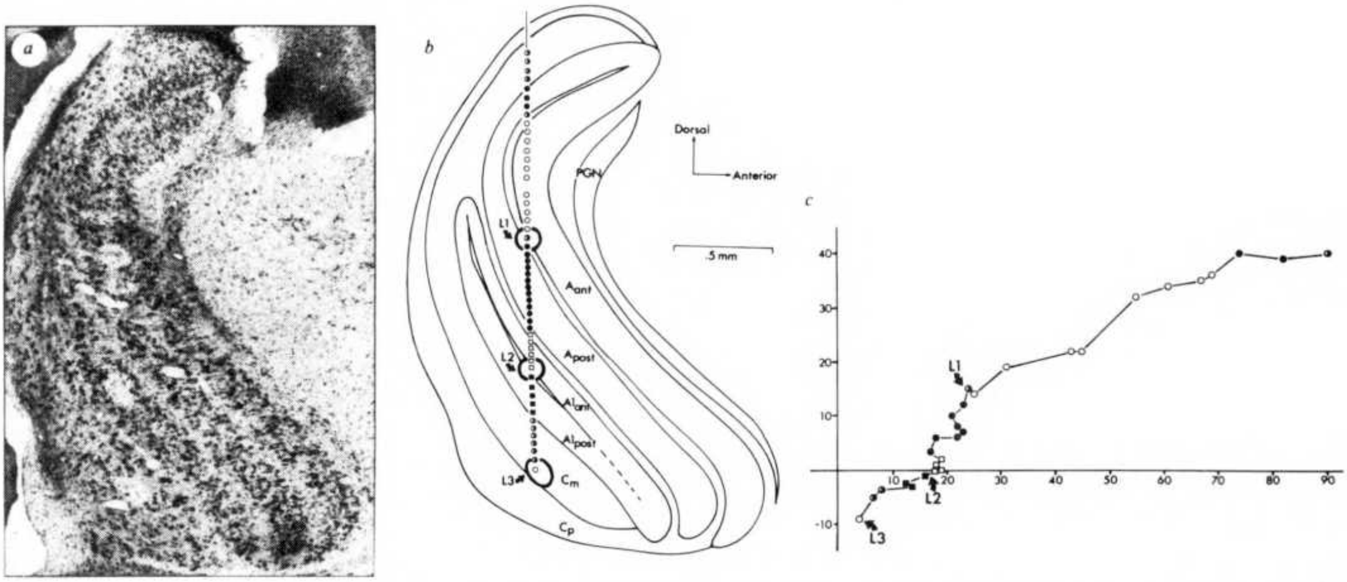

Fig. 1 Reconstruction of an electrode penetration through the left LGN of a mink. *a*, Parasagittal section (anterior to the right) stained with cresyl violet. Three electrolytic lesions made during the penetration are visible as pale spots. *b*, Key to *a*, showing the outlines of the layers, the positions of the three lesions (L1, L2, L3) and the responses obtained at 50-μm intervals along the track (intervals were corrected for differential shrinkage). Circles indicate responses to the contralateral eye and squares to the ipsilateral eye. Open symbols indicate ON-centre responses, filled symbols indicate OFF-centre responses, and half-filled symbols indicate mixed responses. The first two lesions (L1 and L2) mark transitions from ON-centre to OFF-centre responses, and lie between the anterior and posterior leaflets of layers A and A1 respectively. The third lesion (L3) marks the end of the penetration. *c*, Progression of receptive fields across the contralateral (right) visual field, for the penetration illustrated in *a*, *b*. The axes represent the vertical and horizontal meridians. Symbols as in *b*. Each symbol is placed at the centre of the unitary or multi-unit activity recorded at a single site. Only those recording sites that gave distinct shifts in receptive field position are indicated. Fields moved downwards and medially during the penetration.

0028-0836/82/470350—02$01.00

Table 1 Laminar distribution of ON- and OFF-centre responses in the mink LGN

	A_{ant}	A_{post}	$A1_{ant}$	$A1_{post}$	C
ON-centre	107 (100%)	0	23 (96%)	1 (7%)	24 (38%)
OFF-centre	0	62 (97%)	1 (4%)	14 (93%)	9 (14%)
Mixed	0	2 (3%)	0	0	30 (48%)

Responses at 210 recording sites in 14 penetrations are pooled The electrodes were advanced in 50-µm steps; a step was counted as a recording site if· (1) there was a distinct shift in receptive field position from the previous site, and (2) the laminar location of the site was subsequently determined histologically The anterior leaflets of layers A and A1 contained predominantly ON-centre responses, the posterior leaflets OFF-centre responses, and the C layers mixed responses.

Results obtained from a further 13 penetrations in 6 animals corroborated this pattern of organization (Table 1). ON-centre responses (both single unit and multi-unit activity) were found in the anterior leaflets of A and A1 and OFF-centre responses in the posterior leaflets. This was true for both the binocular and monocular portions of the LGN. Exceptions to this pattern were found at only 4 recording sites out of a total of 210 sites in these layers. Eight ON/OFF transitions were marked with lesions; in each case, the lesion lay between the anterior and posterior leaflets of A or A1. In the C layers, on the other hand, mixed responses predominated, although we twice encountered sequences of pure ON-centre responses and must therefore leave open the possibility of some functional segregation.

Because a vertical penetration through the LGN passed roughly parallel to the layers, receptive field positions traversed a wide extent of the visual field map (Fig. 1*c*). Starting at the far periphery of the contralateral field at a high elevation, fields progressed downwards and medially, and ended near the vertical meridian in the lower quadrant. We have not examined the layout of the visual field map in detail, but it seems to resemble that seen in the posterior upturned portion of the cat LGN[4].

Aside from the segregation of ON- and OFF-centre responses, receptive field properties of cells in the mink LGN also resembled those seen in the cat[5,6]. Most cells in the A and A1 layers exhibited a typical centre-surround organization. They responded optimally to the onset or offset of a small light spot (1–2.5 deg diameter); increasing the spot size diminished the response but never reversed its sign. Responses of opposite sign could be obtained by stimulating the surround with annuli. No colour-coded responses were found when cells in layers A and A1 were tested with red, green or blue spots and annuli. In one animal, we tested 19 units in the A and A1 layers for linearity of spatial summation using a counterphased square wave grating. For some of these cells we could find a null position of the grating; others had no null position, but showed a frequency doubling[7]. Our findings suggest that, as in the cat[6], X- and Y-like cells are intermingled in layers A and A1. We did not examine the properties of layer C cells in detail.

Our results demonstrate that the laminar organization of the mink LGN has a clear functional significance, serving to segregate cells not only by eye preference but also on the basis of ON- or OFF-centre responses. The pattern of lamination in the LGN varies considerably among mammalian species. Available physiological evidence suggests that the layers may separate different aspects of visual information in different ways. For example, the mink and cat do not seem to segregate X- and Y-like cells sharply, but such a segregation has been reported for the monkey[8], tree shrew[9] and bush baby[10]. ON/OFF segregation has been reported for the tree shrew[9], while the macaque monkey appears to segregate ON- and OFF-centre units to some degree[11]. Among carnivores, the cat mixes ON- and OFF-centre cells within each layer, whereas recent work on the ferret (K. Zahs and M. P. Stryker, personal communication), a close relative of the mink, suggests an organization similar to that found in the present study.

One function of laminar specialization in the LGN may be to preserve the separation of functional channels up to the cortical level. Segregation of ON- and OFF-centre channels is already evident in the stratification of ganglion cell dendrites in the inner plexiform layer of the retina[12]. Because it is thought that ON- and OFF-centre geniculate neurones are driven by retinal ganglion cells of the same sign[5], it seems likely that axon terminals of ganglion cells terminate selectively in the appropriate leaflets of layers A or A1 in the mink LGN. Anatomical studies in several species have shown that individual layers of the LGN may project differentially to visual cortex: their terminals may occupy separate columns or layers[13,14]. It would be interesting to examine whether the ON and OFF sublaminae of the mink LGN also project differentially to visual cortex.

Another possibility is that laminar segregation permits separate modulation of different channels of visual information. Transmission of information through the LGN is under the influence of reticular, corticofugal and intrageniculate systems[15,16]. The segregation of ON- and OFF-centre channels into separate layers may facilitate their independent modulation, but the advantage to the mink of such an arrangement is unclear.

We thank R. Leibowitz for histological assistance, D. Hubel, T. Wiesel and T. Sejnowski for comments on the manuscript, and W. Budd for providing toothless minks. This work was supported by NIH grant EY-R01-1960 and NSF grant SPI81–66337.

Na^+–K^+–Cl^- co-transport in the intestine of a marine teleost

Mark W. Musch*, Stephanie A. Orellana*, Leigh S. Kimberg*, Michael Field*, Dan R. Halm†, Edward J. Krasny Jr† & Raymond A. Frizzell†

† Department of Physiology and Biophysics, University of Alabama, Birmingham, Alabama 35254, USA

A key element in the absorption of salt and water by various epithelia is the presence, in the apical or brush border membrane, of a mechanism for directly coupling the inward movements of Na^+ and Cl^- (ref. 1). In this way the downhill gradient for Na^+ from lumen to cell, which is maintained by the cell's Na^+/K^+ pump, can provide the energy for cellular accumulation and transepithelial transport of Cl^-. A requirement for K^+ at the serosal surface of the epithelium has long been accepted as essential to the operation of the Na^+/K^+ pump and therefore to salt absorption. Until very recently, however, the effect of luminal K^+ on NaCl absorption has not been explored. We show here that luminal K^+ stimulates NaCl absorption in the intestine of a marine teleost, the winter flounder,

***Pseudopleuronectes americanus.* Furthermore, K^+ uptake across the brush border membrane depends on the presence of both Na^+ and Cl^- in the bathing medium and is inhibited by furosemide, which also inhibits the coupled uptake of Na^+ and Cl^- (ref. 2). Thus, flounder intestine seems to have a Na^+–K^+–Cl^- co-transport system similar to that demonstrated in erythrocytes[3–5], cultured tumour cells[6], cultured kidney cells[7] and squid giant axon[8]. Electrophysiological studies of the thick ascending limb of Henlé's loop in mammalian kidney[9] and the diluting segment in amphibian kidney[10] also indicate that luminal K^+ is required for salt absorption. Co-transport of Na^+, K^+ and Cl^- may therefore be characteristic of a variety of cells and tissues, including salt-absorbing epithelia.**

Flounder intestine is morphologically less heterogeneous than the intestines of higher vertebrates; in particular, it contains no crypts[11]. (Possibly for this reason, it cannot be stimulated to secrete NaCl and water[12], differing in this respect from avian and mammalian intestine, both of which possess crypts.) In short-circuit conditions and in normal Ringer's solution containing 5 mM K^+, flounder intestine absorbs both Na^+ and Cl^- (ref. 11); neither is absorbed, however, in the absence of the other[11]. The site of direct coupling between Na^+ and Cl^- movements is the brush border membrane, and the coupling ratio is close to 1 : 1 (ref. 2).

We have examined the effect of a K^+-free luminal medium on Cl^- fluxes and the effects of ion substitutions, furosemide, bumetanide and Ba^{2+} on both K^+ fluxes and the electrical potential difference across the apical membrane (Ψ_a). Unidirectional and net transepithelial ion fluxes and initial rates of uptake from the luminal solution into the epithelium (unidirectional influxes) were measured using radioisotopes as described previously[2,11]. Conventional voltage-sensing microelectrodes were used to determine Ψ_a (ref. 13). K^+ transport was evaluated by measuring ^{86}Rb fluxes in tissues preincubated in K^+-free, Rb-containing Ringer's. Preliminary studies indicated that transepithelial fluxes of 5 mM ^{42}K and ^{86}Rb across flounder intestine are identical and that the transepithelial potential difference (Ψ_t), short-circuit current (I_{sc}) and Ψ_a are equally well maintained whether Rb-Ringer's or K^+-Ringer's is used[14,15].

Table 1 shows the effects of Ba^{2+} and furosemide on transepithelial Rb fluxes. In their absence, short-circuited flounder intestine secretes Rb; This seems to be due to active uptake across the basolateral membrane by the Na^+–K^+ pump and diffusional exit across the apical membrane[13]. When Ba^{2+} is added to the luminal bathing medium, the direction of Rb transport reverses from secretion to absorption. Consistent with its effect on K^+ channels in several epithelia[16–18], Ba^{2+} blocks an apical membrane K^+ channel in flounder intestine[14,15]. When furosemide is then added to the luminal bathing medium, the Ba^{2+}-stimulated Rb absorption ceases.

Table 2 demonstrates that this inhibitory action of furosemide is exerted on a K^+ uptake process in the brush border membrane. Other characteristics of this process are also shown in Table 2: (1) Rb influx is reduced by 80% by furosemide so that, at most, 20% is paracellular. (2) Cl^- removal reduces Rb influx to the same level as does furosemide. (3) Na^+ removal reduces Rb influx to the same level as does Cl^- removal. (4) Rb influx is 6–10 times greater than the unidirectional transepithelial Rb flux from mucosa→serosa, suggesting that K^+ transport across the basolateral membrane is normally rate-limiting in transepithelial K^+ absorption. (5) Ba^{2+}, despite its profound effect on transepithelial Rb fluxes, has no discernible effect on Rb influx. This surprising observation suggests that ^{86}Rb entry into the cell via the apical membrane K^+ channel is normally small. This channel, therefore, seems to strongly rectify Rb movements. Similar rectification of K^+ transport has been demonstrated in turtle colon[19] and in excitable tissues[20].

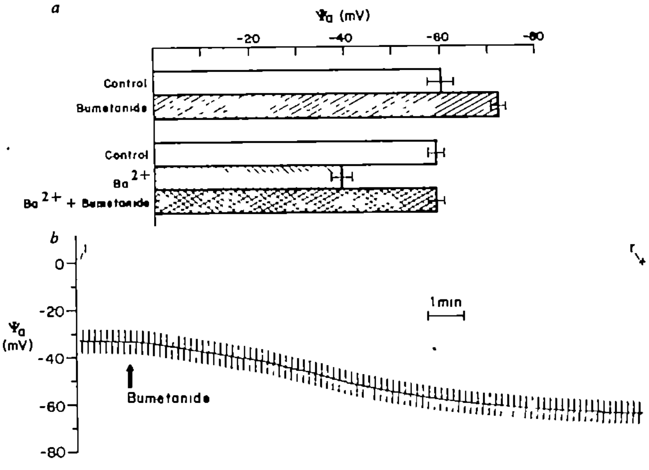

Fig. 1 Effect of bumetanide on the electrical potential difference across the apical membrane (Ψ_a). *a*, Bumetanide (10^{-4} M) was added to the mucosal solution in the presence ($n = 14$) or absence ($n = 8$) of mucosal Ba^{2+} (2.0 mM). Brackets indicate ±1 s.e. Note the depolarization of Ψ_a by Ba^{2+}, due to blockage of apical K^+ conductance, and hyperpolarization of Ψ_a by bumetanide in the presence or absence of Ba^{2+}. Similar results were obtained with Cl^--free mucosal solutions (see text). At least four separate recordings of Ψ_a were obtained in each experimental condition, for each tissue. *b*, Single recording of Ψ_a obtained in the presence of mucosal Ba^{2+} (2.0 mM) showing the hyperpolarization induced by addition of bumetanide (arrow) to the mucosal solution. i, Impalement of cell; r, electrode retracted. The deflections in Ψ_a result from passage of bipolar, constant-current pulses across the tissue for determination of fractional apical membrane resistance.

The data in Table 2 suggest that K^+ influx across the brush border is linked to the influxes of both Na^+ and Cl^-. To determine the influence of luminal K^+ on Cl^- transport, transepithelial Cl^- fluxes and Cl^- influxes were measured in the presence and absence of luminal K^+ (Table 3). Removing luminal K^+ (with serosal K^+ maintained at 5 mM) reduced net Cl^- flux by 60% (Table 3*a*) and also reduced Cl^- influx (Table 3*b*); indeed, the furosemide-sensitive portion of the Cl^- influx was reduced by 70%. Although not directly measured, Na^+ influx is almost certainly also reduced by removing K^+ from the lumen as K^+ influx requires luminal Na^+ (Table 2) and because furosemide reduces Na^+ influxes[2] as well as Cl^- and K^+ influxes. The furosemide-inhibitable Cl^- influx remaining

Table 1 Effects of luminal Ba^{2+} and furosemide on transepithelial Rb fluxes across short-circuited flounder intestinal mucosa

	J_{ms}	J_{sm}	J_{net}	I_{sc}	G
Control (9)	0.34±0.05	1.04±0.09	−0.70±0.09	−3.58±0.22	26.5±1.1
Ba^{2+} (9)	1.09±0.10	0.48±0.10	+0.63±0.09	−0.82±0.26	21.2±1.8
Ba^{2+}+furosemide (4)	0.50±0.02	0.48±0.06	+0.02±0.08	−0.21±0.38	23.8±2.2

Values shown are mean±s.e. for (n) experiments. J_{ms} and J_{sm} are unidirectional fluxes from mucosa (m)→serosa (s) and s→m respectively; $J_{net} = J_{ms} - J_{sm}$. Rb fluxes and short-circuit current (I_{sc}) are in μequiv. h^{-1} cm^{-2} and conductances (G) in mS cm^{-2}. Intestine stripped of muscularis and mounted in chambers was bathed in K^+-free, Rb-containing Ringer's. The medium was buffered to pH 8.0 with 5 mM N-2-hydroxyethyl piperazine sulphonic acid and also contained (in mM): NaCl, 170; $RbNO_3$, 5; $CaCl_2$, 1.25; $MgCl_2$, 1.1; Na_2HPO_4, 3; D-glucose, 20. It was maintained at 15 °C and continuously bubbled with room air. Flux measurements were begun 45–60 min after adding ^{86}Rb and 15 min after adding Ba^{2+} (to 5 mM) or furosemide (to 0.4 mM) to the luminal side.

Table 2 Effects of furosemide, Ba^{2+} and Cl^- and Na^+ replacements on lumen-to-epithelium influx of Rb

	Rb influx, μequiv. h^{-1} cm^{-2}	
	−Furosemide	+Furosemide
Effect of Ba^{2+}(4)		
Control	2.13±0.32	0.48±0.16
Ba^{2+}	2.39±0.27	0.38±0.06
Effect of Cl^- replacement (4)		
Control	3.30±0.18	0.70±0.12
Cl^--free	0.64±0.09	0.71±0.15
Effect of Na^+ replacement (8)		
Control	2.80±0.24	–
Na^+-free	0.69±0.12	–

Values shown are ± 1 s.e. for (n) experiments. Control tissues were preincubated in the Rb-containing Ringer's solution described in Table 1. Where indicated, Cl^- was replaced by gluconate and Na^+ by either N-methyl-D-glucamine or tetraethylammonium. After 60 min, ^{86}Rb was added and its influx determined over 90 s (Rb uptake is linear with time for at least 120 s). Tissues were short-circulated during the influx measurements The influx technique is described in detail elsewhere[2]. Ba^{2+} (to 5 mM) and furosemide (to 0.4 mM) were added to the luminal side 15–20 min before adding ^{86}Rb.

after K^+ removal from the luminal bathing medium may result from the persistence of small amounts of K^+ in the unstirred layer at the brush border surface, as the enterocytes normally secrete K^+.

The coupling stoichiometry of the brush border Na^+–K^+–Cl^- co-transport process remains to be accurately determined. Tables 2 and 3b suggest more than one Cl^- per K^+. Our previous determinations of furosemide-inhibitable Na^+ and Cl^- influxes yield a coupling ratio (±1 s.e.) of 1.3±0.4 Na^+ per Cl^-, which does not differ significantly from 1 : 1 (ref. 2). These estimates of transport stoichiometry, although admittedly inexact, suggest that in flounder intestine the brush border co-transport process is electrogenic, translocating more cations than anions.

Transport-related changes in Ψ_a are consistent with these kinetic data. Inhibition of transport by addition of the furosemide analogue, bumetanide, hyperpolarized Ψ_a by 12 ± 2 mV (Fig. 1a). Similarly, complete replacement of luminal Cl^- with gluconate hyperpolarized Ψ_a by 14 ± 5 mV ($n = 3$). Cl^- replacement would be expected to depolarize Ψ_a if significant Cl^- conductance were present in the apical membrane. Finally, complete replacement of luminal Na^+ with N-methyl-D-glucamine hyperpolarized Ψ_a by 15 mV (mean of two experiments). All these changes are consistent with inhibition of a positively charged co-transporter. Similar hyperpolarizations have been reported for two other epithelia exhibiting K^+-dependent NaCl co-transport: the thick ascending limb of Henle's loop in mammalian kidney[9] and the diluting segment in amphibian kidney[10].

Table 3 Dependence of Cl^- fluxes on luminal K^+

a Transepithelial fluxes (9)

$[K^+]_m$	J_{ms}	J_{sm}	J_{net}	I_{sc}
5 mM	6.17±0.48	2.63±0.33	3.54±0.32	−1.78±0.16
0	3.93±0.62*	2.49±0.44	1.44±0.56*	−0.93±0.10*

b Influxes (9)

$[K^+]_m$	−Furosemide	+Furosemide	Δ
5.mM	15.83±2.09	8.20±1.75	7.63±0.80
0	12.24±1.29†	9.97±1.42	2.27±0.56†

Values shown are mean μequiv h^{-1} cm^{-2} ± 1 s.e. for (n) experiments. The medium was the same as that described in Table 1 except that KCl replaced $RbNO_3$. Serosal K^+ concentration was always 5 mM. $[K^+]_m$, luminal K^+ concentration. The net Cl^- flux in a is about one-third less than that usually measured [2,11,12]. Cl^- influx was measured with ^{36}Cl over 35 s. Furosemide was added (to 0.4 mM) to the luminal side 15 min before influx measurements. See Tables 1 and 2 for further details. Less than control: * $P < 0.05$; † $P < 0.01$.

The hyperpolarization of Ψ_a observed with inhibition of co-transport was even larger in the presence of Ba^{2+}. Addition of Ba^{2+} to the luminal solution depolarized Ψ_a (Figure 1a) and increased the fractional apical membrane resistance ($\Delta\Psi_a/\Delta\Psi_t$ in response to constant current pulses) from 0.19±0.02 to 0.61±0.03 ($P < 0.01$; $n = 25$). This is consistent with the inhibitory effect of Ba^{2+} on apical membrane K^+ conductance[14]. In the presence of Ba^{2+}, Ψ_a hyperpolarized by 20±2 mV when bumetanide was added (Fig. 1a) and by 21±4 mV when Cl^- was replaced by gluconate ($n = 4$). Figure 1b shows the time course ($t_{1/2} = 5$ min) of the bumetanide-induced hyperpolarization. The time required for bumetanide to block the brush border co-transporter is unknown. Since the apical K^+ conductance channel is parallel to the co-transport pathway, Ba^{2+} would be expected to magnify the effect on Ψ_a of blocking an electrogenic co-transporter. The hyperpolarization of Ψ_a was probably not due to changes in cellular K^+ or Cl^- activities that might have resulted from inhibition of co-transport as hyperpolarization persisted when apical membrane K^+ conductance was blocked by Ba^{2+} and because significant basolateral membrane K^+ or Cl^- conductances have not been detected in ion replacement studies[14]. However, the possibility that there is an obligatory inverse relationship between apical membrane K^+ conductance and co-transport rate cannot be excluded. Additional studies are needed to define whether the epithelial co-transport process (in contrast to that of avian erythrocytes[5]) is affected by changes in membrane potential.

The results presented here suggest that what was initially conceived to be an epithelial membrane Na^+–Cl^- co-transport is in fact a Na^+–K^+–Cl^- co-transport; the involvement of this triple co-transport in cell homeostasis is largely unexplored. It may facilitate regulation of cell volume in non-epithelial cells and regulation of fluid transport across low resistance epithelia. As long as the basolateral membrane Na^+–K^+ pump operates normally, Na^+ and Cl^- activities in the epithelial cell are less than their extracellular activities. In an electrically neutral co-transport process involving only Na^+ and Cl^-, entry is in the direction of the chemical potential differences for both ions and net transport could only be regulated by modifying co-transport capacity through the action of intracellular mediators such as Ca^{2+} or cyclic nucleotides. If K^+ also participates in the co-transport process, however, the outwardly directed K^+ gradient could, in principle, assist in regulation of net Na^+ and Cl^- entry. Conditions that might alter net flux through the co-transport pathway, including its voltage-dependence and affinities for the transported ions, remain to be defined.

Oocyte extracts reactivate developmentally inert *Xenopus* 5S genes in somatic nuclei

Laurence J. Korn*, J. B. Gurdon† & Jennifer Price*

* Department of Genetics, Stanford University School of Medicine, Stanford, California 94305, USA
† MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, UK

In *Xenopus* and other amphibians, there are two major classes of 5S RNA gene[1]. One class, which codes for somatic-type 5S RNA, is expressed in both oocytes and somatic cells[2]; the other, which is 50 times more abundant[3] and which codes for oocyte-type 5S RNA, is expressed in oocytes but not in somatic cells[2,4]. The developmentally inactivated oocyte-type genes are reactivated when erythrocyte nuclei are injected into most oocytes (activating oocytes)[5]. As the injected nuclei are induced to take on the natural activity of the host cell, the activation of oocyte-type 5S genes may represent a normal control mechanism. A special opportunity to investigate this mechanism is provided by the existence of certain individual animals whose oocytes consistently fail to activate 5S genes (non-activating oocytes). We have injected extracts of activating or non-activating oocytes, together with erythrocyte nuclei, into oocytes of each kind. We show here that the transcription of 5S genes is induced by extracts of activating oocytes (positive regulation) and is not inhibited by similar extracts of non-activating oocytes. The activating factor is sensitive to protease and heat treatment, suggesting that a protein is involved.

The procedures for preparing oocyte extracts and somatic nuclei from erythrocytes[5,6] are given in Fig. 1 legend. Somatic nuclei from mature erythrocytes were injected, either alone or after mixing with extracts prepared from either activating or non-activating oocytes, into the germinal vesicles of both types of oocyte. The oocytes were then injected with 1 μCi [α-^{32}P]GTP and incubated at 19 °C for 36 h[5]. Labelled transcripts were extracted and electrophoresed on non-denaturing 17% polyacrylamide gels to differentiate between somatic- and oocyte-type 5S RNA[5].

The results are shown in Fig. 1. As found previously[5], the oocyte 5S genes are transcribed in nuclei injected into activating oocytes (Fig. 1, lanes 3–5), but not in those injected into non-activating oocytes (lanes 1 and 2). When somatic nuclei were mixed with extracts of activating oocytes and injected into non-activating oocytes, the previously inactive oocyte-type 5S RNA genes in the somatic nuclei were transcribed about as efficiently as when such nuclei were injected into activating oocytes (Fig. 1, lanes 6 and 9). Thus, activating extracts have a strongly positive effect. On the other hand, extracts from non-activating oocytes injected with somatic nuclei into activating oocytes did not diminish the expression of the oocyte-type 5S RNA genes (Fig. 1, lanes 14 and 15). In addition, activating extracts mixed with non-activating extracts in a 1:1 ratio and injected with somatic nuclei into non-activating oocytes, continue to induce efficient transcription of oocyte-type 5S genes (data not shown). Thus, non-activating oocytes or extracts prepared from these oocytes do not contain inhibitors or nucleases specific for the oocyte-type 5S genes or their products. Extracts from activating or non-activating oocytes had no effect when injected into the same kind of oocyte (Fig. 1, lanes 10–13). In all injected oocytes, the somatic-type 5S genes of the somatic nuclei were transcribed efficiently (see Fig. 1); this serves as an internal control of the viability of the oocytes and their ability to transcribe the injected 5S genes. As activating extracts exert their influence in non-activating oocytes and not vice versa, it seems that at least one factor controlling the reactivation of oocyte 5S genes regulates 5S transcription in a positive fashion.

We have analysed the activating extract by incubating it at 70 °C for 3 min, or by incubating it with the protease papain. Somatic nuclei were mixed with the heated extract and injected into oocytes, as described above, and RNA was extracted and analysed (Fig. 1, lane 16). The oocyte 5S genes were not activated, indicating that at least one component of the activating factor is heat-labile. Activating extracts were also protease-treated by incubating with papain and neutralizing with antipain as described in Fig. 2 legend, before being mixed with somatic nuclei and injected into the germinal vesicles of non-activating oocytes. Activating potential was destroyed by the protease (Fig. 2, compare lanes 12–14 with lanes 9–11). However, when untreated activating extract was added back to the papain-antipain-treated extract, and injected as above, the oocyte-type 5S genes were transcribed (Fig. 2, lanes 15–17). Somatic nuclei mixed with activating extracts that had been pre-incubated in papain digestion buffer alone were also injected into non-activating oocytes as a further control for 5S transcription. In these conditions, the oocyte-type 5S RNA genes are transcribed (Fig. 2, lanes 18–20).

As the activating factor is heat-labile and protease-sensitive, it probably consists of one or more proteins, which act positively to activate 5S transcription. It has previously been shown that

Fig. 1 Transcription of 5S RNA genes with activating and non-activating oocyte extracts. The extracts were prepeared as follows: 200 single oocytes were isolated free of connective tissue, washed twice in distilled water, all excess fluid removed, then gently homogenized in a glass–glass dounce homogenizer. The extract was then centrifuged in an Eppendorf microfuge at 10,000*g* for 10 min at 4 °C, the supernatant was re-centrifuged at 10,000*g* for 15 min and the supernatant used. Somatic nuclei were prepared by lysolecithin treatment of mature erythrocytes[6]. Extracts were diluted 1:1 with somatic nuclei suspended in injection medium, just before injection into oocytes. Oocytes were injected, aiming for the germinal vesicle, with the relevant extract. After 4 h, 1 μCi [α-^{32}P]GTP was injected into the cytoplasm of each oocyte. After incubating at 19 °C for 36 h, labelled transcripts were extracted and run on a non-denaturing 17% polyacrylamide gel[5]. Each lane contains half the RNA from one oocyte. All the oocytes shown received an injection of erythrocyte nuclei. For each lane, the type of oocyte used and the source of extract injected (if any) is indicated: N, A, oocytes or extracts from non-activating or activating females, respectively. In lane 16, the activating extract was heated at 70 °C for 3 min. Lanes 7 and 8 are markers showing somatic- and oocyte-type 5S RNA, respectively (O and S at the left of the figure). The slight increase in oocyte-type 5S RNA in lanes 10 and 11 relative to lanes 1 and 2 is not always observed, and is small compared to the increase in lanes 6 and 9. It is enhanced by the long autoradiographic exposure used in these experiments.

0028-0836/82/470354—02$01.00

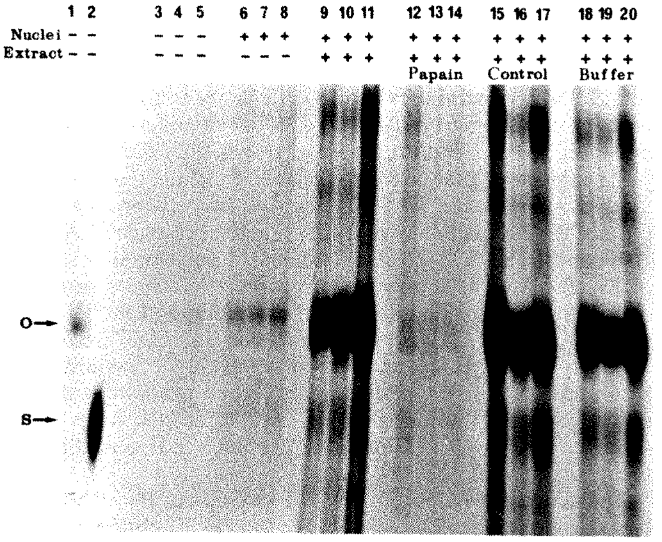

Fig. 2 Transcription of 5S RNA genes injected with activating extracts treated with protease. Oocyte extracts and somatic nuclei were prepared as described in Fig. 1 legend. All injections were into oocytes of non-activating females. Oocytes were injected with the samples and 4 h later with 1 μCi[α-^{32}P]GTP. Labelled transcripts were extracted and analysed[5]. Lanes 1 and 2 contain marker 5S RNAs (O, oocyte-type; S, somatic-type). Lanes 3–20 were either injected (+) or not injected (−), with erythrocyte nuclei and/or with an extract of activating oocytes, as indicated. Lanes 3–5 represent endogenous transcription. Lanes 12–14, injection of somatic nuclei mixed with activating extract, which had been pre-incubated with 0.8 mg ml^{-1} papain (Sigma) at 20 °C for 1 h, followed by neutralization with 1.25 mg ml^{-1} antipain (Sigma) for 10 min at 20 °C. Lanes 15–17, injection of somatic nuclei mixed with a 1:1 ratio of papain–antipain-treated extracts (as in lanes 12–14) and untreated activating extracts. Lanes 18–20, injection of somatic nuclei mixed with activating extract and papain buffer (without papain) which had been incubated together at 20 °C for 1 h.

at least two proteins in addition to RNA polymerase III are required for 5S RNA transcription[7,8]. Only one of these, transcription factor IIIA (TFIIIA), has been purified[7]. However, TFIIIA alone does not account for the activity in activating extracts since injection of somatic nuclei plus purified TFIIIA into non-activating oocytes is not sufficient to reactivate the oocyte 5S genes[5]. Whether the activating factor acts independently of, or in conjunction with, TFIIIA has yet to be elucidated. The factor functions in the absence of DNA replication, since the mature erythrocytes used as a source of somatic nuclei represent a terminal cell type in which no DNA replication occurs[9] and oocytes do not induce DNA synthesis in injected nuclei[10].

The activating and non-activating oocytes used in these experiments represent the extremes of a continuous range of activating potential. All oocytes have sufficient activating factor to ensure the expression of their own oocyte-type 5S genes (unpublished result). However, it seems that only some have an excess sufficient to activate the extra 5S genes from several hundred injected somatic nuclei. The fact that all oocytes of a given female maintain indefinitely the same activating or non-activating property has allowed us to make use of this variation for the experiments described.

The regulation of gene expression, on the molecular level, is not understood for any eukaryotic gene. We have shown for a particular gene system, the oocyte-type 5S RNA genes, that specific, although so far unidentified, protein factors can regulate transcription in a positive fashion. We are now attempting to purify these factors.

T-cell hybridomas which produce B lymphocyte replication factors only

Waldemar Lernhardt*†, Catherine Corbel*, Randolph Wall† & Fritz Melchers*

* Basel Institute for Immunology, CH-4005 Basel, Switzerland
† Molecular Biology Institute, University of California at Los Angeles, Los Angeles, California 90024, USA

B lymphocytes stimulated with BRMF (B-cell replication and maturation factor) expand clonally and mature into immunoglobulin (Ig)-secreting cells. BRMF may be a single or separate factors (BRF, BMF), capable of inducing replication and maturation in B cells[1–3]. Experimental evidence from others[4,5] suggests that BRF and BMF may be distinct molecular entities. We now find that some hybrids of concanavalin A (Con A)-activated splenic T cells and the thymoma BW5147 produce BRF on stimulation with Con A, but do not produce BMF, T-cell growth factor (TCGF), T-cell replacing factor (TRF) or factors stimulating myeloid or erythroid colonies (CSF). Thus BRF and BMF are distinct activities. BRF produced by the T-cell hybridoma A32-26 appears in two major forms with molecular weights of 15,000–20,000 and 80,000–90,000.

BRMFs are made in interactions of helper T cells, Ia-compatible accessory cells and antigen[6–17]. In the absence of antigen and helper T cells, resting B cells respond to BRMF by polyclonal maturation without replication[3]. B-cell maturation-inducing activity can be quantitated in plaque assays as the number of immunoglobulin-secreting cells (plaque-forming colonies, PFC)[18]. In order to replicate in response to BRMF, resting B cells must be raised[3,19] to the 'excited' state, either by concomitant binding of antigen and interaction of helper T cells with Ia (antigen-specific, Ia-restricted, T-dependent activation) or by mitogens, such as lipopolysaccharide (LPS)[20], which circumvent binding to immunoglobulin and Ia (polyclonal, Ia-unrestricted, T-independent activation)[8]. Restimulation of LPS-activated B-blasts has provided a convenient assay for replication-stimulating activity[1,21]. All previous BRMF preparations, as well as LPS, have also been found to induce further maturation to immunoglobulin-secreting PFC.

Cloned, antigen-specific helper T cells, as well as T-cell hybridomas, have been shown to produce several factors, including T-cell growth factor (TCGF, IL-2), BRMF, TRF and factors stimulating erythroid and myeloid colony formation (CSF) (refs 22, 23). Many of these lines have been found to produce more than one of these factors at the same time.

In an attempt to find T-cell hybridomas producing only one of these activities, we have fused BW5147 thymoma cells with activated spleen cells. (The thymoma BW5147 alone does not produce any of the activities tested.) Of 150 cloned hybridomas obtained in one fusion, 15 produced considerable quantities of factors when stimulated with Con A. Six produced TCGF, BRMF and CSF, and three produced TCGF and BRMF and no CSF. Two T-hybridoma produced only CSF and four others produced only BRMF. One of the T-cell hybridomas obtained in a similar fusion by Köhler *et al.*[24], called A32-26, produced also only BRMF (Table 1). This hybridoma which had already been recloned and which produced the highest levels of BRMF, was selected for further studies.

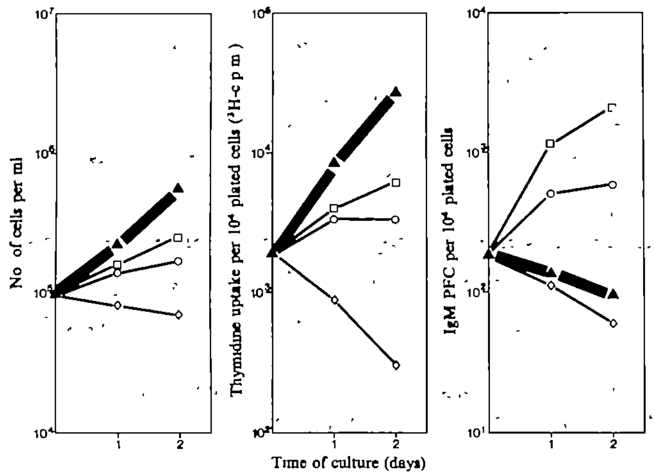

Fig. 1 Replication of LPS-activated B cell blasts (§, Table 1) in the presence of factors produced by Con A-stimulated A32-26 T hybridoma cells (*, Table 1) (—▲—), of factors produced by Con A-stimulated rat spleen cells (†, Table 1) (—□—), of LPS (50 μg ml^{-1}) (—○—), or in the absence of any added factors (—◇—). Replication was measured either by cell counts (left) or by uptake of radioactive thymidine (‡ and §, Table 1) (centre). Maturation was measured as the increase in the number of IgM PFC in culture (right). IgG- and IgA-secreting PFC (not shown in the figure) behaved as the IgM PFC.

First we investigated whether Con A-stimulated A32-26 T hybridoma cells released both replication-stimulating and maturation-inducing factors. For controls the mitogen LPS and factors produced by the interaction of cloned helper cells, antigen and histocompatible macrophages[25] were used. LPS-activated B-blasts could be restimulated to continued replication by A32-26 factors, LPS or factors of T-cell help, as measured either by cell counts or by the uptake of radioactive thymidine (Fig. 1). LPS and factors of T-cell help increased the number of IgM-secreting PFC but factors from A32-26 T hybridoma did not. Replication but no increased maturation was observed over a 300-fold range of concentrations of A32-26 factors of 50–0.15% in culture. In control experiments we found that LPS-stimulation of B cells either in the presence or absence of factors from A32-26 cells developed a similar number of IgM PFC, indicating that these factors did not inhibit IgM secretion or plaque formation. We conclude that on stimulation by Con A the T hybridoma A32-26 cells produce BRF but not BMF. Judging by replication in the presence of A32-26 BRF and LPS, A32-26 BRF stimulates polyclonal activation of B-cell blasts. This polyclonal restimulation is also independent of the H-2 or immunoglobulin haplotype of the B-blasts, since B-blasts of C57BL/6J *nu/nu* mice (Ig^b, H-2^b), BALB/c *nu/nu* mice (Ig^a, H-2^d) and A/J mice (Ig^e, H-2$^{k/d}$) could all be restimulated. This is in line with earlier observations, that neither surface immunoglobulin nor surface Ia have to be occupied by ligands to allow BRF to stimulate B-blast through the next round of division.

The activity of helper T cells in T-dependent B-cell stimulation can be replaced by soluble factors (TRF) obtained in the interaction of helper T cells, antigen and macrophages[8–15]. Thus, B cells of athymic *nu/nu* mice will respond to antigens such as sheep erythrocytes (SRBC) by clonal replication and maturation to secrete SRBC-specific antibody in the presence of such TRF. Factors from T hybridoma A32-26 have no activity detectable as TRF, while other media expected to contain TRF, do, indeed show activity (Table 1). We think that this is because they do not contain BMF which could induce SRBC-specific replicating B cells to cells secreting SRBC-specific antibody, detectable as PFC.

The apparent molecular weight of BRF produced by the A32-26 T hybridoma cells was estimated by gel filtration over a G100-Sephadex column. BRF is detectable in two major molecular forms, with apparent molecular weights of 80,000–90,000 and 15,000–20,000, and two minor forms with molecular weights of ~45,000 and >100,000 (Fig. 2). Both human and murine BRF have also recently been identified in other laboratories[5,26]. Structural studies on the chemical nature of the BRF from A32-26 T hybridoma cells and from other BRF-producing hybridomas should clarify whether the different

* T hybridoma and BW5147 cells were stimulated at 5×10^5 cells per ml for 24 h with 5 μg ml^{-1} Con A in serum-free medium[33] in a CO_2-incubator at 9% CO_2 in air The conditioned media were used at 25% (except the Con A-activated spleen cell superniatants, see below), in the presence of 5mM α-methylmannoside (Sigma). All *in vitro* experiments described here were done in serum-free medium[33].

† 5×10^6 rat spleen cells per ml incubated with 5 μg ml^{-1} Con A for 24 h, supernatant medium concentrated by ammonium sulphate precipitation and partially purified by G100-Sephadex chromatography. Used at 10%.

‡ The CTL-L killer T-cell line was a gift of Dr K. Smith 5×10^4 CTL-L cells per ml were cultured in the conditioned media for 48 h, then 1 μCi ^{3}H-thymidine (2Ci mmol^{-1}, Amersham) was added for 2 h and the incorporation into insoluble material measured as described[33].

§ C57BL/6J *nu/nu* spleen cells activated for 48 h with 50 μg ml^{-1} LPS, partially purified from non-activated and from dead cells by velocity sedimentation[34] as described previously[21] Thymidine uptake as for CTL-L cells

‖ Influenza virus-specific helper T-cell clone vir2-15 (ref. 23), incubated at 2×10^5 cells per ml with 10 haemagglutinating units of PR8 virus and 2×10^6 2,200 rad X-irradiated BALB/c spleen cells.

¶ 50 μg/ml.

Helper T cells were the cloned, influenza virus-specific cell line vir2-15, kept on virus and syngeneic irradiated spleen cells as described[25], partially purified from dead cells and virus before use by repeated sedimentation over a layer of fetal calf serum. Thymidine uptake was done as with CTL-L cells (see ‡).

** Culture containing 2.5×10^6 SRBC (sheep erythrocytes) and 2×10^6 *nu/nu* C57BL/6J spleen cells, assayed at day 5 of culture as described previously[1,19].

†† Colony stimulating factor (CSF) activity was detected in methylcellulose culture by growth of colonies (macrophage, monocyte, granulocyte and erythrocyte colonies) from bone marrow precursor cells[35] as described previously[36].

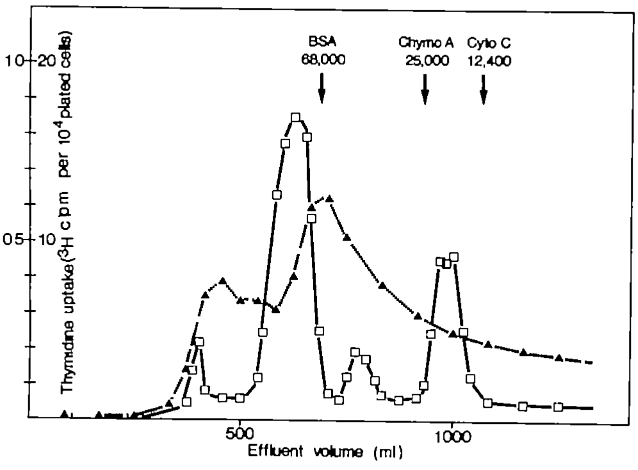

Fig. 2 Gel filtration on G100-Sephadex (column size 5 × 90 cm) of BRF produced by Con A-activated A32-26 T hybridoma cells (for details see Table 1). BRF from 1 l of conditioned medium concentrated by precipitation with ammonium sulphate (80% saturation) and dialysed against the column buffer (0.9% NaCl, 5 mM HEPES pH 7.3) was applied to the column at 4 °C. The eluate collected in 10-ml fractions was monitored for absorbance at 280 µm (···▲···) and for BRF activity at 3% in culture (—□—) as described in Table 1 legend. The same column, in a parallel run, was calibrated with BSA (molecular weight 68,000), chymotrypsinogen A (25,000) and cytochrome *c* (12,400).

molecular species are structurally different, or whether they share common structural elements involved in BRF action, derived through a precursor–product relationship[27–29], in a free factor/receptor-bound factor relationship[30,31] known to exist for growth factors of other eukaryotic cells or, more trivially, by factors bound to molecules of the tissue culture medium such as bovine serum albumin.

The finding that BRF and BMF are separate activities has important bearing on our understanding of the mechanisms and the physiology of B cell regulation. Resting B cells might express BMF but not BRF receptors, while excited B cells might express both. The establishment of continuous B-cell lines and clones, analogous to functional T-cell lines and clones[32] has so far been difficult. We hope that the stimulation by BRF in the absence of BMF of excited B cells not yet induced to mature will help in this experimental difficulty. Replication of B lymphocytes in the presence of BRF may continue for longer periods of time as long as the terminating action of BMF is absent.

We thank Ms Denise Richterich, Annick Peter and Lori Kato for technical assistance, Dr Georges Köhler, for allowing us to screen T-cell hybridomas made in 1977 (ref. 22) for BRF activity, Dr Jan Andersson for discussions and Drs Stephen Fazekas de St. Groth, Christopher Paige and Max Schreier for reading the manuscript. LFA-1 but not Lyt-2 is associated with killing activity of cytotoxic T lymphocyte hybridomas

The mechanism by which cytotoxic T lymphocytes (CTL) recognize and lyse target cells is largely unknown. Recently, two lymphocyte cell-surface glycoproteins, Lyt-2[1–4] and LFA-1 (lymphocyte function-associated antigen)[5–8], have been implicated in the killing activity of murine CTL. This suggestion was based mainly on the unique ability of antibodies directed against Lyt-2[1–4] and LFA-1[5–8] to inhibit cytotoxicity of CTL by affecting the killer cell. Lyt-2, a glycoprotein composed of subunits of molecular weights of 30,000–35,000 (30–35K), has been proposed as a common marker for CTL[9], essential for specific recognition of target cells[10]. This view, however, is incompatible with other results[11–14]. The newly detected LFA-1 molecule, containing subunits of 95K and 180K[5–8,15], is associated with the ability of CTL to bind target cells[16,17]. Most analyses of CTL structure–function relationships are ambiguous since they have been obtained with heterogeneous CTL populations. We have recently developed CTL-hybridomas which lyse specifically allogeneic tumour cells *in vitro*[18] and grow independently of exogenous stimuli[19]. In this study we have tested the relevance of Lyt-2 and LFA-1 antigens to cytotoxicity by analysing the CTL-hybridomas with a panel of anti-LFA-1 and anti-Lyt-2 monoclonal antibodies. We show that two monoclonal CTL-hybridomas have the phenotype LFA-1$^+$ and Lyt-2$^-$ and that their killing activity is inhibited by anti-LFA-1 but not by anti-Lyt-2. The results suggest that LFA-1 is involved in CTL-cytotoxicity, while Lyt-2 molecules are not required.

CTL somatic hybrids, in which elimination of functionally irrelevant molecules could occur due to chromosomal segregation or to repression controlled by the tumour cell parent, provide a new homogeneous and antigen-specific source for

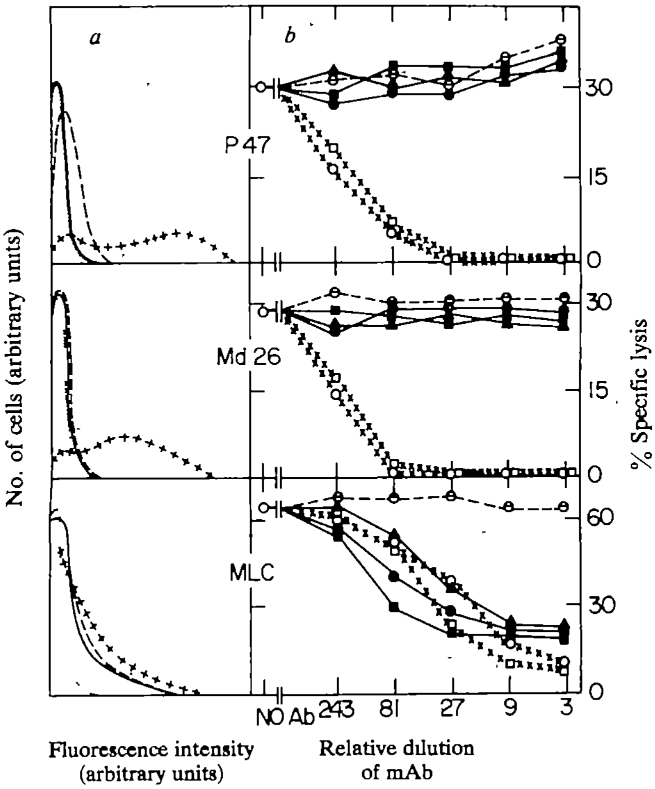

Fig. 1 Expression of Lyt and LFA-1 antigens on CTL-hybridomas and the effect of anti-Lyt and anti-LFA-1 mAb on cytotoxicity. *a*, Cytofluorometric analysis of Lyt-1, Lyt-2 and LFA-1 on CTL and CTL-hybridomas was done by reacting 2×10^6 MLC effector cells (primary BALB/c anti-C57BL/6 spleen cells stimulated for 5 days at 1:1 ratio) or CTL-hybridoma clones P.47 or Md.26 with the following monoclonal antibodies. anti-Lyt-1 (- - - -) and anti-Lyt-2 (——) produced by hybridomas 53.7.3 and 53.6.7, respectively[22] (these were obtained from the Cell Distribution Center of the Salk Institute, San Diego); anti-LFA-1 (+++) produced by hybridoma H35-89.9[7] and concentrated from ascites by 50% $(NH_4)_2SO_4$. Washed cells were stained with fluoresceinated rabbit anti-rat immunoglobin. Samples were analysed using a fluorescence-activated cell sorter (FACS II). For each cell preparation, a control staining with the fluoresceinated reagent alone (· · · ·) is shown. Data are expressed in arbitrary units as obtained from the cell sorter. *b*, The effect of anti-Lyt and anti-LFA-1 monoclonal antibodies on cytotoxicity of MLC and CTL hybridomas was studied by incubating 10^4 effector cells in microtitre plates with different dilutions of the following monoclonal antibodies: anti-Lyt-1, 53.7.3[22] five times concentrated (- - - - ○); anti-Lyt-2 were 53.6.7[22] five times concentrated (▲); H35-17.2[17] 1:3 diluted (●); and M12/7.2[5] 1:10 diluted (■); anti-LFA-1 were H35-89.9[7] at 1:1,000 dilution (+++○); and M17/5.2[5] at 1:30 dilution (+++□). The concentrations of antibodies listed above indicate the original stocks which were serially diluted in the assay. After 20 min incubation at 37 °C in 100 µl reaction medium (RPMI-containing 10% fetal calf serum and 10 mM HEPES *p*H 7.4), 10^4 ^{51}Cr-labelled, neuraminidase-treated[18] EL4 target cells were added in 50 µl reaction medium. Plates were spun for 5 min at 500 r.p.m. and incubated for 5 h at 37 °C. Lysis was stopped by cooling, plates were spun for 10 min at 2,000 r.p.m. and 75 µl supernatants were taken to determine the ^{51}Cr release. Spontaneous release was 12%.

studies of specific effector structures participating in cytotoxicity. We analysed the effect of various monoclonal antibodies on two unrelated CTL-hybrid subclones, Md. 26 and P. 47, that had been derived from BALB/c anti-EL4 (H-2^d anti-H-2^b) CTL following secondary stimulation either in mixed lymphocyte culture (MLC) or *in vivo* (peritoneal exudate lymphocytes, PEL), respectively[18]. These monoclonal CTL-hybridomas retained their killing specificity towards H-2^b tumour target cells during prolonged continuous growth in culture[20] and exhibited this capacity while the studies described here were carried out. The monoclonal antibodies examined had been raised against CTL and selected according to their ability to inhibit killing by binding to the effector cells[5,7,17,21].

The presence of the differentiation antigens Lyt-1, Lyt-2 and LFA-1 on the CTL hybridomas and heterogeneous MLC population was examined by immunofluorescence staining. The analysis (Fig. 1*a*) demonstrates the presence of all three antigens on MLC, low levels of Lyt-1 on P but not on M hybridomas and high density of LFA-1 on both hybridomas. None of the CTL-hybridomas were stained with anti-Lyt-2. Additional monoclonal anti-Lyt-2 (H35-17.2[7,17], M12/4, M12/5 and M12/7.2[21]), failed to stain the hybridomas, while several anti-LFA-1 monoclonal antibodies (H35-89.9[7] and M17.5.2[5]) stained over 85% of the hybrid cells (not shown). The relevance of Lyt-2 and LFA-1 to the killing activity was further studied by testing the effect of the monoclonal antibodies on cytotoxicity (Fig. 1*b*). The hybridomas or BALB/c anti-C57BL/6 MLC were incubated with ^{51}Cr-labelled EL4 target cells in the presence of diluted antibody and specific killing was determined. As previously reported, cytotoxicity of MLC was inhibited by anti-Lyt-2[1–4] and by anti-LFA-1[5–8] and was unaffected by anti-Lyt-1. The killing activity of both CTL-hybridomas was likewise unaffected by anti-Lyt-1 and completely abolished by two anti-LFA-1 antibodies. However, unlike parental MLC, the cytotoxicity of the hybridomas was unaffected by three different anti-Lyt-2 monoclonal antibodies. The absence of detectable Lyt-2 on the surface of the CTL-hybridoma was further confirmed by preincubation of both M and P hybrid cells with two different anti-Lyt-2 antibodies in the presence of complement (Fig. 2). Such pretreatment completely eliminated the cytotoxicity of parental MLC but did not affect the cytolytic potential of hybridomas. The inability to detect Lyt-2 on the

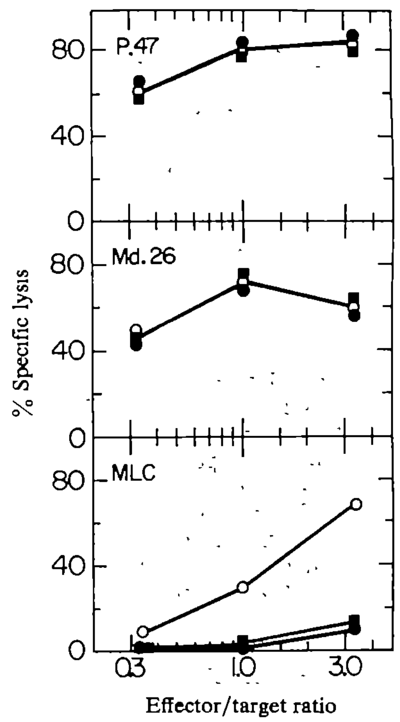

Fig. 2 The effect of pretreatments with anti-Lyt-2 and complement on the cytotoxicity of CTL-hybridomas and MLC. CTL-hybridomas and primary MLC (see Fig. 1 legend) were preincubated for 45 min at 37 °C with anti-Lyt-2, H35-17.2[17] (●) or M12.7.2[5] (■) and 1:10 dilution of fresh guinea pig serum as complement or with complement alone (○). After washing, treated cells were diluted and cytotoxicity was tested on 10^4 neuraminidase-treated ^{51}Cr-labelled EL4 target cells. E/T ratio was calculated according to number of effector cells before treatment. Incubation was for 5.5 h and spontaneous release was 18%.

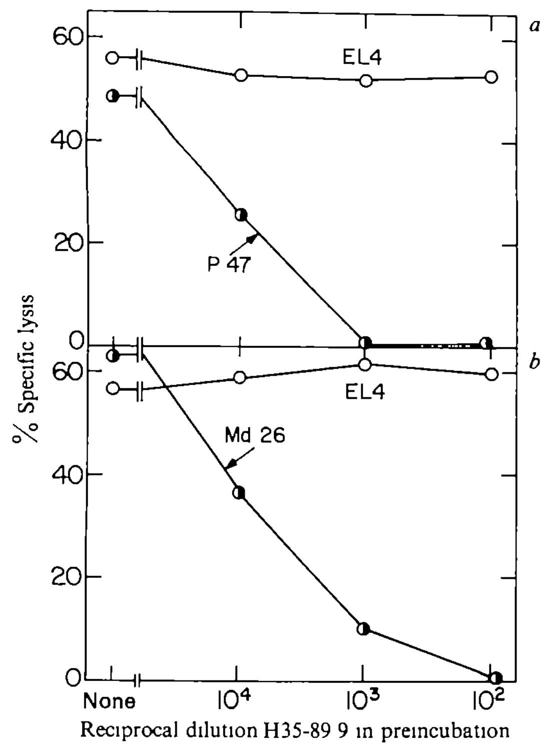

Fig. 3 Preincubation of CTL-hybridomas but not of EL4 target cells with monoclonal anti-LFA-1 inhibits cytotoxicity. Isolated CTL-hybridomas or neuraminidase-treated ^{51}Cr-labelled EL4 cells were incubated with anti-LFA-1 H35-89.9[7] at the indicated dilutions for 60 min at 37 °C. Cells were washed three times from excess of monoclonal antibody and cytolytic reactions were completed with an equivalent number of the missing untreated effector or target cells. Killing assays contained 10^4 CTL-hybridomas (either P.47 (*a*) or Md.26 (*b*)).

CTL hybridomas did not result from a wrong specificity or a low titre of the antibody used; since antibody 53.6, which recognizes a nonpolymorphic portion of Lyt-2 molecule[22] and two other monoclonal anti-Lyt-2 molecules, did bind to parental MLC killers and inhibited very effectively their cytotoxicity, while the same monoclonal antibodies could neither bind to the hybrid cells (Figs 1*a* and 2) nor affect their killing activity (Fig. 1*b*). Furthermore, more than a single Lyt-2 antigenic determinant was absent, since the hybridomas were unreactive with antibodies M12/4, M12/5 and M12/7, which define three topographically distinct Lyt-2 determinants (not shown).

In contrast to anti-Lyt-2, four different monoclonal anti-LFA-1 molecules were all equally effective in inhibiting specific killing of EL4 and ALB.B2 target cells by the hybridomas (Fig. 1*b* and not shown). Since LFA-1 molecules are expressed not only on the CTL-hybridomas but also on EL4 (ref. 15 and our unpublished results), which had been used as target cells in these experiments, it was necessary to examine whether anti-LFA-1 exerts its inhibitory effect on killing through its binding to the target cells or to the effector cells, as previously suggested[5-8]. This was tested by preincubating anti-LFA-1 separately with either isolated CTL-hybridomas or EL4 cells and combining treated and untreated components for the killing assay after excess of the antibody was removed. Cytotoxicity of preincubated CTL hybridomas was completely abolished by bound anti-LFA-1 molecules (Fig. 3), while pretreated EL4 target cells were unaffected, showing that indeed, anti-LFA-1 inhibited killing by affecting primarily the CTL-hybridomas rather than EL4 target cells.

The hypothesis that Lyt-2 is associated with the CTL receptor was based on a genetic linkage between Lyt-2-3 locus and the V_k locus[23], on the observation that anti-Lyt-2 inhibits killing at the recognition-adhesion stage[24], and on a mutagenized CTL Lyt-2$^+$ clone which lost in parallel Lyt-2 and the ability to kill specifically TC[10]. Recently, however, MacDonald *et al.*[14] reported that some CTL which express Lyt-2 are not inhibited by anti-Lyt-2. In addition, it becomes apparent that CTL populations[12] and long-terms lines[11,13] directed against Ia antigens (class II) major histocompatibility complex (MHC) are Lyt-1$^+$2$^\mp$ and helper cells specific for class I MHC antigens are Lyt-1$^+$2$^+$ and their helper function is inhibited by anti-Lyt-2[26]. These results prompted Swain[26] to suggest that Lyt phenotype correlates primarily with the class of MHC antigen recognized rather than with function (see also ref. 27 for a recent discussion). Our observation that functional CTL-hybridomas are Lyt-2 negative support the notion that Lyt-2 molecules are not required for specific cytotoxicity. The H-2 specificity of these CTL-hybridomas was recently mapped to the *D* region of *H-2*^{b} by using target cells from recombinant mice[28] and by inhibition of the hybridoma-mediated target cell killing with anti-H-2D^b[19]. In this respect, the CTL-hybridomas seem to be exceptional, since all CTL directed against class I MHC were reported so far as Lyt-2$^+$. However, hybridomas are often subjected to selective loss of some parental chromosomes or to repression of specific genes, hence it is possible that the CTL hybridomas analysed here originated from Lyt-2$^+$ parental CTL whose Lyt-2 expression was lost. Regardless of the history of these cells, the mere fact that they specifically lyse target cells without expressing Lyt-2 antigens strongly suggests that Lyt-2 molecules are not essential for either target cell recognition or binding. This is in contrast to previous suggestions that Lyt-2 is an antigen receptor. However, it is possible that Lyt-2 is a non-antigen-specific receptor that, together with the antigen receptor, contributes to the avidity of the CTL for the target cells[17,21]. In cases where the antigen receptor has low avidity, loss of the Lyt-2 interaction would result in loss of CTL activity, explaining the antibody inhibition[1-4] and Lyt-2 mutant results[10]. Thus, while in some cases Lyt-2 may contribute to CTL activity, we conclude that it is not essential and is distinct from the antigen receptor.

LFA-1 molecules, unlike Lyt-2, may be an essential structure of functional CTL. This conclusion is based on the observation that *all* CTL populations and clones examined so far express LFA-1 and their cytotoxicity is inhibited by anti-LFA-1[5-8]. The formation of effector target cell conjugates is inhibited by anti-LFA-1[16,17], indicating that the binding stage is affected. The ability of anti-LFA-1 to inhibit specific lysis irrespective of the TC specificity[7,16], as well as concanavalin A mediated nonspecific killing[7,17], emphasizes the general role of LFA-1 in a fruitful CTL target cell interaction. Previous findings that anti-LFA-1 interfere with other T-cell functions like proliferative MLC responses, macrophage-dependent antigen-specific proliferation, and T cell-dependent antibody responses to red cells[7,16,21], suggest that LFA-1 is crucial for the interaction of T cells with other cells. The fact that a panel of anti-LFA-1 monoclonal antibodies inhibited very efficiently the specific cytotoxicity of CTL-hybridomas (Figs 1*b*, 3) and immunoprecipitated from the hybrid cells the 95K and 180K LFA-1 subunits (not shown) indicates that the same LFA-1 molecules that participate in parental CTL cytotoxicity also participate in the specific target cell killing induced by the hybridomas. The monoclonal CTL hybridomas which grow rapidly in culture and retain specific killing activity for months without added stimuli, provide an unlimited and homogeneous source for studying the molecular basis for the role of LFA-1 in T cell-mediated cytotoxicity.

We thank Mrs T. Oren and Ms T. Waks for technical assistance. This research was supported by United States-Israel Binational Science Foundation grant no. 2642/81 and USPHS grant CA 31798.

Restricted expression of viral glycoprotein in cells of persistently infected mice

Michael B. A. Oldstone & Michael J. Buchmeier

Department of Immunology, Scripps Clinic and Research Foundation, La Jolla, California 92037, USA

For a virus to cause persistent infection in a host, a unique host–virus relationship is required. The virus *per se*, or variant(s) arising *in vivo*, must be noncytopathic for the host cell that it infects. Furthermore, the infected cell must escape recognition by the host's immune system, which eliminates virus and virus-infected cells. Several models of persistent infection *in vitro* demonstrate selective loss of viral gene products normally represented at the cell surface as opposed to viral products found inside the cell[1–5]. Decreased glycoprotein (gp) expression on the surface of an infected cell correlates directly with the ability of that cell to resist killing by both cytotoxic lymphocytes and cytotoxic antibody and complement[1,3,6]. The question remains of whether a corresponding selective loss of viral glycoprotein expression occurs in persistently infected cells *in vivo*. We have used monoclonal antibodies as probes to define the viral glycoprotein and nucleoprotein (NP) molecules expressed in individual cells from several tissues of mice persistently infected with lymphocytic choriomeningitis virus (LCMV). We report here a selective decrease in the expression of viral glycoprotein in single cells, during persistent infection *in vivo*.

LCMV is noncytopathic and easily induces persistent infection in its natural host, the mouse (for review see refs 7, 8). The virus contains a negative-stranded two-segmented RNA genome and three structural polypeptides. Of these, two are glycosylated (gp1 and gp2), and one is the nonglycosylated NP; the molecular weights are 4.3×10^4, 3.6×10^4 and 6.3×10^4 for gp1, gp2 and NP, respectively[7]. Collectively, the glycoproteins make up ~30% of the virion mass. The gp1 and gp2 form in infected cells in equimolar amounts by proteolytic cleavage from a common precursor, gpC, and are distinct according to tryptic peptide mapping[9]; gp1 is the predominant viral polypeptide accessible to radiolabelling or antibody binding on the surfaces of infected cells or virions[9]. A large battery of monoclonal antibodies against these three structural LCMV polypeptides was obtained by using a modification of the Kohler–Milstein method[10]. Specificities of the various monoclonal antibodies were then determined after immune precipitation of ^{35}S-labelled LCMV polypeptides, as described elsewhere[10]. The antibodies were used as molecular probes to analyse the expression of gp1, gp2 and NP by indirect immunofluorescence assay[6,10].

We first determined the expression of viral gene products during acute LCMV infection of cultured cells and subsequently of intact, adult animals. Viral gp1, gp2 and NP were evident in the cytoplasm of both L929 and BALB/clone (Cl) 7 cells 2 days after initiating infection (see Fig. 1). Similar results were obtained when either hybridoma cells or N115 neuroblastoma cells were similarly infected and analysed for each viral polypeptide, or when individual cells were stained with two fluorochrome dyes[11] (one dye was used to detect the NP, the other to detect viral glycoproteins). For these and other studies, the antiviral gp1 and gp2 monoclonal antibodies were pooled and used as a reference glycoprotein reagent. The plasma membrane showed expression of molecules of viral glycoprotein only on the surfaces of acutely infected cells. In subsequent tests, ependyma, choroid and meningeal cells from several individual adult mice of the C3H/St, BALB/WEHI and SWR/J strains acutely infected with LCMV (60 plaque-forming units (PFU), i.c.) expressed both types of viral glycoprotein and NP when sampled 5 days after infection (Fig. 2).

In contrast to our findings in acutely infected mice and cells, mice persistently infected *in vivo*, as well as cultured mouse cells persistently infected *in vitro* with LCMV, selectively lost viral gp expression with time but retained viral NP. For example,

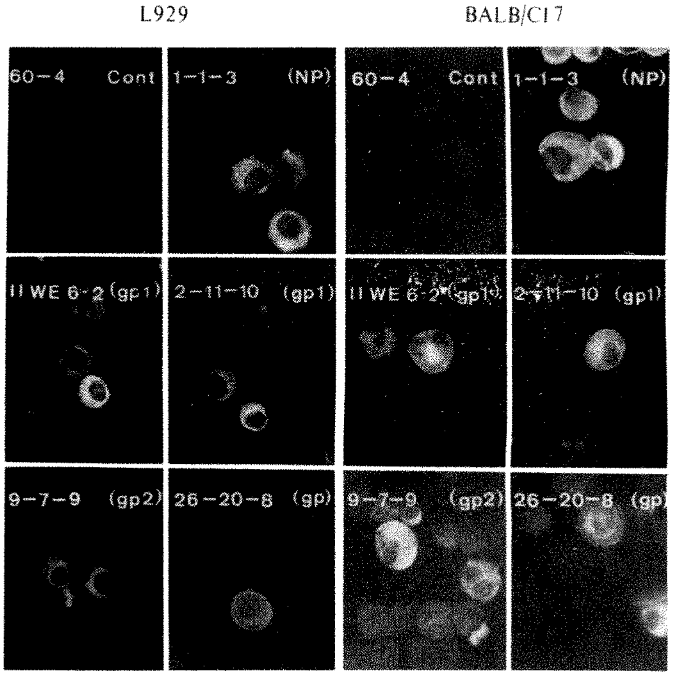

Fig. 1 Expression of viral glycoprotein and NP by cultured cells during acute infection with LCMV, Armstrong 1371 strain. L929 or BALB/Cl 7 cells were infected with LCMV at a multiplicity of infection (MOI) of 3 and studied 2 days later for the expression of viral gp1, gp2 or NP. Cells were fixed with ether/alcohol (1 : 1) for 20 min, 95% ethanol for 10 min, then washed in buffer and stained with the monoclonal antibodies shown. 60–4 is a monoclonal antibody to the glycoprotein (G) protein of vesicular stomatitis virus and served as a negative control. After 30 min incubation, the cells were washed twice in buffer and stained with monospecific goat anti-mouse immunoglobulin antibody conjugated to rhodamine. After 20 min, the cells were triple-washed in buffer, covered with glycerol–Tris buffer and a coverslip and studied by fluorescence microscopy.

0028–0836/82/470360—03$01.00

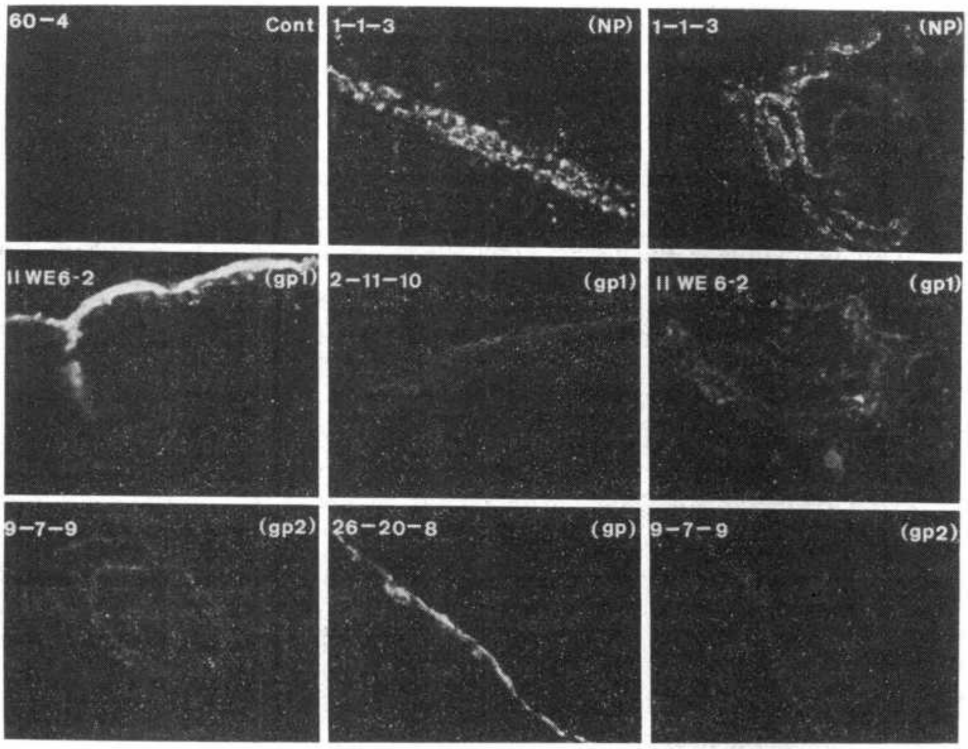

Fig. 2 Expression of viral glycoprotein and NP during acute infection of adult C3H/St mice with 60 PFU of LCMV, Armstrong 1371 strain. Expression of both viral glycoprotein and NP is evident in cells of the ependyma (centre—upper row), choroid plexus (right—upper row; right—middle row; left—lower row) and meninges (left and centre—middle row; centre and right—lower row). Brains collected 5 days after infection were snap-frozen with liquid nitrogen, cut into 4-μm sections in a cryostat and mounted on glass slides. Slides containing the brain sections were fixed and stained as described in Fig. 1 legend. Similar results were seen when anti-gp1 and -gp2 monoclonal antibodies were pooled and then used as a staining reagent. Similar results were observed with SWR/J and BALB/W mice.

at 60 days after the initiating infection, and for as long as 360 days after the experiment ended, persistently infected cells expressed no detectable viral gp on their surfaces and only rarely was it found in the cytoplasm. This observation has been confirmed in studies of single cells from animals infected *in vivo* (Fig. 3 and Table 1). For the *in vivo* study, persistent infection was established by inoculating newborn SWR/J, BALB/WEHI or C3H/St mice i.c. with 60 PFU of LCMV, Armstrong 1371 strain[12]. Such neonatally infected mice carry virus in their tissues throughout life despite mounting an antiviral immune response[7,12]. We evaluated cells from the brain, liver, kidney and pituitary tissues of such mice at 2, 5, 15, 30, 60, 84 and 180 days after initiating infection, for expression of viral glycoprotein or NP, using monoclonal antibodies (Table 1). At the second and fifth days after infection, neurones of the central nervous system (CNS), parenchymal cells of the liver, tubular epithelial cells of the kidney and cells in the anterior lobe of the pituitary expressed viral glycoprotein and NP in a manner similar to acutely infected cells from adult mice (Fig. 2) and acutely infected cells in culture (Fig. 1). By 15 days after infection, most but not all infected cells demonstrated both glycoprotein and NP polypeptides. However, at 30 days and later, individual infected cells located in the CNS, liver, kidney and anterior lobe of the pituitary had lost viral glycoprotein but retained the expression of viral NP (Fig. 3, Table 1).

Table 1 Dissociated expression of LCMV glycoprotein and NP during persistent virus infection

		Expression of viral gene products in neurones							
		Acute infection		Persistent infection					
		Day 3–5		Day 5		Day 15		Day > 80	
Strain		gp	NP	gp	NP	gp	NP	gp	NP
C3H/St	Adult	8/8[*]	8/8	—[†]	—	—	—	—	—
BALB/W	Adult	5/5	5/5	—	—	—	—	—	—
SWR/J	Adult	8/8	8/8	—	—	—	—	—	—
C3H/St	Newborn	—	—	5/5[*]	5/5	9/15	15/15	1/8	8/8
BALB/W	Newborn	—	—	5/5	5/5	ND	ND	1/20	20/20
SWR/J	Newborn	—	—	5/5	5/5	ND	ND	3/25	25/25

Individual neurones were studied for the expression of viral glycoprotein (gp) or NP by using appropriate monoclonal antibody and antibody to mouse immunoglobulin conjugated to rhodamine or fluorescein isothiocyanate. Sections (4 μm) through the anterior one-third of the temporal lobe were fixed in ether/alchohol (1 : 1) and 95% alcohol before staining as described elsewhere[12]. At least 100 individual neurones per section were studied. Acute infection was induced in 4–5-week-old mice by i.c. inoculation of 60 PFU of LCMV, Armstrong strain 1371; persistent infection followed inoculation of newborn mice with a similar route of inoculation and dose of virus. Infected mice were killed after infection, on the days indicated. ND, not determined.

[*] Number of mice studied that contained one or more cells expressing a specific viral polypeptide/total number of mice.

[†] The virus dose used in adult mice for acute infection leads to death by day 6–8.

These studies suggest that the synthesis of viral glycoprotein decreases in cells during persistent infection *in vivo*, resulting in a decrease in its expression on the surfaces of the cells. Decreased viral glycoprotein expression possibly allows persistently infected cells to resist assault by virus-specific immune reactants. By this means, a noncytopathic virus may persist throughout the lifespan of an infected cell and the cell could remain alive, unaffected by the host immune surveillance mechanism.

Although the cellular content of viral glycoprotein diminished, that of viral NP did not. Despite the accumulation of viral NP in specialized cells of the host, no morphological alteration was evident by either light or electron microscopy[13,14]. Further, electron microscopic study of infected neuronal cells from persistently infected mice reacted with monoclonal antibodies confirmed that NP accumulated inside the cell, usually aggregated in the area of polyribosomes[14], while viral gp inside the cell was reduced and the virus became restricted from budding at the cell surface.

These findings in individual neuronal, hepatic, epithelial and endocrine cells from mice persistently infected with LCMV *in vivo* extend the results seen *in vitro*[1–5,15,16]. Such persistently infected cells develop a quantitative 10- to 50-fold decrease in viral glycoprotein synthesis and glycoprotein expression compared to NP synthesis and expression in acutely infected cells[1,15]. Our *in vitro* studies suggest that the decrease in glycoprotein expression parallels the generation of defective interfering virus (DIV)[1,15]. Whether DIV is generated *in vivo* during natural or experimentally induced LCMV infection is unknown, but is now being studied.

Persistent LCMV infection of cultured differentiated neuroblastoma cells correlates directly with a significant dysfunction in the synthesis or degradation of acetylcholine due to the reduction in acetylcholine transferase or esterase, respectively[16]. Similar alterations in differentiated functions have

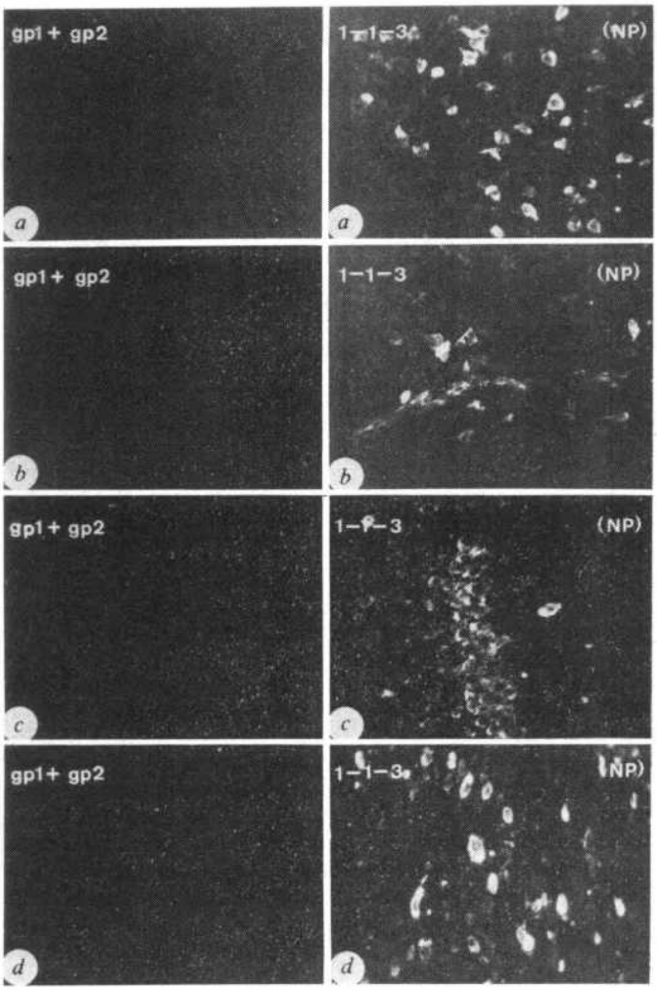

Fig. 3 Lack of viral glycoprotein but presence of NP in individual neuronal cells from C3H/St mice persistently infected with LCMV. Newborn mice were inoculated with 60 PFU of LCMV, Armstrong 1371 strain and killed 84 days later. Neuronal cells of four mice (*a–d*) expressed NP, but in the adjunct 4-μm section no glycoprotein is apparent for the same cell. The collection, sectioning and staining of the tissues was the same as described in Fig. 2 legend, except that antibodies to gp1 and gp2 from hybridomas were pooled and then used as the staining reagent. Similar results were observed for SWR/J and BALB/W mice.

recently been observed after viral infection *in vitro* when hybridoma cells no longer produced monoclonal antibodies, and *in vivo* when differentiated growth hormone-producing cells made significantly less growth hormone[3,17]. Hence, by avoiding immune responses directed against the cells they infect, noncytopathic viruses may significantly alter physiological homeostasis by causing a dysfunction in the cells of the endocrine, immune or other differentiated systems; the end result is a new mechanism for the production of virus-induced diseases. Whether these biochemical dysfunctions at the cellular level are directly related to the accumulation of viral products in a manner akin to a storage disease is a matter for further study. The results reported here for persistent LCMV infection resemble the overall pattern observed during persistent measles virus infection (subacute sclerosing panencephalitis). Neuronal cells in biopsies from these patients showed a decrease in or lack of measles virus glycoprotein but they accumulated measles virus nucleocapsids internally[18]. Thus, other persistent infections may produce similar findings *in vivo*.

DNA strand breaks and ADP-ribosyl transferase activation during cell differentiation

Farzin Farzaneh, Rosalind Zalin*, David Brill & Sydney Shall

Cell and Molecular Biology Laboratory, University of Sussex,
Brighton, East Sussex BN1 9QG, UK

The nuclear enzyme ADP-ribosyl transferase (ADPRT) catalyses the formation of poly(ADP-ribose)-modified chromatin proteins from NAD$^+$ (refs 1–5) and is entirely dependent on DNA[6] containing nicks[7–11]. Nuclear ADPRT activity is required for efficient DNA excision repair[12,13], probably because it regulates DNA ligase activity[14]. Indirect evidence has suggested that ADPRT activity may also be involved in control of gene expression and cell differentiation[15–21]. We report here an obligatory involvement of ADPRT activity in the differentiation of muscle cells. Inhibitors of ADPRT activity reversibly inhibit both fusion of myoblasts to form multi-nucleate muscle fibres and the differentiation-specific increase in creatine phosphokinase (CPK) activity. These two markers of differentiation can also be reversibly inhibited by depriving the cells of nicotinamide and thus lowering their cellular NAD content. Specific gene expression sometimes requires gene rearrangements or DNA transposition; this implies that DNA strand-breaking and rejoining might be involved in gene expression. We also describe the appearance during cytodifferentiation of single-strand DNA breaks which are not due to a general deficiency in DNA repair.

Primary chick myoblasts in culture undergo an initial phase of proliferation before terminal differentiation which is marked by the fusion of myoblast cell membranes to form multinucleate syncytia of muscle fibres, the cessation of DNA biosynthesis and cell division, and a substantial increase in CPK activity, largely due to *de novo* synthesis of a muscle-specific isozyme of this protein (Fig. 1).

ADPRT activity can be estimated by the rate of incorporation of radioactivity from ^{3}H-adenine-NAD$^+$ into acid-insoluble material in permeabilized cells. Two forms of ADPRT activity may be measured[10]; the intrinsic, physiological, endogeneous activity in the absence of any experimentally induced DNA strand breaks, and the total, potential enzyme activity displayed by deoxyribonuclease to generate the optimal number of breaks.

---

* Present address: Department of Anatomy, University College London, Gower Street, London WC1, UK.

During the initial, proliferative phase of culture there is a low, constant physiological ADPRT activity (Fig. 1). Just before the onset of cell fusion, however, the physiological activity begins to rise, most of the increase taking place before 45 h. By 72 h, when ~70% of the cells have fused, the specific activity of ADPRT has increased threefold (Fig. 1). In contrast, the total potential ADPRT activity is higher than the physiological activity at all times and does not alter significantly (Fig. 1), implying that the increase in the physiological activity is due to enzyme activation, and not to an increase in the number of enzyme molecules. ADPRT activation precedes both cell fusion and the rise in CPK activity (Figs 1, 2*b*, *d*).

We have analysed the function of ADPRT by the use of enzyme inhibitors[13]. In the continuous presence of either 3-aminobenzamide or 3-methoxybenzamide[22], myoblast fusion is inhibited in a concentration-dependent manner. 3-Aminobenzamide (8 mM) or 3-methoxybenzamide (5 mM) inhibit myoblast fusion essentially completely, myoblast proliferation is not inhibited (results not shown, but see Fig. 2). In contrast, the non-inhibitory analogues 3-aminobenzoate and 3-methoxybenzoate cause no significant inhibition of fusion at corresponding concentrations. Inhibitors of ADPRT block reversibly both myoblast fusion (Fig. 2*a*) and the usual increase in CPK activity (Fig. 2*b*). The replacement of 3-aminobenzamide-containing medium with medium from control cultures of the same age, at 44 or 54 h of culture, reversed the inhibition and cell fusion began 10 or 14 h later respectively (Fig. 2*a*). Removal of the inhibitor at 54 h of culture results in a rise in CPK activity 12 h later (Fig. 2*b*).

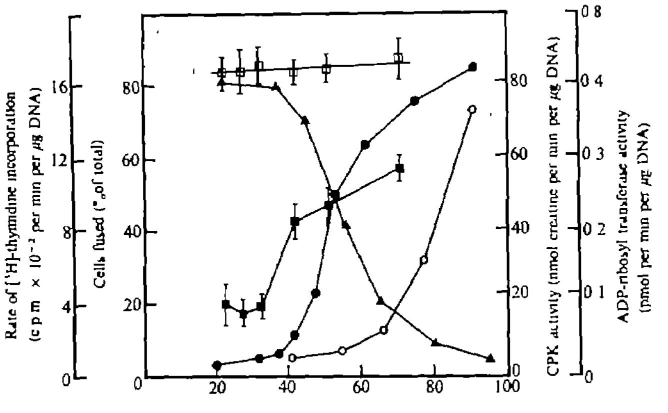

Fig. 1 Muscle cell differentiation *in vitro*. Myoblasts were isolated from the thigh muscle of 12-day-old chick embryos by mechanical dissociation and selective plating according to the method of Mân *et al.*[31]. Cell suspensions were seeded at 0.5×10^6 cells per 6-cm collagen-coated plates in 2.5 ml M199 medium (Earle's salts) supplemented with 10% (v/v) selected horse serum, 2.5% (v/v) embryo extract, 1 mM glutamine, 50 U/ml^{-1} penicillin and 50 µg ml^{-1} streptomycin. Cultures were then incubated, at 37 °C, in 95% air 5% CO_2 and subjected to a complete change of medium at 24 h. The specific substrate of ADPRT is NAD^+, to which intact cell membranes are impermeable. Isolated nuclei are unsuitable because the process of nuclear isolation induces DNA strand breaks and activates ADPRT[9,10]; thus it is necessary to use permeabilized cells to measure ADPRT activity. The myoblast and myotubes were made permeable to ^{3}H-NAD by a mild, brief hypotonic treatment by a modification of the method of Reinhard *et al.*[32]. Muscle cells on 6-cm plates were washed three times with ice-cold Pucks saline A (5.4 mM $MgCl_2$, 137 mM NaCl, 4.2 mM $NaHCO_3$ and 5.5 mM glucose). The plates were then flooded with 1.0 ml of a hypotonic solution containing 9 mM HEPES *p*H 7.8, 5 mM dithiothreitol, 4.5% (w/v) dextran (average molecular weight 110,000), 1 mM EGTA and 4.5 mM $MgCl_2$. The plates were then kept at 4 °C, until more than 90% of the cells had become permeable to Trypan blue; this was routinely achieved after ~20 min for both myoblasts and myotubes; the kinetics were similar in the two sets of cells (data not shown). Permeabilization was monitored by studying plates set up in parallel. After permeabilization, the plates were transferred to a water bath at 25 °C, and the ADP-ribosyl transferase assay was started by the addition of 200 µl of a solution containing 200 mM HEPES *p*H 7.8, 750 mM KCl, 5 mM dithiothreitol, 4.5% (w/v) dextran, 1.35 M sucrose, 7.0 mM EGTA, 4.5 mM $MgCl_2$, 6.0 mM isonicotinic acid hydrazide, 18 mM NaF and 600 µM ^{3}H-NAD (20 mCi mmol^{-1}). The enzyme incubation was continued for 10 min and then terminated by the addition of 2 ml of ice-cold 20% (w/v) trichloroacetic acid (TCA), containing 1% (w/v) nicotinamide and 2% (w/v) tetrasodium pyrophosphate. The acid-insoluble radioactivity was then estimated by scintillation counting. The DNA content of each sample was determined by the method of Kissane and Robins[33]. The acid-insoluble radioactivity was demonstrated to be poly(ADP-ribose)[34]. Incorporation was linear for at least 10 min at all stages of culture studied. The permeabilization procedure induced no detectable DNA strand breaks and at the end of the ADPRT assay the single-strand DNA molecular weight on alkaline sucrose gradients was the same as that in the untreated cells (results not shown). Total ADPRT activity was estimated by including a final concentration of 0.5% (v/v) Triton X-100 and 100 µg ml^{-1} of DNase I in the assay mixture. ■, Physiological ADPRT activity; □, total potential ADPRT activity. The fraction of muscle cells fused (●) was determined as previously described[29]. Each point in the figure is the mean of at least six measurements in three separate experiments; the bars represent the standard error of the mean. Percentage of fused myoblasts (●) and CPK activity (○) were measured as previously described[35]. The rate of DNA synthesis (▲) was estimated by pulsing the cultures with 1 µCi ml^{-1} ^{3}H-thymidine (1 Ci mmol^{-1}) for 1 h.

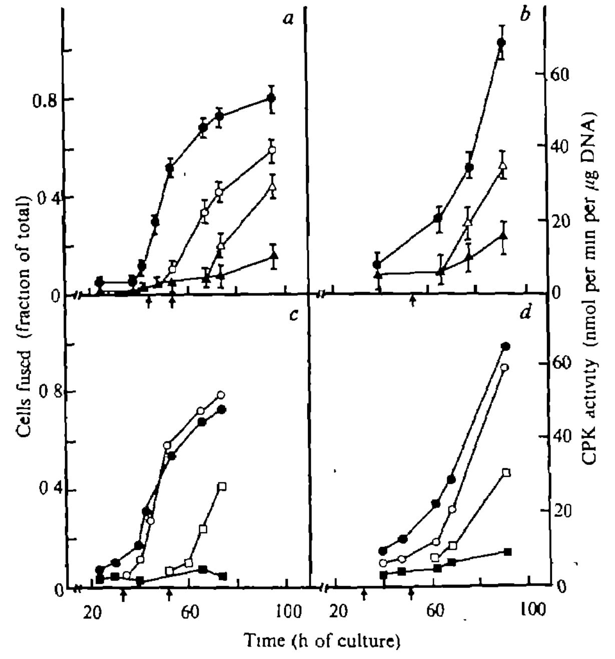

Fig. 2 Reversible inhibition of myoblast terminal differentiation. Reversible inhibition by 3-aminobenzamide (*a*, *b*) and by depletion of NAD levels (*c*, *d*). *a* And *c* show myoblast cell fusion, *b* and *d* show CPK activity. *a*, *b*, Muscle cells were prepared and cultured as described in Fig. 1 legend. ●, Control; ▲, continuous presence of 8 mM 3-aminobenzamide. The medium containing inhibitor was removed and replaced with medium from parallel control cultures of the same age at 44 h (○) or 54 (△) h. Each point is the mean of six measurements in three separate experiments; the bars are the standard errors. CPK activity was estimated as previously described[35]. *c*, *d*, Muscle cells were cultured in nicotinamide-free medium with dialysed serum and embryo extract. ■, No nicotinamide; 1 mM nicotinamide added at the time of plating (0 h ●), at 34(*c*) or 32(*d*) h of culture (○), or at 52 h of culture (□) Each point is the mean of at least two independent experiments. The arrows indicate the time at which the inhibitor was removed or nicotinamide returned in each experiment, as indicated above.

Because of a possible objection to the use of enzyme inhibitors, we also experimentally manipulated ADP-ribosylation by partially depleting the cells of their NAD content, by nicotinamide starvation[13]. After 44 h of culture in a nicotinamide-free medium the NAD level had fallen to 29 ± 3% (mean ± s.e.m., $n = 6$ in two separate experiments). Nicotinamide (1 mM) can restore the control NAD level within 4.5 h. The NAD-depleted myoblasts do not fuse to form multinucleated fibres (Fig. 2*c*), nor do they show the usual rise in CPK activity (Fig. 2*d*). This block in cell differentiation is reversible; the re-addition of 1 mM nicotinamide to the depleted cultures at 32 or 52 h reverses the inhibition 6 or 8 h later respectively (Fig. 2*c*, *d*).

In several cases, in both prokaryotes and eukaryotes, alterations in gene activity involve changes in the DNA, including DNA modification, gene rearrangement and DNA transpositions[23,24]. We might therefore expect DNA strand breaks to appear during certain types of change in gene expression and cytodifferentiation.

In alkaline sucrose gradients which estimate the size of single-stranded DNA, the DNA from proliferating cultures has a high molecular weight (Fig. 3*a*). At 44 h, when only 15% of the cells have fused (see Fig. 1), there is a significant reduction in the molecular weight of the cellular DNA (Fig. 3*b*). By 53 h the maximum number of single-strand breaks are present (Fig. 3*c*), although only 50–60% of the myoblasts have fused. The molecular weight then remains constant up to 92 h of culture (Fig. 3*c*–*f*). Only single-strand breaks appear in the DNA; there is no decrease in the molecular weight of the DNA in neutral sucrose gradients containing ionic detergents between 25 and 92 h of culture (Fig. 3*g*). We have been unable to establish what happens after 92 h of culture, so we do not yet know whether the DNA breaks persist or are subsequently rejoined. The experiments displayed in Fig. 3 are also 'mixing' experiments, and show that in our experimental conditions, mixing of early (without strand breaks) and late (with strand breaks) cells does not induce strand breaks in the DNA of early cells (see Fig. 3*b*–*f*).

Alkaline sucrose gradients detect single-strand breaks that are induced by the alkaline conditions of the gradients (for example, apurinic sites), as well as true single-strand breaks which had been generated enzymatically. We have distinguished between these two phenomena by examining the sedimentation rate of nucleoids[25]. In neutral sucrose gradients containing 1.0 M NaCl, nucleoids from 24 and 38 h cultures sediment rapidly; in contrast, 6 h later, at 44 h, the nucleoids sediment more slowly, and by 68 h a considerable number of metabolically induced single-strand DNA breaks are evident (Fig. 4*a*). Increasing the salt concentration of the gradients to 1.95 M NaCl, and thus stripping the nuclei of yet more of their protein, does not alter the results significantly (Fig. 4*a*). Thus, the reduction in the sedimentation of the nucleoids is not due to changes in the protein composition of the chromatin.

This inference is also drawn from several experiments with ethidium bromide. In the presence of 5 μg ml^{-1} ethidium

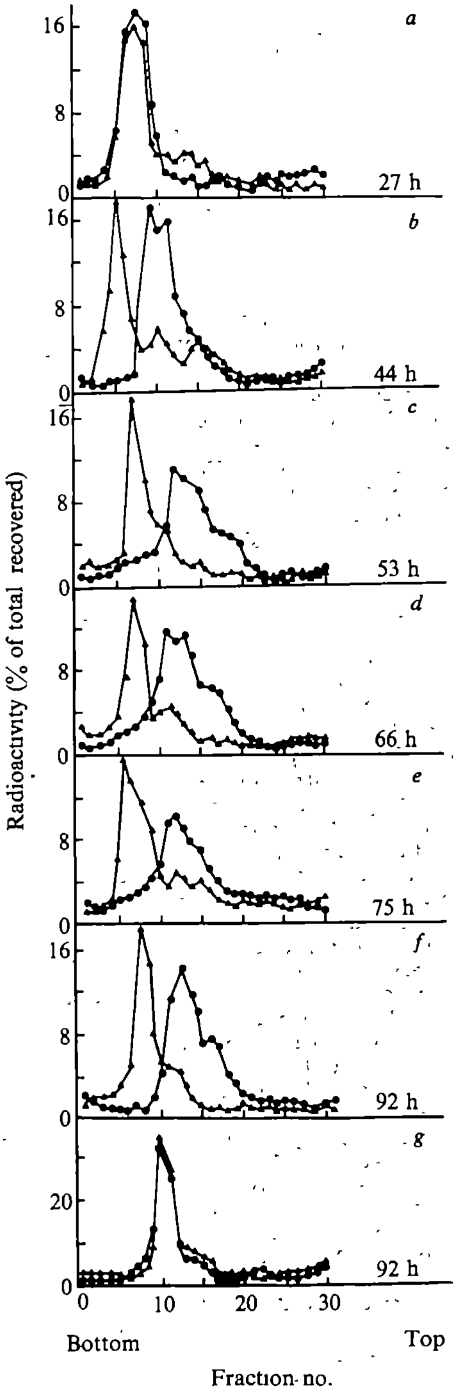

Fig. 3 *a*–*f*, Molecular weight analysis of muscle cell DNA by alkaline sucrose gradients. Muscle cell cultures were radioactively labelled by the continuous presence of 1 μCi ml^{-1} ^{3}H-thymidine, or of 0.2 μCi ml^{-1} ^{14}C-thymidine. Before collecting the cells for the analysis of DNA molecular weight they were incubated in fresh medium for a further 3 h in the absence of radioactive nucleosides. The plates were washed twice in phosphate-buffered saline (PBS) containing 10 mM EDTA, and then cells were scraped off in the PBS-containing EDTA using a rubber policeman. 50 μl of ^{3}H-labelled and 50 μl of the ^{14}C-labelled cell suspensions, each containing the equivalent of $1–2 \times 10^4$ nuclei, were mixed and deposited in 400 μl of lysis buffer (100 mM NaOH, 100 mM NaCl, 10 mM EDTA, 0.2% (w/v) sarcosyl) over a 12-ml, 5–25% linear sucrose gradient containing 100 mM NaOH and 100 mM NaCl. The gradients were kept in the dark for 30 min at 20 °C, and then centrifuged for 2 h at 25,000 r.p.m. in a Beckman SW27 rotor. 400-μl fractions were collected on filter strips from the bottom of the gradients and the TCA-insoluble radioactivity estimated by scintillation counting. ▲, 27-h cultures labelled with ^{14}C-thymidine; ●, 44-, 53-, 66-, 75- and 92-h cultures labelled with ^{3}H-thymidine. g, Molecular weight analysis of muscle cell DNA by neutral sucrose gradients. Muscle cell cultures were radioactively labelled and collected as described above. The equivalent of $1–2 \times 10^4$ nuclei were deposited in 400 μl of lysis buffer (0.2% (w/v) sarcosyl, 0.08% (w/v) sodium deoxycholate, 1.5 M NaCl, 100 mM sodium citrate and 20 mM EDTA, *p*H 8.9) over a 12 ml 5–25% linear sucrose gradient containing 2.0 M NaCl, 10 mM sodium citrate and 1.0 mM EDTA, *p*H 8.9, over a cushion of 0.5 ml 60% sucrose. The gradients were kept in the dark for 1 h at 20 °C, and then centrifuged for 1 h at 20,000 r.p.m. in a Beckman SW27 rotor. 400-μl fractions were collected on filter strips from the bottom of the gradients and the TCA-insoluble radioactivity estimated by scintillation counting. ▲, 25-h culture labelled with ^{14}C-thymidine; ●, 92-h culture labelled with ^{3}H-thymidine.

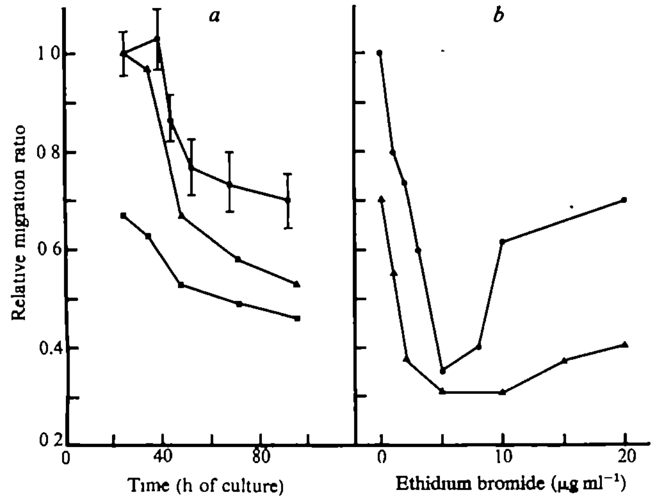

Fig. 4 *a*, The nucleoid sedimentation rate of muscle cells at different stages in culture. 50 μl of muscle cells suspended in PBS (containing the equivalent of $1\text{–}5\times10^5$ nuclei) were deposited inside 150 μl of lysis buffer (giving a final concentration of 2 mM EDTA, 0.5% (v/v). Triton X-100 and 100 mM Tris-(hydroxymethyl)-aminomethane *p*H 8.0) over a 4.6 ml 15–30% linear sucrose gradient containing 1 mM EDTA and 10 mM Tris-(hydroxymethyl)-aminomethane *p*H 8.0. The lysis mixture and the gradients also contained 1.0 M NaCl (●), 1.95 M NaCl (▲), or 1.95 M NaCl and 5 μg ml⁻¹ ethidium bromide (■). The gradients were kept in the dark for 30 min at 20 °C and then centrifuged at 10,000 r.p.m. in a Beckman SW50.1 rotor for 30 min. The gradients were collected from the bottom of the centrifuge tubes and pumped through a flow cell. The positions of the nucleoids were determined by measuring the absorbance at 254 nm, and are expressed as a fraction of the distance migrated by the nucleoids of 24-h cultures in the same conditions (●, ▲) or in 1.95 M NaCl (■). The error bars represent the standard error of the mean of at least three measurements. Nucleoids are residual nuclei stripped of most of their proteins by high-salt solutions and neutral detergents. Single-strand breaks in local domains of supercoiled DNA relieve the supercoiling, and lead to an expansion of the volume of the nucleoids and to a slower rate of sedimentation. *b*, The effect of ethidium bromide on the sedimentation rate of muscle cell nucleoids. Procedure as in *a* except that the lysis mixture and the gradients contained 1.95 M NaCl and the indicated concentration of ethidium bromide. Nucleoids from 24-h (●) or 72-(▲) h cultures were kept in the lysis mixture for only 15 min before being centrifuged at 10,000 r.p.m. for 45 min. The nucleoid sedimentation rate is expressed as a fraction of the distance migrated by nucleoids from 24-h cultures in the absence of ethidium bromide. The binding of intercalating agents, such as ethidium bromide, to DNA molecules under topological constraint produces a characteristic biphasic effect. With increasing concentrations of intercalating agents the number of superhelical turns are reduced and eventually a minimum value is reached. Increasing the concentration further introduces 'negative' turns in the DNA[36]. The introduction of single-strand breaks in the local DNA domains eliminates the topological constraint and reduces the characteristic effect of the intercalating agent on the nucleoid as a whole. These changes in the extent of DNA supercoiling are reflected in the sedimentation rate of the nucleoids in neutral sucrose gradients[37].

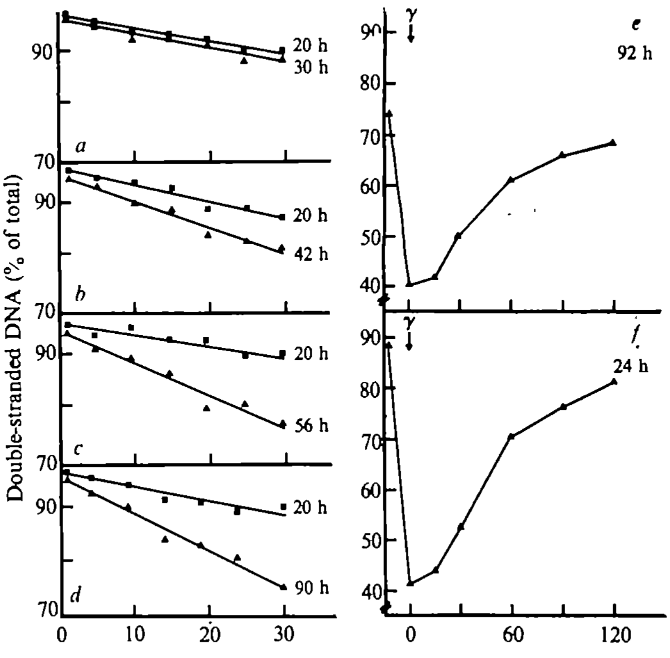

Fig. 5 *a–d*, Rate of DNA strand separation in alkali. The rate of DNA strand separation in alkali was measured with the Rydberg[27] modification of the Ahnström–Erixon alkaline denaturation and hydroxyapatite procedure[26,28]. Briefly, DNA strand separation was initiated by the injection of 50 μl of cell suspension containing the equivalent of $1\text{–}2\times10^4$ nuclei from a 20-h culture labelled with ^{14}C-thymidine (■) and $1\text{–}2\times10^4$ nuclei from ^{3}H-thymidine-labelled cultures at 30, 42, 56 or 90 h of culture (▲) into 1 ml of the alkaline solution containing 30 mM NaOH, 10 mM Na_2HPO_4 and 900 mM NaCl, *p*H 12.0. The injection was forceful to ensure adequate and immediate mixing of the cell suspension and the alkaline solution. This mixture was immediately placed in the dark and kept at 20 °C for the required period. The DNA strand separation was terminated at intervals by the injection of 1 ml of ice-cold 34 mM HCl. Within 5 s of the neutralization, the solution was sonicated for 15 s. Before separating the single- and double-stranded DNA on hydroxyapatite columns, 80 μl of 10% (w/v) SDS solution was added to each sample (~2.0 ml) to obtain a final SDS concentration of 0.4%. Samples were then loaded on 5×30 mm hydroxyapatite columns equilibrated with 10 mM potassium phosphate buffer, *p*H 6.9. The unbound nucleotides were eluted with 2 ml of 10 mM potassium phosphate buffer and the single- and double-stranded DNA was eluted with 3×0.5 ml of 125 mM and 400 mM phosphate buffer respectively. The total radioactivity loaded, and the single- and double-stranded DNA recovered, were measured by scintillation counting. A standard curve was established by exposing 24-h myoblast cultures to 50–300 rad of γ-radiation (results not shown). These cultures have accumulated very few endogenous single-strand breaks at this time. The logarithm of the percentage of double-stranded DNA remaining after 30 min in alkali declines linearly with the applied dose of radiation. Chick muscle cell DNA as a molecular weight of $\sim10^{12}$, calculated from a diploid DNA content of 2.5 pg per nucleus. We estimate that approximately two single-strand breaks are formed per 10^{12} daltons per rad[38]. We can now convert the percentage of double-stranded DNA remaining to the number of single-strand breaks per 10^{12} daltons. *e*, *f*, Rate of DNA repair following γ-radiation. 24- And 92-h muscle cell cultures were irradiated with 300 rad of γ-radiation. The rate of strand-rejoining was estimated by measuring the rate of DNA strand separation in alkali following the re-incubation of the irradiated cells in fresh medium for the indicated times.

bromide, the sedimentation of nucleoids from 24-h cultures is reduced from 1.0 to 0.67 (Fig. 4*a*). However, the same concentration of ethidium bromide has a much smaller effect on the sedimentation at 96 h, which is only reduced from 0.56 to 0.46. In nucleoids from 24-h cultures, increasing concentrations of ethidium bromide induce the biphasic effect characteristic of DNA molecules under topological constraints (Fig. 4*b*), whereas nucleoids from 72-h cultures are affected less (Fig. 4*b*), probably due to the presence of single-strand breaks. We have estimated the number of single-strand DNA breaks[26–28] in differentiating muscle cell DNA, from 20 to 90 h (Fig. 5*a–d*); few single-strand breaks were detectable in the DNA at either 20 or 30 h, but by 42 h approximately 50–100 single-strand breaks per 10^{12} daltons (per diploid genome) had appeared. By 56 h they had increased to 100–300 per genome (Fig. 5*c*), and did not increase thereafter (Fig. 5*d*).

The presence of DNA strand breaks in differentiating cells may be attributed to a general deficiency of DNA repair.

However, these differentiating muscle cells are proficient in repair and can readily rejoin single-strand breaks. There is no detectable decline in the ability to rejoin DNA strand breaks caused by γ-irradiation (Fig. 5*e*, *f*). In the 92-h cultures (Fig. 5*e*), a significant number of DNA strand breaks exist before irradiation; exposure to 300 rads of γ-radiation would be expected to introduce a further 600 breaks, about twice as many as were metabolically engendered. The rate at which these breaks were rejoined was the same as that in 24-h myoblasts—but rejoining stopped when the number of breaks had dropped to the endogenous level. This implies that these endogenous breaks are retained in the face of a proficient DNA strand-rejoining capacity, perhaps because they are of a special character or occur at specific nucleotide sequences; alternatively, there may be a shift in the steady-state level of breaks.

Our observations have been confirmed and extended in subsequent studies showing that ADPRT activity is required for the differentiation of the protozoan *Trypanosoma cruzi* (G. T. Williams, personal communication), the stimulation of resting circulating human lymphocytes[29] and the cytodifferentiation of hepatocytes[30]. The involvement of DNA strand breaks in some categories of cellular differentiation may be the molecular basis for the requirement of ADPRT in cytodifferentiation.

Thus we propose that a reduction in the single-strand molecular weight of the DNA and the consequent obligatory increase in the intrinsic, physiological ADPRT activity are integral and early events in the cellular differentiation of primary chick myoblast cultures. The single-strand breaks may signify some underlying mobility of the genome. The results reported here are consistent with the notion that nuclear ADPRT participates commonly in situations where nicking and rejoining of DNA occur.

The nuclear enzyme ADP-ribosyltransferase (ADPRT) catalyses the postsynthetic modification of chromatin proteins[1]. The significance of [ADP-ribose]$_n$-modified chromatin proteins for the regulation of chromatin function is not understood[1]. Recently, [ADP-ribose]$_n$ biosynthesis has been demonstrated to participate in the repair of some types of DNA damage[2–4]. Here we demonstrate that another function of [ADP-ribose]*n* biosynthesis is related to the regulation of the expression of two fetal functions of cultured hepatocytes—the K-type (III) isozyme of pyruvate kinase, and γ-glutamyltranspeptidase, which is also a marker of early neoplastic transformation of liver cells[5].

An involvement of ADP-ribosylation in cellular differentiation has been inferred from the observation of a temporal relationship between alterations in ADPRT activity and engagement of cells in terminal differentiation[6–11]. However, [ADP-ribose]$_n$ might primarily regulate the proliferative activity[12,13] of cells undergoing terminal differentiation. It has therefore not been possible to ascribe definitively the expression of individual cellular functions during differentiation to changes in ADP-ribosylation activity[1]. The recent introduction of 3-aminobenzamide, the most specific inhibitor of ADPRT known, has made it possible to determine directly the potential involvement of this enzyme in a particular biological process[2,3]. We have used this inhibitor to determine the role of ADPRT in the expression of fetal functions by adult rat hepatocytes in primary monolayer culture.

We found that in rat hepatocytes cultured on collagen gel-nylon meshes[14], ADPRT activity sharply increased to a maximum after 3 days in culture and then decreased to the low levels seen in freshly isolated hepatocytes (Fig. 1*a*). Coincident with the decrease in ADPRT activity, the activities of γ-glutamyltranspeptidase and the fetal (K-type) isozyme of pyruvate kinase sharply increased (Fig. 1*b*). These two enzyme activities are normally high in fetal hepatocytes *in vivo* but disappear shortly after birth[15,16]. Previous studies in cultured hepatocytes have clearly shown that the expression of fetal pyruvate kinase isozyme activity is the result of induction of the isozyme protein[16]. We observed that induction of the fetal pyruvate kinase isozyme was totally inhibited in hepatocyte cultures treated with 3-aminobenzamide (10 mM) or nicotinamide (25 mM), two inhibitors of ADPRT (Fig. 2); this indicates that induction of the isozyme and alterations in ADP-ribosylation activity (Fig. 1) are causally related. The specificity of action[3] of the ADPRT inhibitors was indicated by the inability of the non-inhibitory analogue[2], 3-aminobenzoic acid (1–10 mM), to prevent the expression of the fetal pyruvate kinase isozyme (Fig. 2*a*). In addition, the dose–response curves and the apparent K_is for the actions of 3-aminobenzamide and nicotinamide on ADPRT and pyruvate kinase in intact hepatocytes were very similar[4]. When hepatocytes were maintained for 2–7 days in medium containing 10 mM aminobenzamide or 25 mM nicotinamide, a 70–95% inhibition of ADPRT activity was observed. This inhibition was reversible,

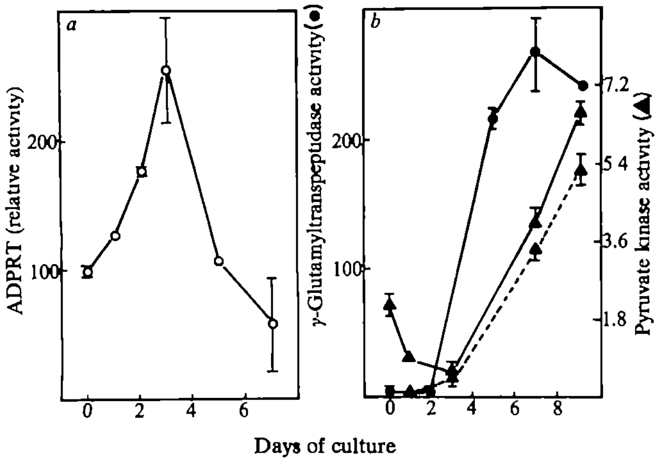

Fig. 1 Alterations in the activities of ADPRT, γ-glutamyltranspeptidase and pyruvate kinase of adult rat hepatocytes cultured on collagen gel-nylon meshes. *a*, Hepatocytes were isolated from male Holtzman rats (200–250 g, fed *ad libitum*) and cultured on collagen gel–nylon meshes as described previously[14] At the times indicated, hepatocytes were recovered from the substratum by brief collagenase treatment[14] and ADPRT activity measured as described elsewhere[4] using ^{3}H-NAD as substrate in cells made permeable with digitonin[23]. All activities are expressed relative to the activity of freshly isolated hepatocytes. Separate experiments indicated that the ADPRT activities measured as ^{3}H-NAD incorporation into hepatocytes following gentle permeabilization with digitonin[23] reflect the physiological enzyme activity of intact cells Thus, a much higher proportion of [2,8-^{3}H]adenosine radioactivity added to the medium of intact hepatocytes was found to be covalently linked to chromatin proteins after a labelling period (3-h pulse) that coincided with high ADPRT activity (day 3 of culture) (Fig. 1) compared to an identical labelling period immediately after plating of cells. This incorporation of [2,3-^{3}H]adenosine radioactivity was inhibited in hepatocytes cultured in the presence of 3-aminobenzamide (10 mM) or nicotinamide (25 mM). *b*, Activities of γ-glutamyltranspeptidase (●—●) and pyruvate kinase (▲—▲) were determined as described[14,16]. ▲---▲, Fetal (K-type) isozyme activity of pyruvate kinase. γ-Glutamyltranspeptidase activity is expressed as nmol *p*-nitroaniline formed per μg DNA per h[14] and pyruvate kinase activity reflects the change in absorbance at 340 nm per μg DNA per h[16]. Bars indicate mean ± s.d of 3–5 measurements in separate cell batches; symbols without bars represent the averaged values from two determinations in two separate cell batches.

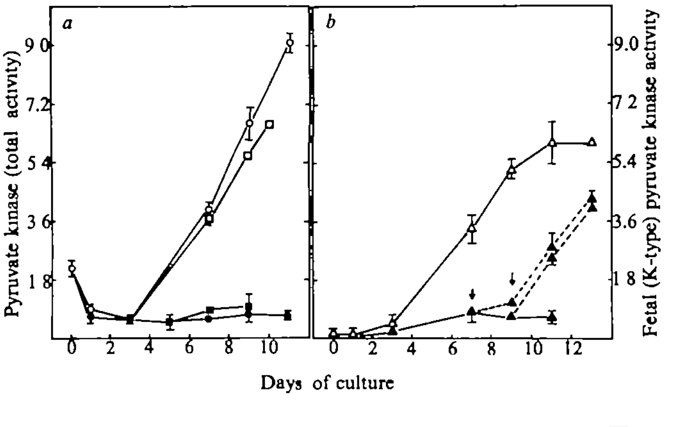

Fig. 2 Effects of the ADPRT inhibitors, 3-aminobenzamide (■, 10 mM) nicotinamide (●, 25 mM), and the non-inhibitory analogue 3-aminobenzoic acid (□, 10 mM), on the expression of pyruvate kinase activity by hepatocytes cultured on collagen gel–nylon meshes. *a*, Total pyruvate kinase activity of hepatocytes maintained in the presence of the above and in control cultures (○). *b*, Activity of the fetal (K-type) isozyme of pyruvate kinase in untreated control (△—△) and nicotinamide-treated (▲—▲) hepatocyte cultures. ▲---▲, Fetal isozyme activity after withdrawal (arrows) of nicotinamide from the culture medium. Bars indicate mean ± s.d. of 3–5 separate cell prepartions; symbols without bars represent the averaged values from two determinations in two separate cell batches. None of the ADPRT inhibitors had any direct effect on pyruvate kinase activity *in vitro*.

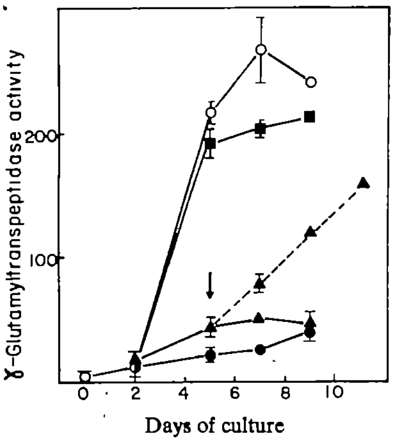

Fig. 3 Effect of nicotinamide (▲—▲, 25 mM), 3-aminobenzamide (●—●, 10 mM) and 3-aminobenzoic acid (■—■, 10 mM) on the expression of γ-glutamyltranspeptidase activity by hepatocytes cultured on collagen gel–nylon meshes. ○—○, Enzyme activities of untreated control cultures. ▲---▲, Enzyme activity after withdrawal (arrow) of nicotinamide from the culture medium. Inhibition of γ-glutamyltranspeptidase expression was also observed with other ADP-ribosylation inhibitors such as isonicotinamide, benzamide and theophylline[4]. Results expressed as mean ± s.d. of 3–5 separate measurements; symbols without bars represent the averaged values from two determinations in two separate cell batches. None of the ADPRT inhibitors had any direct effect on γ-glutamyltranspeptidase activity *in vitro*.

as was the repression of the fetal pyruvate kinase isozyme (Fig. 2*b*).

We then investigated the possibility that ADP-ribosylation might have a coordinative function in the expression of hepatocellular functions *in vitro*. We studied the effect of 3-aminobenzamide and nicotinamide on the expression in cultured hepatocytes of albumin, α-fetoprotein and γ-glutamyltranspeptidase[14]. The expression of γ-glutamyltranspeptidase activity was suppressed by this treatment (Fig. 3), whereas the expression of α-fetoprotein and albumin was unaffected (data not shown) as judged by immunological quantification of these proteins using monospecific antibodies[14]. The inhibition of γ-glutamyltranspeptidase expression required the presence of ADP-ribosylation inhibitors during the first 5 days of culture. Treatment of hepatocytes after day 5 of culture, that is, when ADPRT activity had returned to low levels (Fig. 1), caused only marginal inhibition (~10%) of this expression. The specificity of action for ADPRT inhibitors was indicated by the inability of the non-inhibitory analogue[2], 3-aminobenzoic acid (1–10 mM), to inhibit the expression of γ-glutamyltranspeptidase activity (Fig. 3). A histochemical study[17] revealed that γ-glutamyltranspeptidase was uniformly suppressed in all hepatocytes of a culture dish, indicating that the actions of these ADPRT inhibitors were not selective for a small cell population within the liver (data not shown). In addition, the effect of these inhibitors on γ-glutamyltranspeptidase expression was reversible (Fig. 3).

Nicotinamide has been reported to inhibit general protein synthesis during the first 24 h of hepatocyte culture [18]. Although we could confirm this observation, we found that both nicotinamide (25 mM) and 3-aminobenzamide (10 mM), stimulated ^{3}H-leucine incorporation into total hepatocellular proteins after this initial culture period. Therefore, we conclude that the effects of these two ADPRT inhibitors on the expression of pyruvate kinase and γ-glutamyltranspeptidase are not due to a general inhibition of protein synthesis. Similarly, previous studies from our laboratory demonstrated the independence of the expression of fetal functions by cultured hepatocytes from DNA synthesis activity[14], which increases after 2–3 days in culture in the absence of measurable cell replication. Although this increase in DNA synthesis was slightly inhibited by nicotinamide (25 mM), continuous treatment of hepatocyte cultures for up to 9 days with 3-aminobenzamide did not affect this activity (data not shown). Thus, the action of ADPRT inhibitors on pyruvate kinase expression by the hepatocytes was not related to effects on DNA synthesis. These data also suggest that the presumed specificity of some ADPRT inhibitors might not be absolute. Similarly, effects on extranuclear ADP-ribosylation reactions cannot be totally excluded.

There is increasing evidence that ADPRT activity is largely dormant in the cell nucleus unless factors inducing DNA fragmentation are manifest[1,19–21]. In general, DNA fragmentation presumably then initiates the activation of ADPRT. To test this, we examined hepatocellular DNA for the presence of DNA strand breaks in relation to changes in ADP-ribosylation. Using a slight modification[4] of the sensitive technique of Birnboim and Jevcak[22], we were unable to find an increase in the number of DNA strand breaks either before or concomitant with changes in ADPRT activity (Fig. 1) although we observed a gradual but slow increase in the number of DNA strand breaks with increasing time in culture. This increase was unaffected by 3-aminobenzamide or nicotinamide (data not shown). These results suggest that the transient and spontaneous alterations in ADPRT activity seen in primary cultures of hepatocytes (Fig. 1) are not causally related to DNA fragmentation, which agrees with the observation of Jackowski and Kun[6] who found age-dependent variations in the ADPRT activity of cardiocyte nuclei in the absence of measurable DNA fragmentation.

Our results show that [ADP-ribose]$_n$ metabolism is involved in the regulation of the expression of two fetal functions by adult hepatocytes in primary culture. It will be interesting to determine whether carcinogen-induced alterations in cellular [ADP-ribose]$_n$ metabolism[1] are related to some of the well known functional phenotypic changes associated with neoplastic transformation[5,15].

Role of DNA breaks and ADP-ribosyl transferase activity in eukaryotic differentiation demonstrated in human lymphocytes

Alan P. Johnstone & Gwyn T. Williams

Immunology Department, St George's Hospital Medical School,
London SW17 0RE, UK

ADP–ribosyl transferase (ADPRT) is a DNA-dependent nuclear enzyme which covalently attaches ADP–ribose moieties derived from NAD to proteins to form mono- or poly-ADP–ribosyl derivatives[1,2]. ADPRT activity is strongly stimulated by breaks in DNA[3,4] and the enzyme is required for efficient DNA repair[5–7]. Several reports have suggested that the metabolism of poly- or mono-(ADP–ribose) might also be involved in differentiation in various eukaryotes[1,2,8–12]. In the most convincing of these, inhibitors of ADPRT were shown to block the differentiation of chick myoblasts *in vitro*[11,12], and differentiation was accompanied by the appearance of single-strand breaks in DNA. We present here evidence that ADPRT activity is obligatory early in the mitogen-induced activation of human peripheral blood lymphocytes. The requirement for this enzyme coincides with a rapid (1–8 h) rejoining of single-strand breaks present in the DNA of quiescent lymphocytes. Hence, DNA breaking and rejoining, regulated by ADPRT, may be involved in a general mechanism of differentiation.

Quiescent lymphocytes can be stimulated to differentiate by various polyclonal activators, or 'mitogens', which mimic the effect of specific antigens on individual cells[13–15]. This differentiation involves a change in morphology, initiation of proliferation and acquisition of various effector functions. In the present study human peripheral blood lymphocytes, comprising ~70% T cells, were activated by three mitogens: pokeweed mitogen (PWM), concanavalin A (Con A) and *Phaseolus vulgaris* phytohaemagglutinin (PHA)[13].

The effect of several inhibitors of ADPRT, that is, benzamide[16], 3-aminobenzamide[17], 3-methoxybenzamide[17] and 5-methylnicotinamide[18], on the mitogen-stimulated incorporation of ^{3}H-thymidine was studied. If they were added slightly before or at the same time as the mitogen, all of the inhibitors significantly decreased the response to all three mitogens; 3-methyoxybenzamide and 5-methylnicotinamide were the most effective (Fig. 1). Conversely, if the inhibitors were added to the cells 24 h after PHA or Con A, before any DNA synthesis had occurred, a substantial response was observed (Fig. 1*b*, *c*). The incorporation of ^{3}H-thymidine at day 2 was near to normal and only the cells responding more slowly and synthesizing DNA at days 3 and 4 were substantially affected by this later addition of inhibitors.

At the concentrations used, the inhibitors did not affect lymphocyte viability, assessed by exclusion of eosin, over a period of 7 days in culture. Similarly, they did not inhibit the lymphoid cell cycle in the absence of differentiation as evidenced by their lack of significant effect on the proliferation in culture of previously stimulated lymphoblasts (Fig. 1*b*, *c*), human T lymphoblastoid cell lines Molt 4 and CEM (unpublished observations) and murine leukaemic cells L1210[5].

To define more precisely the time during their response at which the cells are susceptible to inhibition, lymphocytes were stimulated with PHA or Con A, and 3-methoxybenzamide or 5-methylnicotinamide was added to the cultures at various times. Figure 2 shows the response observed at day 2. Within 1 h of PHA stimulation, a significant proportion (~20%) of the cells synthesizing DNA at day 2 had escaped from the inhibitable stage and by 12–16 h a plateau was reached when 60–70% of cells had passed through the phase at which they were susceptible to inhibition. The time of addition of inhibitors which corresponded to a response at day 2 of 50% of normal was 15.1±2.3 h for Con A and 8.0±4.2 h for PHA. This is

0028–0836/82/470368—03$01.00

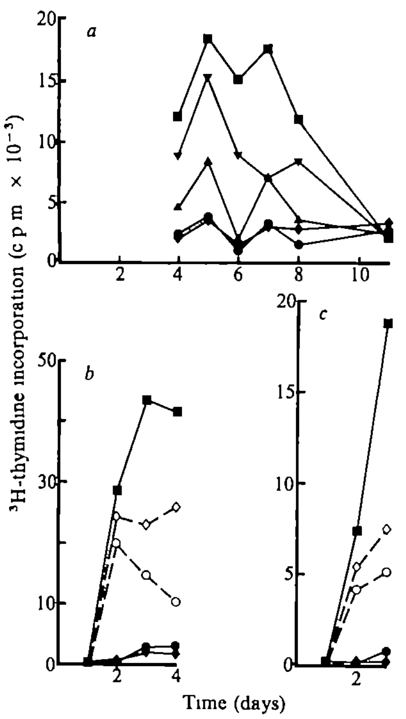

Fig. 1 Effect of inhibitors of ADPRT on lymphocyte transformation. Mononuclear leukocytes, comprising 95% lymphocytes, were islolated from human peripheral blood[28] and incubated at 10^6 cells ml^{-1} at 37 °C in an atmosphere of 5% CO_2 in RPMI 1640 medium containing 25% human AB serum and 1/250 dilution of PWM (Gibco) (*a*), 5% fetal calf serum and 2.5 $\mu g\ ml^{-1}$ PHA leukoagglutinin (Pharmacia) (*b*), or 5% fetal calf serum and 1 $\mu g\ ml^{-1}$ Con A (Sigma) (*c*). The cells were incubated with medium containing no inhibitor (—■—), 2.5 mM benzamide (—▼—), 5 mM 3-aminobenzamide (—▲—), 2.5 mM 3-methoxybenzamide (—◆—) or 5 mM 5-methylnicotinamide (—●—) from 30 min before the addition of mitogen. Alternatively, freshly dissolved 2.5 mM 3-methoxybenzamide (--◇--) or 5 mM 5-methylnicotinamide (--○--) was added to the cultures 24 h after addition of mitogen. [6-^{3}H]thymidine (5 Ci $mmol^{-1}$; Amersham) was added to a final concentration of 2 $\mu Ci\ ml^{-1}$ for the final 6 h before the cells were collected onto Whatman GF/C paper and washed with water using a cell harvester at the times indicated after mitogen stimulation. Each point represents the mean c.p.m. incorporated into DNA of duplicate 200-µl cultures. Control cultures without mitogen incorporated 300–1,000 c.p.m. The time course of the PWM response is invariably slower than that of the other two mitogens.

consistent with the slower response to Con A compared with PHA in our system (Fig. 1).

ADPRT is involved in increasing DNA ligase II activity[7] and so the depression of the lymphocyte response by inhibitors of ADPRT suggests that ligation of DNA might be an obligatory early event during lymphocyte activation. To test for this, the migration of lymphocyte 'nucleoids' on sucrose density gradients was observed at various times after mitogen stimulation (Fig. 3). Nucleoids are prepared from eukaryotic cells by lysis in a non-ionic detergent in the presence of high salt and EDTA[19,20]. They have lost most of the nuclear protein and consist of DNA in a supercoiled conformation. Any breaks in DNA decrease the constraints on the supercoiled structure, allowing it to expand and causing the nucleoid to migrate more slowly in the density gradient. Determination of the nucleoid sedimentation rate is therefore a very sensitive method for detecting single-strand breaks[21,22].

Nucleoids from PHA-stimulated lymphocytes sedimented faster through the density gradients than those derived from quiescent lymphocytes. This difference could be detected as early as 1 h after stimulation and was maximal after about 8 h (Fig. 3). The change in sedimentation rate was much slower if 3-methoxybenzamide or 5-methylnicotinamide was included in the culture medium (Fig. 3, compare *e* with *f* in expt 1; compare *c* with *h*, and *e* with *i* in expt 2). The increased rate of sedimentation of nucleoids from activated lymphocytes demonstrated that single-strand breaks present in the DNA of resting lymphocytes are rapidly rejoined after PHA stimulation. This early ligation of DNA breaks may be directly involved in inducing the expression of new genes responsible for the programmed activation of lymphocytes. Other workers have reported that lymphocyte nucleoids sediment much more slowly than those from most other cells[19,20,22], but the existence of DNA breaks in quiescent lymphocytes was unexpected and intriguing.

There is a close temporal correlation during lymphocyte activation between DNA strand rejoining and susceptibility to blocking of the response by ADPRT inhibitors (compare Figs 2 and 3). This observation, together with the inhibition of strand rejoining by inhibitors of ADPRT (Fig. 3) and the established role of ADPRT in DNA repair[5–7,21], suggests that this enzyme controls the rejoining of DNA strand breaks early in differentiation.

Recently, ADPRT activity has been demonstrated in membranes and implicated, via adenylate cyclase, in the hormonal regulation of certain tissues[23]. It is conceivable that the chemicals we have used produce their effects by inhibiting the membrane enzyme rather than the nuclear enzyme. However, as mitogen stimulation of lymphocytes, unlike the effect of some polypeptide hormones, cannot be attributed simply to adenylate cyclase activity[13], we consider this possibility unlikely.

ADPRT activity and the formation of single-strand breaks in DNA have previously been correlated with differentiation in chick embryo myoblasts[11,12]. In addition, the morphological differentiation of the protozoan parasite, *Trypanosoma cruzi*, can be blocked by inhibitors of ADPRT (manuscript in preparation). Most importantly, the enzyme activity does not seem to be involved in cell cycle processes because its inhibition does not affect proliferation in the absence of differentiation in any of the three systems. This illustrates the operational specificity of the inhibitors. The concordant results obtained in these diverse systems support the hypothesis that ADPRT and transient DNA breaks are widely involved in the differentiation of eukaryotic cells.

It is possible that these events are involved in a specific rearrangement of genetic material as a ubiquitous mechanism for coherently altering gene expression during differentiation. Indeed, recent data suggest that there are some differences in

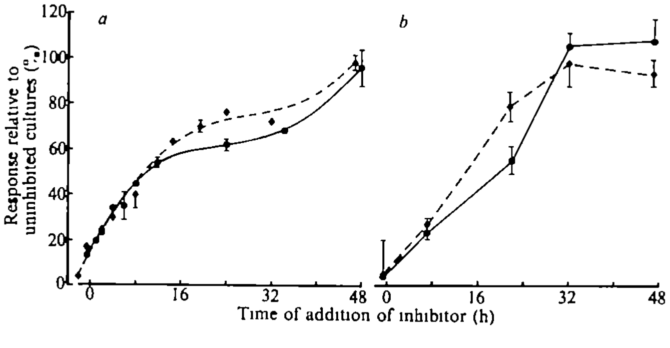

Fig. 2 Kinetics of susceptibility to inhibition during lymphocyte activation. In four separate experiments, lymphocytes were isolated from four individuals and cultured with PHA (*a*) or Con A (*b*) at time zero as described for Fig. 1. 2.5 mM 3-methoxybenzamide (—◆—) or 5 mM 5-methylnicotinamide (—●—) was added to the cultures at the times indicated before or after addition of mitogen. The cultures were pulsed with ^{3}H-thymidine at 48 h and collected at 52 h as described for Fig. 1. The results are expressed as a percentage of the response (c.p.m. incorporated into DNA) in control cultures to which medium was added at the same time as inhibitor solution was added to the test cultures; 100% response represents 25,000–35,000 c.p.m. for PHA and 5,000–10,000 c.p.m. for Con A. Each point represents the mean ± s.e.m. for triplicate 200-µl cultures.

the arrangement of genetic material between different tissues of an individual person[24]. The controlled appearance of temporary breaks in the DNA backbone could also be required to relax the tightly packed chromatin structure in particular areas, thus allowing the transcription of new genes[25-27].

In addition to the exciting theoretical concepts outlined above, our present report suggests that chemicals which inhibit ADPRT activity may have several practical clinical uses. For example, if mitogen-induced activation of lymphocytes *in vitro* is indeed a valid model for antigenic stimulation of the immune system *in vivo*, the inhibitors should specifically block new immune responses while allowing established ones to continue. This would be very useful for many applications requiring immunomodulation, in particular during tissue transplantation.

We thank Dr Farzin Farzaneh and Professor Sydney Shall for encouragement and advice throughout this study and for the gift of 5-methylnicotinamide; also Dr Leslie Hudson and Dr Mike Clemens for much helpful discussion, Caroline Bullock for technical assistance, and the numerous colleagues who donated blood. This work was supported by grants from the Cancer Research Campaign, the Overseas Development Administration and the MRC.

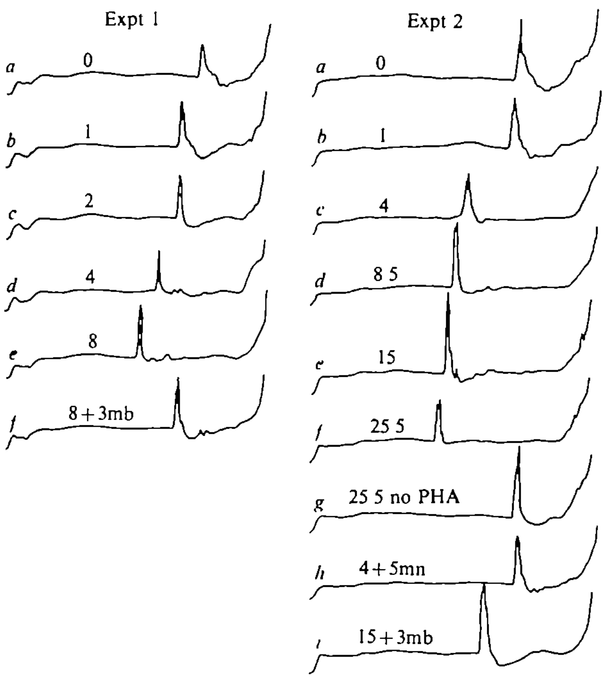

Fig. 3 Changes in nucleoid sedimentation rate during lymphocyte activation. In two separate experiments, lymphocytes were isolated from two individuals and 5×10^5 cells cultured with PHA as described for Fig. 1*b*. After varying times, the cells were washed once with ice-cold 10 mM sodium phosphate, 0.15 M NaCl *p*H 7.3 and deposited (in ~100 µl) inside a layer of 400 µl of 0.5% Triton X-100, 10 mM Tris, 10 mM EDTA, 2 M NaCl *p*H 8.0 lying on top of a 11.5 ml gradient of 5–20% (w/v) sucrose in 10 mM Tris, 10 mM EDTA, 2 M NaCl *p*H 8.0 in a Beckman SW41 centrifuge tube. After incubation for 15 min at 20 °C, the gradients were centrifuged at 25,000 r.p.m. ($100{,}000g_{max}$) for 30 min at 20 °C and eluted from the bottom through the flow cell of a Unicam SP8000 recording spectrophotometer set at 260 nm. The absorbance profiles (bottom of gradient on the left) obtained from the following cultures are presented. Expt 1: lymphocytes incubated at 37 °C with PHA for: *a*, 0; *b*, 1 h; *c*, 2 h; *d*, 4 h; 8 h (*e*, *f*). Before addition of mitogen, cells were incubated for 16 h at room temperature in medium alone (*e*) or 2.5 mM 3-methoxybenzamide (*f*). Expt 2: lymphocytes incubated at 37 °C for: *a*, 0; *b*, 1 h; *c*, 4 h; *d*, 8.5 h; *e*, 15 h; *f*, 25.5 h; *h*, 4 h; *i*, 15 h with PHA or for 25.5 h without PHA(*g*). Before addition of mitogen, cells were incubated for 4 h at 37 °C in medium alone (*c* and *e*) or 5 mM 5-methylnicotinamide (*h*) or 2.5 mM 3-methoxybenzamide (*i*). Each nucleoid does not sediment totally independently and so the peaks obtained represent the average migration of a heterogeneous population.

A new wild-derived *H-2* haplotype enhancing *K-IA* recombination

Toshihiko Shiroishi, Tomoko Sagai & Kazuo Moriwaki

Department of Cytogenetics, National Institute of Genetics,
Mishima Yata-1111, Shizuoka-Ken, Japan 411

It is generally accepted that the overall recombination frequency between the *H-2K* and *H-2D* loci of the mouse major histocompatibility complex (*H-2*) is at a low level of about 0.4%[1]. However, the value fluctuates depending upon the combinations of *H-2* haplotypes in the heterozygote[1]. We re-examined the intra-*H-2* recombination frequency, using three B10.W congeneic strains which carry the *H-2* complex of Japanese wild mice. Of the three, one strain, B10.MOL-SGR($H\text{-}2^{wm7}$), showed an extremely high incidence of recombination (about 3%) in all combinations with three different inbred B10 congeneic strains. The serological typing of these recombinants revealed that most of the crossing-over points had occurred between the *H-2K* and *IA* loci. These results suggest that the *wm7* haplotype enhances specific recombination irrespective of *H-2* partners in heterozygous parents.

In the past five years we have produced several new *H-2* congeneic strains by introducing the *H-2* complex of Japanese wild mice into the C57BL/10J (B10) genetic background[2]. Japanese wild mice, *Mus musculus molossinus*, are genetically very remote from the European subspecies, *Mus musculus domesticus*. It is estimated that ancestral mice diverged into these subspecies about one million years ago[3,4]. Consequently, many genetic mutations seem to have accumulated in their genomes. Recent genetic research has shown that most inbred laboratory strains are derived from the European subspecies[5]. This finding prompted us to re-examine the intra-*H-2* recombination frequency in heterozygotes between inbred B10 congeneic strains and the B10.W strains produced in our laboratory.

All mice used in the present study are shown in Table 1, together with serological typing of their *H-2K*, *IA*, *IE*, *Ss-Slp* and *H-2D* loci. Table 2 summarizes the recombination

H–2 alloantisera were produced in our laboratory according to the immunization schedules described in the NIH catalogue[6]. These are D23(anti-K 23), D33(anti-K.33), D4(anti-D.4), D32(anti-D.32) and D2(anti-D.2). Monoclonal anti-Ia antibodies were kindly given by Dr K. Ozato of NIH. These are 26-7-11S(anti-Ia.2), 26-8-16S(anti-Ia.18), 25-9-35(anti-Ia.20), 14-4-S(anti-Ia.7) and 17-3-3S(anti-IE^k). For the last one, the antigenic specificity detected is unidentified. Ss-Slp typing was performed by Ouchterlony double diffusion analysis using rabbit anti-Ss serum and Slp alloantiserum which were kindly given by Dr S. Sakai of Kanazawa University. The microcytotoxicity test was carried out using the flat-type titration plate method previously described[7]. Titres of H–2 antisera and Ia antibodies are indicated as the maximum dilution which kills more than 90% and 50% of the cells respectively.

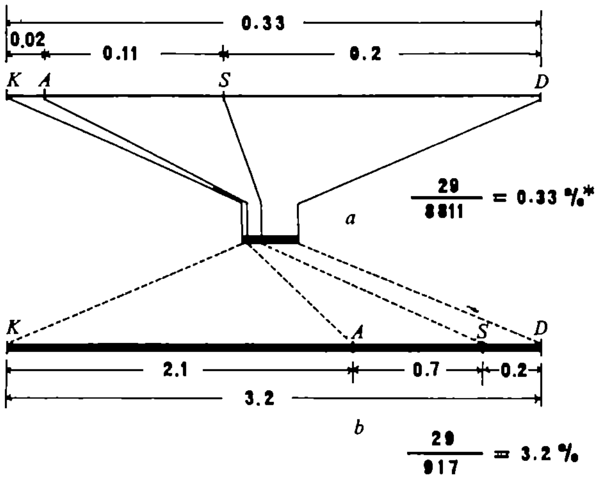

Fig. 1 Comparison between two genetic maps of *H–2* complex. *a*, Standard genetic map previously reported[1]. The map distances represent the average recombination frequency (%) in various combinations of *H–2* haplotypes for males and females together. *b*, Map constructed from the data shown in Table 3. The distances between each loci are slightly underestimated, because two recombinants, *aw16* and *kw1*, whose crossing-over origins were unidentified, were excluded from the calculation of distances*. Data from ref. 1.

frequencies estimated from the present experiments. We screened 1,510 mice and detected 30 recombinants. The overall recombination frequency was estimated to be 1.9%, but the values were strikingly different among the combinations of *H–2* haplotypes. Of the five combinations, *a/wm1* and *a/wm11* showed the standard frequency as reported previously by many investigators. On the other hand, the frequency in the heterozygotes between *wm7* and three different inbred *H–2* haplotypes, *a*, *k* and *b*, was 3–4%, which is almost one order of magnitude higher than the normal recombination frequency.

In order to define the positions of crossing-over in the above three *H–2* combinations, the genotypes of the *IA*, *IE* and *Slp* loci were determined by serological typing. Table 3 demonstrates two features of the recombination event involving the *wm7* haplotype. First, the crossing-over positions are concentrated in the chromosomal segment between *H–2K* and *IA* loci, a segment which many laboratories have observed to have the lowest incidence of recombination (0.02%)[1]. This is conspicuous in the *k/wm7* and *b/wm7* heterozygotes. Of the 27 recombinants examined, at least 19 are derived from crossing-over in this segment. It should be noted that the average recombination frequency among the three combinations is 2.1%. On the other hand, crossing-over between the *Slp* and *D* loci is rare. Crossing-over between these segments was found in only two recombinants, although this is the site with the highest incidence of crossing over that has been observed in combinations of inbred *H–2* haplotypes so far. This site-specific enhancement of recombination can be clearly demonstrated by comparing the genetic map constructed from the present data with the standard map. Figure 1 shows that the relative distance between each marker locus becomes larger toward *H–2K* end in the present map, compared with the standard map. Second, reciprocal recombinant types do not seem to occur with equal frequency. In the eight *b/wm7* heterozygotes, only K^bD^w recombinants were detected except for *bw7*. This tendency is also shown in the *a/wm7* heterozygote, although the K^wD^a type is dominant in this case.

Some of these recombinants were crossed with a third party mouse and the offspring serologically typed with *H–2* antisera. All recombinants examined were confirmed by the test (Table 3). Furthermore, fourteen recombinants derived from the *a/wm7* heterozygote have been established as *H–2* recombinant strains and are now maintained by sib-mating. These were again serologically typed, this time using anti-*H–2*^{wm7} antiserum. For this purpose, (B10.BR×DBA/2J) anti-B10.MOL-SGR alloantiserum was produced and subsequently absorbed by B10.A(R201) (*H–2*^{aw1}, $K^kA^wE^wS^wD^w$) and B10.A(R217) (*H–2*^{aw17}, $K^wA^wE^wS^dD^d$) respectively. It is expected that the resultant two antisera will detect either *H–2D* or *H–2K* specific antigens of the *wm7* haplotype. The reaction of these two antisera to the established recombinant strains was consistent with that expected from the genotypes determined by the antisera detecting the inbred *H–2* haplotypes (Table 3), indicating that genetic rearrangement had occurred in these strains.

This is the first report describing a genetic factor that enhances intra-*H–2* recombination. The mechanism by which the B10.MOL-SGR strain raises the recombination frequency in combinations with other strains is, at present, not clear. However, as all the mice used in the present cross experiment carry the common genetic background of the B10 mouse, the

Table 2 Frequency of intra-*H–2* recombination

H–2 haplotype of heterozygous parents	Method of screening	No. of mice screened	No. of recombinants	Recombination frequency (%)
a/wm1	HA*	294	1	0.3
a/wm11	HA	299	0	—
a/wm7	HA	539	16	3.0
k/wm7	CT†	174	5	2.9
b/wm7	CT	204	8	3.9
Total		1,510	30	1.9

To detect the recombinants, the females of F_1 hybrids between inbred B10 congenic strains and three B10.W strains were backcrossed to the respective parental B10.W strains. The offspring were screened with two H–2 alloantisera which direct either the H–2K or H–2D private antigens carried by the parental inbred *H–2* haplotypes. For the typing, haemagglutination test was used if the antiserum was suitable, if not microcytotoxicity tests against inguinal lymph node cells were carried out. * Haemagglutination test; † cytotoxicity test.

difference in the recombination frequency seems to be a direct result of the *H-2* complex. It seems likely that the chromosomal structure of the *H-2K* end, especially between *H-2K* and *IA*, of the *wm7* haplotype is different from that of other haplotypes. The ultimate interpretation should be made through investigations on the DNA level.

Generally, the intra-*H-2* recombination frequency is higher in the female than in the male. The total frequency in the female was 0.32%, and in the male, 0.19%, based on the progeny-tested recombinants[1]. Therefore, the frequency of female recombination estimated in the present experiment is still one order greater than the normal value. We are now proceeding to evaluate male recombination frequency in heterozygotes, between the *wm7* and several other *H-2* haplotypes.

The B10.MOL-SGR strain will provide a powerful tool for investigating the structure and functions of *H-2* genes, because we can obtain the recombinant derived from *K*-end specific crossing-over by screening at most 30–40 mice, probably irrespective of *H-2* haplotypes. Moreover, the resultant recombinants would be useful in detecting unknown Class I and Class II loci if they are located at the *H-2K* end, especially between the *H-2K* and *IA* loci.

Allelic polymorphism and complexity of the genes for HLA-DR *β*-chains—direct analysis by DNA–DNA hybridization

Claire T. Wake, Eric O. Long & Bernard Mach

Department of Microbiology, University of Geneva Medical School, 1205 Geneva, Switzerland

HLA-DR antigens are highly polymorphic cell surface glycoproteins involved in the control of the immune response. They are important in allograft rejection and in their linkage to certain disease susceptibilities. The allelic polymorphism of HLA-DR antigens is carried by the β-chain. We have isolated cDNA clones encoding several distinct HLA-DR β chains and other β-chains from related loci, including DC, making it possible to analyse this complex genetic system directly by Southern hybridization and to demonstrate the polymorphism of these DNA sequences in the human genome. Hybridization patterns obtained with DNA of one DR-heterozygous and three DR-homozygous cell lines suggest the presence of a number of different genes for these two β-chain loci. Extensive polymorphism of the restriction pattern was detected in individuals of different DR specificities, with each of the three restriction enzymes used. Analysis of HLA-DR directly at the DNA level may lead to a simpler typing procedure and may eventually refine the specificities so far determined either serologically or by cellular assay.

The I region of the mouse major histocompatibility complex (H-2) controls the immune response[1]. These genes encode polymorphic glycoproteins (Ia antigens) expressed mainly at the cell surface of macrophages and lymphocytes and involve

Fig. 1 Maps of cDNA clones encoding two distinct human Ia antigen β-chains. Clones were isolated as described elsewhere[14]. Clone DR β − 1 encodes a β-chain of HLA-DR antigen. Clone Ia-like β-1 encodes a β-chain of another related antigen, probably DC. The sites for several restriction endonucleases are indicated by the following symbols: *Pst*I (|), *Hin*dIII (▼), *Bam*HI (⫯), and *Eco*RI (T). Wavy lines represent pBR322 sequences. The diagram of the β-chain structure is based on the sequence of a human Ia antigen β-chain determined by Kratzin *et al.*[23]. The transmembrane region, shown by a hatched box, and the cytoplasmic region have not been sequenced.

cellular interactions essential for the immune response. The equivalent antigens in humans are coded for by the HLA-D region of the major histocompatibility complex[2,3]. The best known, HLA-DR antigens, consist of an invariant heavy or α-chain[2] and a highly polymorphic light or β-chain[4,6]. Monoclonal antibodies have distinguished subsets of DR antigens[7]. Typing of the polymorphic DR specificities, important for successful organ transplantation[8], is done by serological tests and by the mixed lymphocyte reaction[9]. In addition, there is significant linkage between some HLA-DR specificities and susceptibility to certain diseases[10]. Besides DR, other human Ia antigens have been identified serologically. Their genes (DC) are in close linkage disequilibrium with the classical polymorphic DR locus[11,12]. A third locus, termed SB, has been shown to encode polymorphic Ia antigens[13].

We have cloned cDNA sequences encoding β-chains of HLA-DR antigens and other related Ia-like antigens[14]. Initial studies of these clones, and of other recombinant clones containing corresponding DNA sequences from genomic DNA, strongly suggest the existence of several distinct genes for the HLA-DR β chain and for related Ia-like antigen β chain (data not shown). The availability of these β-chain cDNA clones makes possible a direct analysis of this polymorphic genetic system at the level of the DNA. Using the cloned β-chain sequences as probes we have analysed digested human DNA transferred to nitrocellulose filters by the method of Southern[15]. First, determining the number of different DNA fragments hybridizing to the β-chain probes will yield information about the complexity of these loci. Second, a comparison of the DNA from individuals with different HLA-DR specificities will quantify the allelic polymorphism of the system.

Restriction enzyme maps of the two β-chain sequences used as hybridization probes are shown in Fig. 1. Both cDNA clones were derived from the lymphoblastoid cell line Raji, which is heterozygous at the DR locus (DR 3, w6). HLA-DR β-1 encodes the DR β chain[14]. Ia-like β-1 encodes the β-chain of another human Ia antigen and has been shown to correspond in the mouse to the I-A β chain gene of the I region[16]. Since structural studies have now established a correlation between the α-chains of mouse I-A and human DC[17], we can tentatively consider the 'Ia-like' β-1 clone as specific of DC β chain. DNA from one DR-heterozygous and three DR-homozygous human lymphoblastoid cell lines were analysed: Raji (DR 3, w6), HHK (DR w6, w6), IBW9 (DR 7, 7), and LG2 (DR 1, 1).

The results of hybridizing the two β probes to the four genomic DNAs are shown in Fig. 2. A fairly complex pattern is evident. Depending on the cell line and the restriction endonuclease used, 4–13 bands hybridize with the HLA-DR

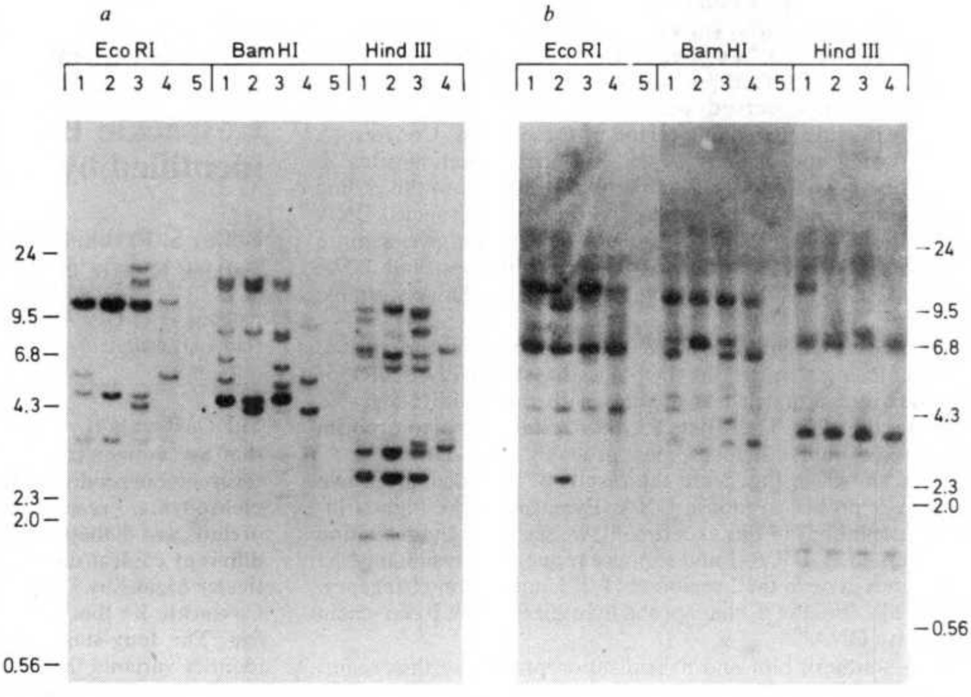

Fig. 2 Hybridization of cDNA sequences of the β-chains of HLA-DR and another Ia-like locus to human and mouse DNA. ^{32}P-labelled probes were purified inserts from cDNA clones HLA-DR β-1 (panel *a*) or Ia-like β-1 (panel *b*). DNA samples were from: 1, human B cell line Raji (DR 3, w6); 2, human B cell line HHK (DR w6, w6); 3, human B cell line IBW9 (DR 7, 7); 4, human B cell line LG2 (DR 1, 1); and 5, BALB/c mouse embryo (H–2^d). Size markers are given in kilobases. High molecular weight DNA was isolated as described elsewhere[19]. Restriction endonuclease digestions were done at 37 °C with *Eco*RI (Boehringer Mannheim), *Bam*HI or *Hin*dIII (Bethesda Research Laboratories) using standard buffer conditions with 1 unit enzyme μg^{-1} for 4 h, at which time another 1 unit enzyme μg^{-1} was added and incubated overnight. Reactions were stopped with EDTA, extracted once with chloroform/isoamyl alcohol (24 : 1), and ethanol-precipitated. Pellets were resuspended in 10 mM Tris-HCl, *p*H 7.6, 1 mM EDTA, 0.1% SDS, 0.05% bromophenol blue, 0.05% xylene cyanol, and 5% glycerol for 4 h at 37 °C. Samples were heated for 5 min at 65 °C just before loading on to 0.6% agarose gels in 200 mM glycine, 15 mM NaOH, *p*H 8.3. About 7 μg of LG2 DNA and 9 μg of the other DNA samples were loaded. Gels were run at 60–100 V for 12 h, treated and transferred to 0.2 μm nitrocellulose filters (Schleicher and Schuell) as described[24]. After transfer, the filters were rinsed in 4 × SSC (SSC = 150 mM NaCl, 15 mM trisodium citrate), then baked for 2 h at 80 °C in a vacuum oven. Filters were prewashed in 5 × SSC, 5 × Denhardt's solution for 1–2 h at 65 °C with gentle shaking, then prehybridized for 2 h at 65 °C in 1 × Denhardt's, 0.75 M NaCl, 5 mM EDTA, 50 mM sodium phosphate buffer, *p*H 7.0, 10% dextran sulphate, 0.1% SDS, and 50 μg ml^{-1} sonicated denatured herring DNA. Hybridization was for 8–12 h at 65 °C in the same buffer as used for prehybridization with 1×10^6 c.p.m. ml^{-1} of ^{32}P-labelled DNA ($>10^8$ c.p.m. μg^{-1}). Filters were washed at 65 °C for 30 min twice with each of the following solutions: 5 × SSC, 1 × Denhardt's, 0.1% SDS, 0.1% sodium pyrophosphate; 2 × SSC, 0.1% SDS; 0.5 × SSC; 0.1 × SSC.

β-1 clone and 3-9 bands hybridize with the Ia-like β-1 clone. This multiplicity of bands contrasts markedly with the simple pattern obtained when the cDNA clone encoding the non-polymorphic HLA-DR α-chain is used as probe[18,19]. However, the degree of complexity of the HLA-DR β chain sequences observed here contrasts also with the more extensive complexity found in class I genes of both man[20] and mouse[21,22], where up to 40 DNA fragments hybridize to the specific HLA or H-2 probes.

The finding of multiple hybridizing bands is a strong indication of the existence of several genes for the β-chains of both HLA-DR and the Ia-like (or DC) loci. This is in complete agreement with our recent finding in genomic and cDNA clones from homozygous cell lines of several distinct genes for both the HLA-DR β-chain and the β-chain of the DC locus, as well as several additional genes for other related Ia-like β chains, not yet identified (data not shown). Some of the weakly hybridizing bands could result from sequence differences between the probe (isolated from Raji cells) and the homologous sequences in other cell lines. The existence of strongly cross-hybridizing bands in each of the cell lines indicates highly conserved regions in the β-chain gene. In addition, weak signals can also result from DNA fragments containing only a short region of homology.

The genetic polymorphism of the HLA-DR locus, which previously could be demonstrated and assayed only at the level of the expressed proteins, is detected here directly at the level of the DNA. The four cells lines with different DR specificities generated different patterns of hybridizing bands with all three restriction endonucleases tested (Fig. 2*a*). For example, with *Bam*HI digestion, only one weak band is shared by all four cell lines out of their 4–11 bands. Only a few of these 4–11 fragments are unique to any one cell line. This analysis of genomic DNA can detect not only polymorphic endonuclease restriction sites located within the coding region, and corresponding to polymorphic changes seen in the antigens, but also possible polymorphic sites located within non-coding introns or in sequences flanking the DR genes. The *Eco*RI, *Hin*dIII and *Bam*HI restriction sites present in the coding regions will probably not account for all of the observed polymorphism. This indicates that the polymorphism observed with an HLA-DR β-chain probe extends outside the coding region of these genes. Conversely, by choosing specific probes and specific restriction sites, it should be possible to focus and limit the analysis to the coding region concerned in the polymorphism of the antigens. DNA from the DR-heterozygous line Raji does not give a more complex pattern than the homozygous cell lines, and DNA from a HLA-DR 1,1 homozygous shows a relatively simple pattern.

Significant polymorphism is also observed at the related Ia-like β locus when the DNA is digested with *Eco*RI or *Bam*HI, but is much less obvious with the *Hin*dIII-digested samples (Fig. 2*b*). These data therefore establish polymorphism at another human Ia locus, most probably HLA-DC.

Also shown in Fig. 2 are the results of hybridizing the two human β probes to mouse DNA. Even under the high stringency conditions of this experiment, we see cross-hybridization between HLA-DR β-1 and a mouse sequence, presumably the analogous gene in the I region of H-2. Under lower stringency, the Ia-like (or DC) β-chain probe hybridizes to the I-A β-chain in mouse DNA[16].

The Southern blot and hybridization procedure thus seems to be a simple and precise technique for detecting HLA-DR allelic polymorphism directly at the DNA level. A more extensive investigation would be necessary to correlate the DR specificities determined classically by serological and cellular tests with the hybridization pattern of the DNA. Such a study would test the feasibility and reliability of 'DNA typing' for DR specificity. In addition, Southern blot analyses might reveal subtle differences in the DNA patterns which could allow a further subdivision of the known DR specificities. Increased precision and large-scale availability of HLA-DR typing would be important because of the association between particular HLA-DR specificities and susceptibility to certain diseases.

We thank G. Mottet for technical assistance, M. Giphart for supplying the HHK cell line, and S. Carrel and R. Accolla for providing Raji, IBW9 and LG2 cells. High frequency of antigenic variants among naturally occurring human Coxsackie B4 virus isolates identified by monoclonal antibodies

Bellur S. Prabhakar, Martin V. Haspel, Patrick R. McClintock & Abner Louis Notkins

Laboratory of Oral Medicine, National Institute of Dental Research, National Institutes of Health, Bethesda, Maryland 20205, USA

The Coxsackie B virus group consists of six serotypes (B1–B6) that are antigenically distinct. In patients, the Coxsackie B4 serotype can produce a variety of clinical diseases (for example, pleurodynia, respiratory illness, meningitis, myocarditis, orchitis and diabetes)[1,2]. It is not known, however, whether the different clinical diseases are due to chance infection of particular organs by Coxsackie B4 or due to antigenic variants of Coxsackie B4 that are inherently different in their tissue tropism. The long-standing reference hyperimmune sera do not identify variants that may exist within each of the serotypes[3]. In an attempt to identify variants of the Coxsackie B4 serotype, we prepared a panel of 18 monoclonal antibodies that neutralized the prototype Coxsackie B4 strain. These monoclonal antibodies have been characterized as to their subclass, neutralization titres and reactivity patterns with recent clinical isolates. Here we have identified over 13 variants of Coxsackie B4 virus and have shown that there are major antigenic differences among naturally occurring isolates. Using monoclonal antibodies as a selecting agent, we find that the frequency of antigenic mutation may be as high as 10^{-4}.

Fig. 1 Neutralization of clinical isolates by monoclonal antibodies. 100 $TCID_{50}$ of each of the 15 clinical isolates (numbered 2 to 16) and the prototype virus (1) were incubated with each of the monoclonal antibodies and the hyperimmune sera (HI) in a microneutralization assay (see legend to Table 1). The entire experiment was repeated twice with comparable results. Open boxes indicate complete neutralization of virus; hatched boxes indicate that the virus was not neutralized.

Hybridomas which secrete monoclonal antibodies specific for Coxsackie B4 virus were produced by fusing $P_3$653 Ag8 myeloma cells with spleen cells from BALB/c mice that were injected five times intraperitoneally with 10^7 plaque-forming units (PFU) of purified prototype Coxsackie B4 virus (JVB strain) obtained from the American Type Culture Collection (ATCC VR-184). The fusion protocol and selection of clones were as described previously[4,5]. Initially, the hybridomas were selected by screening the culture supernatants for virus-specific antibody in a microneutralization assay against the prototype virus. Cultures that were positive for antibody were cloned using the end point dilution method[6]. Clones grown from a single cell were further tested in a radioimmunoassay (RIA) for the production of antibody.

More than 70 monoclonal antibodies arising from 22 hybridomas that neutralize the prototype Coxsackie B4 virus have been obtained. The properties of 18 of these monoclonal antibodies are shown in Table 1. The monoclonal antibodies were predominantly of the IgG class and exhibited different neutralization titres against the prototype virus and precipitated different amounts of virus by RIA. For example, antibody 225-1 had a neutralization titre of 1,536 but bound only 10.8% of the virus in RIA. In contrast, antibody 38-1 had a neutralization titre of only 96, but bound 100% of the virus in RIA. These differences between RIA and neutralization could be due either to varying capacities of the antibody subclasses to bind to the *Staphylococcus aureus* cells used in the RIA[7] or to different concentrations of various epitopes required for neutralization. Monoclonal antibody 59-3 failed to neutralize the prototype virus and together with 17-1 served as a control. Most of the hybridomas have been grown in BALB/c mice[8], and ascites fluid with neutralization titres greater than 1:130,000 have been obtained. The monoclonal antibodies in Table 1 were also tested by neutralization against other serotypes of the Coxsackie B virus group (B1, B2, B3, B5 and B6) and found to be non-reactive.

The 18 neutralizing antibodies described in Table 1 were used for the antigenic analysis of 15 fresh clinical isolates obtained from two different State Health Departments. Each isolate was passaged three times or less in culture. Although all the isolates were neutralized by type-specific (anti-B4) hyperimmune reference serum, the monoclonal antibodies show that there is considerable antigenic variation among the Coxsackie B4 isolates (Fig. 1). Some of the monoclonal antibodies (that is 86-3, 204-4) neutralized all the isolates, whereas others (128-2, 208-2, 288-3) neutralized none of the isolates. Figure 1 also shows that the monoclonal antibodies recognized 15 different epitopes. The clinical isolates differed from the prototype virus in 2–12 of the 15 different epitopes. Some of the isolates (for example, 11 to 13) appear to be antigenically identical, others differ from each other at only one epitope (for example, 2 and 3; 6 and 7; 8 and 9), and still others differ from each by as many as 10 epitopes (for example, 2 and 16). Analysis of the data revealed 13 different antigenic variants. Although there were some exceptions (for example, 286-1), the monoclonal antibodies that gave the highest neutralization titres against prototype virus (Table 1), usually neutralized the greatest number of clinical isolates (Fig. 1). One possible explanation for such a broad specificity is that the epitopes with which these monoclonal antibodies are reacting are present in high concentration on the surface of prototype virus and are broadly expressed among the clinical isolates.

The identification of a large number of naturally occurring clinical variants by monoclonal antibodies suggested that the rate of mutation of Coxsackie B4 virus might be high. To test

Table 1 Reactivity of monoclonal antibodies with prototype Coxsackie B4 virus

Antibodies	Subclass	RIA (% bound)	Neutralization titre against prototype virus
Hyperimmune serum	–	100.0	1,024

17-1	–†	0.9	<2

Prototype virus and clinical isolates were grown in LLC-MK2 (MK) cells to a maximum titre of 2×10^6 $TCID_{50}$ ml^{-1} (Tissue Culture Infective Dose calculated by the Reed–Muench method[17]) These viruses were diluted to contain 100 $TCID_{50}$ in 0.1 ml before being used in the microneutralization test. The monoclonal antibodies were from tissue culture supernatants. The subclass was determined by double diffusion using rabbit anti-mouse IgG1, IgG2a, IgG2b, IgG3 antisera (Miles Laboratories), and goat anti-mouse IgG (heavy chain) and IgM (heavy chain) (Cappel Laboratories). For the RIA, monoclonal antibodies (50 µl) were mixed with ^{3}H-leucine-labelled purified Coxsackie B4 virus[16] (1,500 d.p.m.) in 150 µl of buffer (0.01 M Tris, 0.1 M NaCl, 0.001 M EDTA, 1 mg ml^{-1} bovine serum albumin and 0.01% Triton X-100). After overnight incubation at room temperature, the immune complexes were precipitated using heat-killed, formalin-fixed *S. aureus* cells[7]. Both the supernatant and the precipitate were counted in a liquid scintillation counter and the per cent radiolabelled virus bound by antibody was calculated To determine the neutralization titre, 100 $TCID_{50}$ of virus in 50 µl were added to wells of a microtitre plate containing 50 µl of threefold serially diluted monoclonal antibodies These were mixed and incubated at 37 °C for 1 h and then 10^4 MK cells in 0.1 ml of growth medium were added to each well. The plates were examined for virus-induced cytopathology 7 days later. All samples were tested in duplicate in two separate experiments with similar results Titres are expressed as the reciprocal of the highest dilution of antibody preventing cytopathology

* Subclass not determined.

Table 2 Frequency of antigenic variants in plaque-purified Coxsackie B4 viruses

	None*	Monoclonal antibodies							
		86-4		102-2		183-5		204-4	
Virus	Titre	Titre	Freq.	Titre	Freq.	Titre	Freq.	Titre	Freq
1-1	6.76	1.60	−5.16	1.48	−5.28	1.79	−4.97	2.00	−4.76
5-2	6.78	1.00	−5.78	ND		ND		1.90	−4.88
9-2	6.58	1.78	−4.80	1.30	−5.28	1.00	−5.58	2 57	−4.01
14-2	6.48	1 84	−4.64	1.00	−5.48	ND		1.78	−4.70
15-4	6.98	2.78	−4.20	2.48	−4.50	2.04	−4.94	2.28	−4.70

The prototype virus (1-1) and four different clinical isolates (5-2, 9-2, 14-2 and 15-4) were plaque-purified twice in MK cells with agarose overlay. The plaque-purified viruses were grown up in MK cell monolayers and virus titres determined. Serial 10-fold dilutions of the virus were incubated at 37 °C for 1 h in the absence or presence of undiluted monoclonal antibodies (ascites fluid with titres >1·130,000). The virus–antibody mixtures were then added to monolayers of MK cells in 60 mm Petri dishes and adsorbed for 90 min. The inoculum was removed and the cultures were overlaid with medium containing the same antibodies used for neutralization plus 5% methylcellulose. This was done to prevent any residual virus from reinfecting cells After 7 days, cells were stained with neutral red and the number of plaques were counted and the virus titre determined (expressed in $\log_{10}$). The frequency of mutation was determined by dividing the virus titre in the absence of antibody by the virus titre in the presence of antibody. ND, no plaques observed due to complete neutralization of virus even at the highest concentration of virus inoculum.

* Ascites fluid from a hybridoma that does not produce antibody against Coxsackie B4 virus.

this, prototype virus and four plaque-purified clinical isolates were selected and incubated with four different monoclonal antibodies. Table 2 shows that virus escaping neutralization was found in 17 of the 20 combinations, and, based on the titre of the residual virus, the frequency of mutation was calculated to be $10^{-4.0}$ to $10^{-5.8}$. To ensure that the residual virus represented true variants, plaques were selected randomly from each of the 17 combinations, grown up and re-tested in the absence or presence of the selecting monoclonal antibody. In each case, the selecting monoclonal antibody failed to neutralize the virus, indicating that true antibody-resistant variants had been obtained (data not shown).

In the present study, 18 of 70 antibodies were characterized and their interaction with 15 fresh clinical isolates revealed that the Coxsackie B4 serotype consists of many antigenic variants. Further experiments with another 36 clinical isolates revealed additional antigenic variants (unpublished data). Previously, Coxsackie B4 variants went undetected because polyclonal reference sera were used for typing. The demonstration of a large number of naturally occurring variants suggests that the different clinical pictures seen in Coxsackie B4 infection might be due to variants having different tissue tropism. There are, in fact, specific receptors for picornaviruses on the surface of cells[9–11]. If the antigenic determinants in question are involved in virus attachment to the cell receptor, this could affect the binding affinity of the virus and influence the tropism of the virus for various tissues. Studies are now underway to characterize the antigenic pattern of a large number of Coxsackie B4 isolates obtained from patients with different clinical diseases. If a correlation between antigenic variation and disease pattern could be established, then monoclonal antibodies might prove useful in classifying subtypes of Coxsackie B4 virus. Furthermore, these monoclonal antibodies may be of use in epidemiological studies of antigenic variants of Coxsackie B4 virus obtained in different years and from different geographical locations.

Our studies with monoclonal antibodies as a selecting agent show that Coxsackie B4 mutates at a high rate and that the frequency of antigenic variants may be as great as 10^{-4}. This is rather higher than that reported for influenza virus[12] but is within the range of several estimates for other RNA viruses[13–15]. The high rate of mutation may account for the surprisingly large number of antigenic variants at Coxsackie B4 found in the human population. The fact that some of the variants differed from prototype virus by as many as 12 epitopes suggests that major antigenic changes may periodically develop and thus account for both the persistence of the virus in nature and the different clinical syndromes.

The P_3 653 Ag8 myeloma cells were supplied by Dr Fred Jensen. We thank Dr Bruce Kleger and Dr Rudolf Diebel for the clinical isolates.

Synthesis *in vitro* of an exceptionally long RNA transcript promoted by an *Alu*I sequence

James L. Manley & Mary T. Colozzo

Department of Biological Sciences, Columbia University, New York, New York 10027, USA

More than 300,000 copies of the ~300 base pair (bp)-long *Alu*I DNA sequence are dispersed throughout the human genome[1–7]. Several *Alu*I sequences have been shown to contain sequences which promote transcription *in vitro* by the enzyme RNA polymerase III[8–11]. While the function(s) of transcripts synthesized from such promoters is unclear, one notion is that RNA polymerase III transcription from an *Alu*I promoter might have an effect on expression of a nearby RNA polymerase II gene, specifically, the β-globin gene (see Fig. 1). However, we found that this *Alu*I promoter is expressed efficiently *in vitro* only in conditions dramatically different from those required for the β-globin and other promoters (both RNA polymerases II and III). Surprisingly, the major transcript produced from this promoter is 2.3 kilobases (kb) long, much longer than any RNA polymerase III transcript described previously.

The DNA structure in the region around the β-globin gene is shown in Fig. 1. The β-globin promoter has previously been shown to be active in the whole-cell lysate transcription system used here[12], although transcription from the *Alu*I promoters was not detected. However, transcription from the distal *Alu*I repeat was observed by one group in a system containing only RNA polymerase III activity[9].

The plasmid pHB8 cleaved with *Eco*RI was used as a template for *in vitro* transcription in an experiment in which the amount of lysate added to reaction mixtures was varied from 60 to 25% of the total reaction volume (Fig. 2*a–d*). At high lysate concentrations, the predominant transcript is a 1.4-kb run-off RNA which arises from RNA polymerase II transcription originating from the β-globin promoter[12]. As the amount of lysate in the reaction mixture is reduced, this RNA is no longer detected. However, a very abundant RNA, ~510 nucleotides long, is now observed (Fig. 2*c*, *d*). As shown below, this RNA results from initiation by RNA polymerase III at the β-globin-distal *Alu*I repeat sequence. (Initiation from the other *Alu*I repeat has not been detected.)

The specific requirements for efficient transcription by RNA polymerase III observed with this promoter are unusual, and not, for example, common to all genes transcribed by this polymerase. Figure 2*e*–*h* shows the results obtained when a cloned fragment of adenovirus serotype 2 (Ad2) DNA containing both an RNA polymerase II and III promoter was transcribed in the same set of conditions used with the globin DNA above. While the RNA polymerase II promoter shows the same response to variations in the amount of lysate added as does the β-globin promoter, the RNA polymerase III promoter is used efficiently at all lysate concentrations tested, with a maximum observed at about 50% lysate (Fig. 2*f*). We have tested one other RNA polymerase III promoter (rat tRNA Leu, obtained from D. Rodi and B. Haas), and found that this promoter responds to variations in lysate concentration in the same manner as the Ad2 RNA polymerase III promoter (results not shown).

When the concentration of lysate is changed, several parameters are simultaneously varied. To determine which of these are responsible for the decrease in transcription of the 510-nucleotide RNA at high lysate concentrations, the following experiment was done. Transcription was first carried out exactly as shown in Fig. 2*d* (that is, 24% lysate). When the concentration of lysate buffer was increased so as to equal the amount present in reaction mixtures containing 60% extract, no specific transcription was detected (results not shown). Therefore, it seems unlikely that the high protein concentration in the reaction mixtures containing 60% extract inhibits transcription. Furthermore, increasing the buffer concentration did not result in synthesis of the 1.4-kb β-globin RNA, indicating that a high protein concentration is required for transcription initiation from this promoter, as has been observed for other RNA polymerase II promoters[13]. The concentration of each buffer component was then varied independently. Increasing $MgCl_2$ from 2.4 to 6.0 mM resulted in an approximately sixfold inhibition; increasing KCl from 24 to 60 mM inhibited transcription threefold, and an increase in glycerol concentration from 4 to 10% caused a 1.5-fold inhibition. The basis for this response is unclear, although an effect on the double-helical structure of the DNA template is a possibility. A similar effect on transcription of an *Escherichia coli* tRNA gene by *E. coli* RNA polymerase has been observed previously[14]. Whether such stringent ionic conditions are required to obtain efficient transcription *in vitro* from any (or all) other *Alu*I promoters is also unknown.

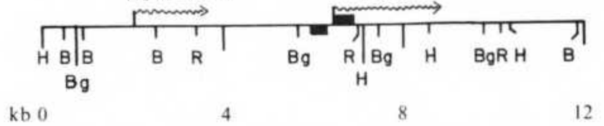

Fig. 1 Map of the human β-globin gene and surrounding sequences. Two inverted *Alu*I repeat sequences are indicated by black boxes. The β-globin primary transcript is indicated by a wavy line, as is the *Alu*I-generated transcript described here. Sizes are in kb. Relevant restriction enzyme sites are: H, *Hin*dIII; B, *Bam*HI; Bg, *Bgl*II; R, *Eco*RI. In the experiments described here, we have used primarily two recombinant plasmids as templates for *in vitro* transcription experiments. One, pHB8 (provided by T. Maniatis) contains a 7.5-kb *Hin*dIII fragment (extending from 0 to 7.5) inserted into pBR322. This fragment contains the entire β-globin gene, as well as two *Alu*I repeat sequences lying downstream from it. The other, pHB9.3, contains a 9.3-kb *Bam*HI fragment (from abou3 to 12 kb) subcloned into pBR322 from a λ phage recombinant, λHβG3 (ref. 5) (obtained from T. Maniatis).

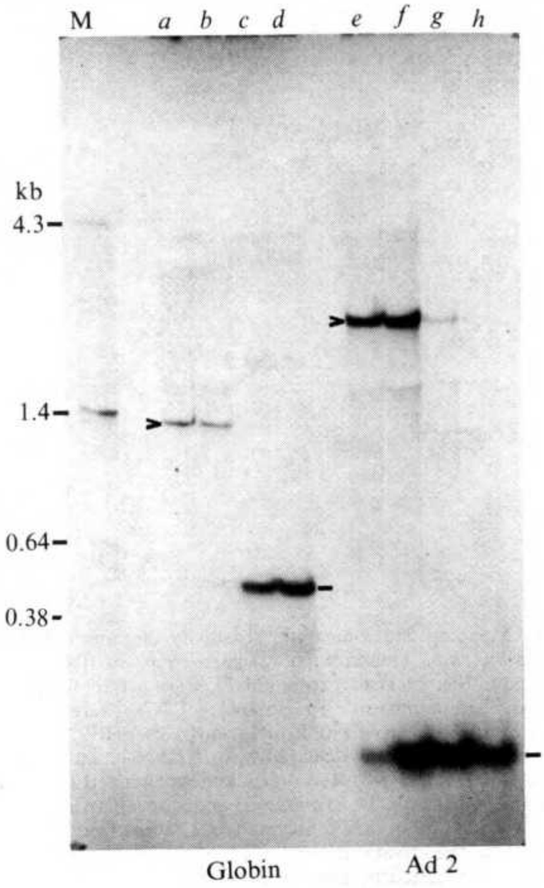

Fig. 2 Response of various promoters to alterations in the concentration of HeLa whole-cell lysate in *in vitro* reaction mixtures. HeLa whole-cell lysates were prepared as described elsewhere[13,20] except that the final dialysis buffer was 40 mM Tris-HCl *p*H 7.9, 100 mM KCl, 10 mM $MgCl_2$, 0.1 mM EDTA, 2 mM dithiothreitol, 17% glycerol. The protein concentration of the lysate used in these experiments was ~25 mg ml^{-1}, although similar results have been obtained with less concentrated lysates. Transcription reactions (25 μl total volume) were carried out as described elsewhere[20] except that the concentration of each ribonucleotide triphosphate was 50 μM, the radioactive precursor was [α-^{32}P]GTP (5 μCi per reaction; NEN), creatine phosphate was present at 4 mM, and the DNA concentration was 90 μg ml^{-1}. The concentrations of the various buffer components were determined entirely by the amount of lysate added to each reaction mixture. The samples shown in *a*–*d* were obtained from reaction mixtures containing pHB8 cleaved with *Eco*RI as template, while the Ad2-derived recombinant pHIIIB*, cleaved with *Kpn*I, was the template in the reaction mixtures represented in *e*–*h*. The Ad2 fragment in this plasmid extends from 16.4 to 31.5 map units (1 map unit (m.u.) = 360 bp) and contains the RNA polymerase II late promoter (16.5 m.u.), as well as the two small viral-associated (VA) genes (29–30 m.u.), which are transcribed by RNA polymerase III. Cleavage with *Kpn*I (23.5 m.u.) leads to the synthesis of a 2.5-kb RNA polymerase II run-off transcript. The RNA polymerase III product, which represents primarily transcription of the VA I gene[21], is ~160 nucleotides. The amount of lysate added to each reaction mixture was: 15 μl (lanes *a* and *e*), 12 μl (lanes *b* and *f*), 9 μl (*c*, *g*), or 6 μl (*d*, *h*). After incubation at 30 °C for 60 min, RNA was extracted, denatured with glyoxal, and one-quarter of each sample resolved by electrophoresis through a 1.4% agarose gel. The autoradiograph was obtained by exposure of the dried gel to Kodak XAR-5 film for 24 h (without intensifying screens). If quantitation was required, gels were scanned with a Gilford densitometer. RNA polymerase II products are indicated by the arrowheads, RNA polymerase III products by the short lines. The marker (lane M) consists of run-off RNAs obtained from *in vitro* transcription of the plasmid p04, as described previously[22].

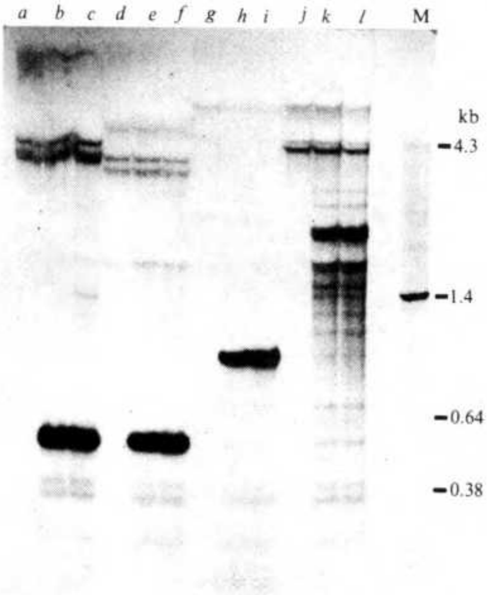

Fig. 3 Mapping and α-amanitin sensitivity of transcripts synthesized *in vitro*. Transcription reactions were carried out as described in Fig. 2 legend, except that 7.5 μl of extract were used in each reaction mixture. The following DNAs were used as templates: pHB8 cleaved with *Eco*RI (lanes *a–c*), pHB9.3 cleaved with *Eco*RI (*d–f*), pHB9.3 cleaved with *Bgl*II (*g–i*) and pHB9.3 cleaved with *Bam*HI (*j–l*). Reaction mixtures contained 200 (lanes *a*, *d*, *g* and *j*), 1 (*b*, *e*, *h* and *k*) or 0 (*c*, *f*, *i* and *l*) μg ml^{-1} α-amanitin. The 1.4-kb β-globin RNA polymerase II transcript is barely detected at this lysate concentration (lane *c*); its synthesis, however, is inhibited by a low concentration of α-amanitin, as expected (compare lanes *b* and *c*). Accumulation of the 510-nucleotide transcript is inhibited only by the higher concentration, as expected for an RNA polymerase III product (lanes *a* and *b*). If the 510-nucleotide RNA does indeed arise from transcription initiation in the β-globin-distal *Alu*I repeat, then the same transcript should be obtained when pBH9.3, which lacks sequences 5′ to the β-globin gene (see Fig. 1), is cleaved with *Eco*RI and used as template. Lanes *d–f* show that this is indeed the case. Further evidence that this RNA initiates at the deduced site was obtained by analysing RNAs transcribed from DNA cleaved with *Hin*dIII or *Bgl*II. The former results in synthesis of a 630-nucleotide run-off transcript (Fig. 4*e–g*), while the latter produces a 910-nucleotide transcript (Fig. 3*g–i*). (The high-molecular weight α-amanitin-resistant species result from end-labelling of DNA.)

Figures 3 and 4 provide further evidence that the 510-nucleotide RNA does in fact arise from transcription initiation by RNA polymerase III in the *Alu*I repeat sequence distal to the β-globin gene. Specifically, the 'run-off' transcription assay[15] was used to map the RNA start site. Transcripts sensitive to high, but not low, levels of α-amanitin and ranging in size from 510 to 910 nucleotides, were detected. These are the sizes expected if transcription begins at the 5′ end of the *Alu*I repeat sequence, and continues to the end of the DNA fragment used as templates.

RNA polymerase III, unlike RNA polymerase II, terminates transcription *in vitro* when a stop signal is encountered (for example, see Fig. 2*e–h*). All *Alu*I-promoted transcripts previously studied terminate at sites within several hundred nucleotides of the repeated element. The largest RNA transcribed from an *Alu*-type repeat previously described is 800 nucleotides[11], and all of the approximately 10 other *Alu*I-promoted transcripts from the human α- or β-like globin clusters are <600 nucleotides long[8,9]. It was therefore rather unexpected that transcription actually continued to the end of the *Bgl*II-cleaved DNA (910 nucleotides). To determine the length of the transcribed region, pHB9.3 digested with *Bam*HI was used as template. Surprisingly, the major product of transcription was 2.3 kb, although several minor transcripts (up to 3.2 kb) were detected also (Fig. 3*j–l*). The transcripts produced from *Bam*HI-digested DNA arise from specific initiation and termination, as the same RNAs are obtained when closed circular DNA is used as template (Fig. 4*a–d*).

The function(s) that *Alu*I repetitive sequences serve in cells is unclear, although several possibilities have been discussed (for example, see refs 3 and 9). It is almost certain that at least some of the repeats that are transcribed by RNA polymerase III *in vitro* are also transcriptionally active *in vivo*. For example, specific low-molecular weight transcripts have been shown to be complementary to cloned *Alu*-type repeated DNA sequences isolated from CHO cells[11]. Also, the observation that the start point of transcription seems to correspond to the first nucleotide of the repeat sequence strongly suggests that the presence of an RNA polymerase III promoter is not coincidental[16,17]. However, it is unknown if any of the *Alu*I promoters in the β-globin locus are ever used *in vivo*.

The results presented here establish several interesting points with respect to RNA polymerase III and the possible role of *Alu*I repeats. First, RNA polymerase III has long been thought to be the enzyme responsible for synthesis of small RNAs. While most of the products of this polymerase are undoubtedly small (for example, tRNAs, 5S RNA), the results shown above

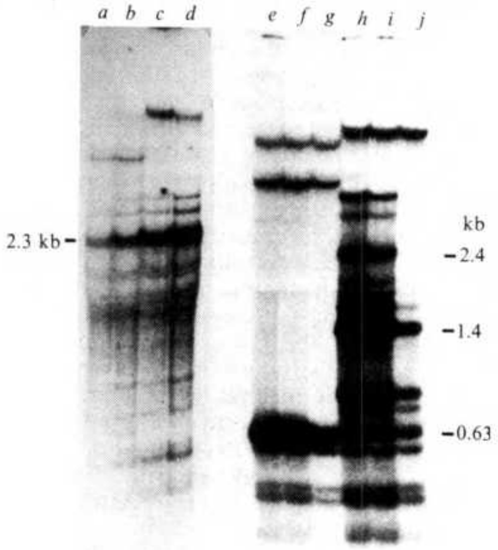

Fig. 4 Comparison of the transcription products obtained from circular and linear DNA. Transcription reactions were as described in Fig. 2 legend except that 7.5 μl of extract were used. The DNA templates were as follows: pHB9.3 cleaved with *Bam*HI, 60 μg ml^{-1} (lane *a*) or 100 μg ml^{-1} (lane *b*); pHB9.3, Form I, 60 μg ml^{-1} (*c*) or 100 μg ml^{-1} (*d*); pHB8 cleaved with *Hin*dIII, 100 μg ml^{-1} (*e–g*); and pHB8, Form I, 100 μg ml^{-1} (*h–j*). α-Amanitin (1 μg ml^{-1}) was included in two reaction mixtures (*f* and *i*) and 20 μg ml^{-1} α-amanitin was included in two others (lanes *g* and *j*). Note that the expected 630-nucleotide run-off transcript is observed with *Hin*dIII-cleaved DNA (lanes *e–g*), but the circular DNA gives rise to predominantly larger transcripts (lanes *h–j*), which arise from termination sites in pBR322. (A stretch of five consecutive T residues is probably responsible for the 2.4-kb RNA, while the 1.4-kb transcript probably results from termination at a stretch of four Ts[23].) These are the only T stretches longer than three in the region of pBR322 that is transcribed, which corresponds, for the most part, to the *tet* gene[24]. Synthesis of these transcripts is resistant to 1 μg ml^{-1} α-amantinin (for example, lanes *h* and *i*). However, an interesting response to 20 μg ml^{-1} α-amanitin (lane *j*) was observed: transcription of the smaller RNAs was inhibited only slightly, while synthesis of the larger species was suppressed almost completely. This could reflect a 'target-size' phenomenon in which polymerases that transcribe a greater DNA length have a higher probability of interacting with the drug. Alternatively, α-amanitin may exert its inhibitory effect early during transcription, and those polymerases that continue are more likely to terminate when a potential termination signal is reached, as has been suggested in the case of transcription of 5S genes[23].

establish that this enzyme can synthesize large RNAs, and that templates for such transcription exist in human cells. Second, the possibility that *Alu*I repetitive sequences might function by promoting transcription of adjacent genes is strengthened by the observation that a long stretch of DNA can be transcribed. For example, although no precedent exists for transcripts synthesized by RNA polymerase III functioning as mRNA, an RNA 2.3 kb long could encode a protein as large as molecular weight 80,000. Indeed, the presence of *Alu*I repeat sequences in cDNA transcripts of polysomal poly(A)$^+$ RNA has been reported[4]. Third, since it has been shown that the *Alu*I repetitive sequence studied here is immediately adjacent to a long (~6 kb) middle repetitive DNA sequence (~5,000 copies per genome)[18,19], we have established the novel situation in which a short, highly repetitive DNA sequence provides a promoter which results in the *in vitro* transcription of a substantial portion of a long, middle repetitive sequence. It will be of interest to determine the function of this transcription, and any role it may have in influencing the expression of the neighbouring β-globin-like genes.

Sequence and structural homologies among type I and type II interferons

William F. DeGrado, Zelda R. Wasserman & Vinay Chowdhry

E. I. du Pont de Nemours & Company, Inc.,
Central Research & Development, Experimental Station,
Wilmington, Delaware 19898, USA

Interferons are proteins with antiviral, antitumour and immunomodulator activities, which are secreted in response to various inducers[1]. The interferons have been classified into two categories on the basis of their biological and physical properties. Type I interferons include fibroblast interferon (IFN-β)[2,3] and the leukocyte family of interferons which is composed of at least 10 subspecies[4–8]. Each member of the type I interferons contains ~165 amino acids, is acid-stable, and competes for the same receptors[9]; furthermore, identical amino acids occupy invariant positions in 23% of their amino acid sequences[7]. In contrast, type II interferon (IFN-γ) is produced in response to mitogens and antigenic stimuli[10], contains ~146 amino acid residues[11], is not acid-stable, and displays no measurable binding to type I interferon receptors[9]. The nucleotide sequence of the cDNA coding for IFN-γ has recently been reported[11], and no statistically significant sequence homology was detected between the deduced amino acid sequences of IFN-γ and any of the type I interferons[11,12]. To determine whether there might be structural similarities between IFN-γ and the type I interferons, we have conducted a predictive analysis of the secondary structure of these proteins[13,14]. IFN-γ as well as each of the type I interferons contain a segment with a high potential to form an amphiphilic α-helix of approximately the same length and hydrophobic/hydrophilic balance (Fig. 1). As we report here, the identification of these segments generates an alignment of sequences which reveals previously undetected sequence homologies among the type I and II interferons (Fig. 2). Thus, we propose that there is a common evolutionary ancestor for both type I and type II interferons.

Phylogenetic relationships among proteins are often elucidated by demonstrating that the protein sequences may be aligned so that a larger number of identical amino acids occupy respective positions along the polypeptide chain (homologies) than might be expected from a chance alignment of unrelated proteins. However, when the relationships are distant, deletions (gaps) or additions of residues may occur between homologous regions in the amino acid sequences of the proteins. This hampers the proper alignment of two marginally related sequences because the introduction of gaps increases the number of homologies which would be expected by chance alignment of sequences[15], and also increases by orders of magnitude the number of possible alignments which must be searched for homologies. Clearly, a nonrandom method which would direct the proper alignment of portions of the sequences of related proteins would be extremely useful. When the three-dimensional structures of two proteins have been solved by

X-ray crystallography, relatedness can be demonstrated by aligning the primary structures based on secondary and tertiary structural similarities between the proteins[16,17]. Unfortunately, the three-dimensional structures of most proteins are not known so we are attempting to make alignments based on predicted secondary-structural similarities. However, most existing methods for secondary structure prediction do not allow precise enough predictions of the positions of initiation or termination of a given secondary structural element[18] to allow unambiguous alignments. Some of these ambiguities might be eliminated by considering the distribution of hydrophobic and hydrophilic residues within a predicted secondary structure. In particular, amphiphilic α-helices have hydrophobic and hydrophilic residues on opposite faces of the α-helix and are known to occur on the surfaces of globular proteins[19] and lipoproteins[20,21]. Furthermore, the occurrence of amphiphilic α-helices may be predicted by locating the portions of amino acid sequences whose hydrophobic and hydrophilic residues repeat in a pattern such that they are segregated on opposite sides of a helix when the chain adopts a helical conformation[19,22]. Thus two or more protein sequences might be aligned at sub-sequences which share a hypertensional to form amphiphilic α-helices of similar length and hydrophobic/hydrophilic balance.

LeIF A, IFN-β and IFN-γ have several segments which are predicted to form amphiphilic α-helices (LeIF A was chosen as representative (Fig. 3) of the leukocyte interferons). Of the amphiphilic α-helical segments in these proteins, one in particular is of uniform length and uniform hydrophobic/hydrophilic balance among all three interferons. These segments, which span residues 56–70 in LeIF A, 58–72 in IFN-β and 51–65 in IFN-γ (Fig. 1), also have high potentials to form α-helices as determined by the Chou and Fasman[14] parameters ($P\alpha = 1.09$, 1.10 and 1.04, respectively). When the sequences of the interferons are aligned so that these regions with high amphiphilic α-helical potential coincide, sequence homologies are observed between residues 64–110 (LeIF A), 66–112 (β) and 59–104 (γ). If a space is inserted between positions 79 and 80 of IFN-γ, IFN-γ and IFN-β share 14 invariant residues between residues 59 and 104 (γ numbering), and an additional 4 residues are structurally conserved (Leu for Ile; Lys for Arg; Asp for Asn; Tyr for Phe). Thus, there is 30% sequence homology between β and γ interferon (Fig. 2) in this region and 39% homology if conservative replacements are included; the corresponding values for the homologies between IFN-γ and LeIF A are 13% and 24%, respectively. Similar degrees of homology are observed between IFN-γ and the other leukocyte interferons (Fig. 3).

The significance of our findings was tested by examining the degree of homology to be expected between randomized sequences of IFN-γ and the type I interferons[23]. A program was written which performed the following operations: (1) Two random sequences were generated with the frequency of occurrence of amino acids identical to that of the proteins under consideration. (2) A segment of desired length m was selected from the first random sequence. (3) This segment was overlayed on the first m residues of the second (longer) sequence of length n and the number of matches determined. (4) A single gap was inserted into the pair of sequences and the number of homologies noted. (5) Step 4 was repeated for all $2(m-1)$ possible locations of the gap. (6) The segment of length m was moved one residue to the right and steps (3), (4) and (5) repeated. (7) Step 6 was repeated until the end of the longer sequence was reached.

The maximum number of homologies observed for the $2(m-1)(n-m+1)$ possible alignments generated by the above process was noted. Steps (1)–(7) were repeated 1,000 times. The mean and standard deviation of the maximum number of homologies observed were computed. The quantities provide a measure of the degree of homology to be expected for the best alignment (that alignment with the highest number of homologies among all possible alignments) of a segment of m residues on another segment of n residues (with one gap) when the amino acids are randomly distributed. Using this program, we find that the mean and standard deviation for the number of

Fig. 3 Partial amino acid sequences of all human interferons thus far reported in the literature. Homologous residues are boxed.

homologies between randomized sequences of IFN-β and a 46-residue segment of IFN-γ is 9.0 ± 1. Further, the frequency of finding 14 or more homologies is less than 10^{-4}. Notably, although 6 homologies between LeIF A and IFN-γ (Fig. 2) are not statistically significant, these homologous residues are also concerved in IFN-β. The frequency of finding 6 homologies within the 14 homologous positions contained in randomized 46-residue sequences with the amino acid composition of LeIF A and IFN-γ is 4×10^{-3}. (A gap was not included in this calculation because the position of the gap was determined by the prior positioning of the β and γ sequences. If a gap is included the probability is 1.32×10^{-2}.) We conclude that the type I and type II interferons are indeed related and probably arose from a common ancestor.

In contrast to our proposed sequence alignment between IFN-γ and LeIF A, Epstein[12] observed only 14 sequence homologies spread throughout the entire sequences of these two proteins. This is below the value expected for the best random alignment of the entire sequences and insertion of a single gap (16.9 ± 1.7), suggesting that the statistical relatedness of this alignment is far less than the alignment suggested by us.

Our results clearly show the potential for using predicted structural features to align distantly related sequences. This method has been used to demonstrate that a feature common to all interferons thus far sequenced is a segment of 15 residues with a high potential to form an amphiphilic α-helix followed by a region of high sequence homology. The specific amino acid sequence of a large portion of these segments with high amphiphilic potential appears to be of little consequence as long as its amphiphilic character is conserved, suggesting that this region might serve a structural role in stabilizing the surface of these proteins. Zav'yalov and Denesyuk[24] and Sternberg and Cohen[25] have also suggested that this region is helical and might serve a structural role in the α- and β-interferons.

The degrees of homology between residues 59 and 104 (IFN-γ numbering) among IFN-γ, IFN-β and LeIF A suggest that the IFN-γ gene separated from the IFN-β gene some time after the separation between leukocyte and fibroblast interferon genes. The lower degree of homology between IFN-γ and LeIF A than between IFN-β and LeIF A clearly shows that the mutation rate for IFN-γ has been greater than that for the leukocyte interferons and IFN-β, consistent with type I interferon having separate receptors from the IFN-γ receptor[9]. The observation that the highest concentration of homologies is in a 46-residue portion of IFN-γ and IFN-β suggests that IFN-γ might be a product of the insertion of a short segment of DNA coding for IFN-β into a gene coding for an unrelated protein. IFN-γ gene contains one or more introns[11], providing a possible mechanism for this insertion.

We thank E. Knight for helpful discussions.

Since submission of this paper the complete sequence of the human immune interferon (IFN-γ) gene including the exon and intron structure has been published[26]. A single exon of 61 amino acids in length contains the entire segment predicted by us here to form an amphiphilic α-helix as well as 44 of 46 amino acids we also show to be homologous. Furthermore, only 9 of the 61 amino acids in this exon do not appear in the structurally and functionally homologous unit proposed by us. This observation further supports previous suggestions[27,28] that exons code for functionally competent domains of proteins.

Nucleotide sequence of $\gamma\delta$ resolvase gene and demonstration that its gene product acts as a repressor of transcription

Randall R. Reed*, Grant I. Shibuya & Joan A. Steitz

Department of Molecular Biophysics and Biochemistry,
Yale University, Box 3333, New Haven, Connecticut 06511, USA

The related transposons $\gamma\delta$ and Tn*3* each encode an efficient site-specific recombination system essential for transposition[1,2]. The recombination occurs at a particular site, *res*, located within the intercistronic region between the two divergently transcribed genes that are required for transposition[2]. The product of one of these genes, resolvase, catalyses the recombination at *res*. Recently, *in vitro* site-specific recombination has been demonstrated using purified resolvase and a model substrate containing two *res* sites[3]. Genetic analysis of mutants in the $\gamma\delta$/Tn*3* *tnpR* gene, which encodes the resolvase protein, suggested that resolvase regulates the frequency of transposition in addition to catalysing recombination[4–6]. Analysis of element-encoded proteins in minicells indicated a direct effect of resolvase on the levels of the element-encoded transposase, as well as on its own expression[7]. Here we report the sequence of the gene encoding $\gamma\delta$ resolvase and compare the predicted amino acid sequence with that of the functionally interchangeable Tn*3* protein[6]. In addition, we have determined the sites at which transcription of the transposase and resolvase genes initiates *in vitro* and have demonstrated that purified resolvase protein specifically represses transcription of both transposition related genes in this *in vitro* transcription system.

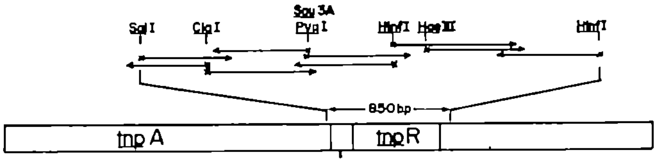

Fig. 1 Genetic map of $\gamma\delta$ and the region sequenced. The element is drawn with the γ end[17] towards the right. Transcription of *tnpA* and *tnpR* is divergent from the central intercistronic region. The right arm appears to encode a 79,000 molecular weight polypeptide of unknown function (unpublished observation). The locations and directions of sequence determinations are indicated by arrows with the 5′ labelled end indicated by X. The DNA was labelled and sequenced as described by Maxam and Gilbert[18]. The $\gamma\delta$ *tnpR* sequences were determined using fragments from the plasmid pOX14, a $\gamma\delta$ transposition into pBR322[17].

Fig. 3 *a*, Sequence of the major *tnpR* and *tnpA* transcripts. *In vitro* transcription reactions (20 μl) consisted of 0.1 pmol of the *Sal*I/*Pvu*I fragment containing the *tnpR*/*tnpA* intercistronic region, 10 mM Tris–HCl *p*H 7.5, 150 mM KCl, 10 mM $MgCl_2$, 0.1 mM EDTA, 100 μM unlabelled NTPs, 0.9 μg *E. coli* RNA polymerase and in separate reactions 10 μM [γ-^{32}P]ATP, or [γ-^{32}P]GTP (specific activity 1,000 Ci $mmol^{-1}$, NEN). The mixtures were incubated at 37 °C for 20 min, and then stopped by addition of SDS to 0.1% before phenol extraction. After addition of an equal volume of 80% formamide in TBE, the samples were heated to 95 °C for 2 min, and applied to a 1.5-mm thick, 10% acrylamide/7 M urea TBE gel[18]. After electrophoresis and autoradiography, bands corresponding to the major transcription products were excised and eluted. These 5′-labelled transcripts were subjected to partial enzymatic degradation and fractionation on 25% acrylamide/7 M urea gels as described by Donis-Keller[11]. CON, undigested transcript; ALK, partial alkaline hydrolysis; T_1, ribonuclease T_1, which cleaves specifically after G residues; U_2, ribonuclease U_2, which cleaves specifically after A residues in the conditions used here. Note that the preparative gel used to isolate transcription products was unable to resolve multiple *tnpR* species. However, analysis of individual bands within the *tnpA* cluster (see Fig. 4*a*) indicated a common 5′ terminal sequence. *b*, The nucleotides at which *tnpA* and *tnpR* transcription initiates are indicated (wavy arrow). The bars indicate the −10 and −35 regions proposed to interact with RNA polymerase and the dots indicate homology between those nucleotides and the canonical *E. coli* promoter sequence of Rosenberg and Court[13]. The positions at which the *res* site is cleaved *in vitro* by resolvase are indicated by the arrows[2].

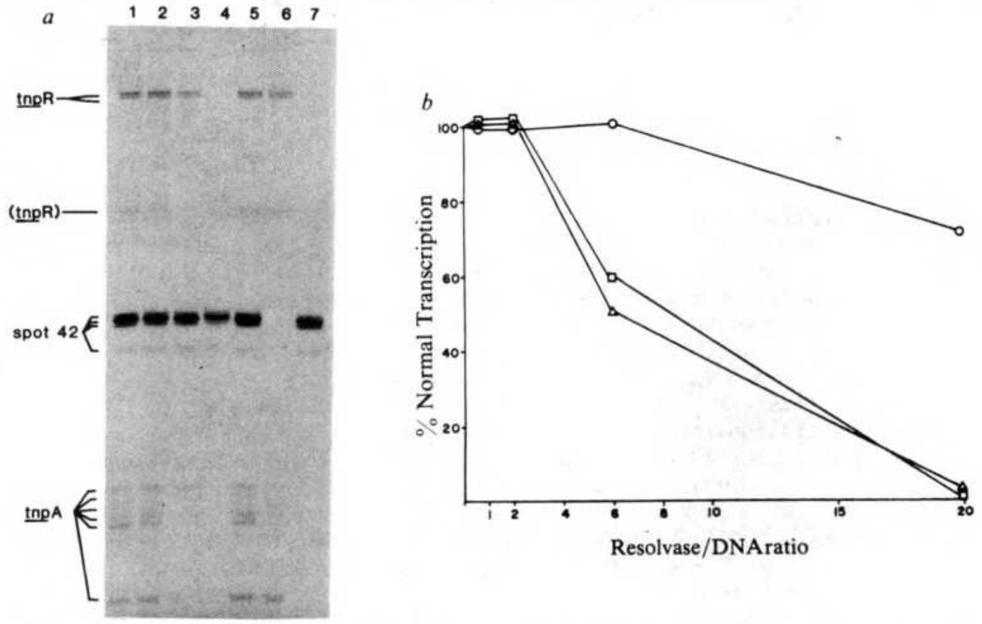

Fig. 4 *a*, Specific repression by $\gamma\delta$ resolvase. Transcription was performed as in Fig. 3 except that [α-^{32}P]GTP (specific activity 50 Ci mmol^{-1}; NEN) was used. As an internal control, the efficiency of transcription 0.1 pM of a 165 bp fragment containing the spot 42 promoter and terminator (C. N. Joyce, personal communication) was also monitored in each reaction. Lanes 1–5 contain both templates, lane 6 only the *res* template and lane 7 only the spot 42 template. Resolvase was added and the reactions incubated for 5 min before the addition of RNA polymerase. Lane 1, 0.1 pmol resolvase; lane 2, 0.3 pmol resolvase; lane 3, 0.6 pmol resolvase; lane 4, 2.0 pmol resolvase; and lanes 5–7, no added resolvase. The identity of each indicated transcript was confirmed by two-dimensional T_1-ribonuclease fingerprinting and by secondary analysis[19]. The multiple bands result from heterogeneity at the 3′ ends of the run-off transcripts. The band labelled (*tnpR*) is a prematurely terminated *tnpR* transcript. *b*, Densitometric analysis of transcriptional repression by resolvase. Lanes 1–5 were scanned and the intensities of each peak determined relative to that in the absence of resolvase (lane 5). The results were then plotted versus the molar ratio of resolvase monomers to *res* template. Spot 42 transcription is indicated by ○, *tnpR* by □ and *tnpA* by △. Decreases in intensity were identical for each band within the *tnpA* cluster.

Figure 1 shows a map of $\gamma\delta$ and of the region sequenced. The DNA sequence has revealed a single open reading frame which is capable of encoding a slightly basic 183-residue polypeptide, corresponding to the $\gamma\delta$ resolvase protein (Fig. 2). The amino acid sequence of $\gamma\delta$ resolvase shows 80% homology with that of the analogous Tn*3* protein[8], the homology being particularly extensive for the N-terminal two-thirds of the sequence. In view of the interchangeability of the $\gamma\delta$ and Tn*3* proteins in both recombination and repressor roles[2], the high degree of homology in the N-terminal region may indicate a conservation of the DNA binding site. Interestingly, the protein which catalyses recombination in the *hin* site-specific recombination system of *Salmonella typhimurium* (which is involved in the expression of flagellar proteins)[9] is homologous to $\gamma\delta$ resolvase, and exhibits a similar pattern of sequence conservation. Resolvase and the *hin* protein are not interchangeable for recombination functions (unpublished observation).

Considerable genetic evidence has suggested that $\gamma\delta$/Tn*3* resolvase regulates expression of element-encoded proteins (resolvase and transposase) at the transcriptional level[10]. We have determined the sites at which transcription of these two genes initiates *in vitro*. A purified 303 bp *Sal*I/*Pvu*I fragment containing all of the intercistronic region between *tnpA* and *tnpR* was used in transcription experiments with *Escherichia coli* RNA polymerase and γ-^{32}P labelled purine triphosphates. The resulting transcripts were sequenced by the method of Donis-Keller[11] (see Fig. 3*a*). Determination of the two start sites allows identification of the regions of the DNA sequence suggested to be involved in RNA polymerase interactions[12] (Fig. 3*b*); homologies between these regions and the canonical *E. coli* promoter sequence[13] are indicated by dots. The -10 region of the two promoters overlap one another, and contain the site at which resolvase cleaves the *res* site to initiate strand exchange[14] (indicated by the arrows in Fig. 3*b*). This cleavage is observed at a significant frequency only in special conditions and thus is unlikely to have a role in regulation.

The divergent transcription of regulatory proteins and of the genes they control has been described previously. However, in the *araC*/*araBAD* operons of *E. coli*[15] as well as in the rightward region of bacteriophage λ (ref. 16) the nucleotides at which divergent transcription initiates are separated by more than 50 base pairs (bp). In the *res* system, RNA polymerase competition for binding at the two promoters may represent an additional regulatory complexity.

Genetic evidence has suggested a role for resolvase in regulation of the *tnpR* and *tnpA* genes. The data in Fig. 4 demonstrate that transcription from the *Sal*I/*Pvu*I fragment used in the previous experiment can be specifically repressed by the addition of resolvase. As an internal control, we monitored the efficiency of transcription of a promoter-containing fragment not expected to be regulated by resolvase (the spot 42 transcript). The resolvase concentration at which a significant reduction of transcription of the *Sal*I/*Pvu*I fragment occurred (~6 protein monomers per template) corresponds closely to that required for resolution (~6–8 monomers per resolution site)[3]. *In vitro* recombination studies have identified the two sites at which resolvase mediates strand cleavage to initiate recombination[14]. Their location within the Pribnow boxes for *tnpA* and *tnpR* transcription strongly suggests that resolvase regulates expression of transposition functions and resolves intermediates in the transposition pathway by acting at a single site or group of sites located within the intercistronic region between the divergently transcribed transposase and resolvase genes.

MATTERS ARISING

Porphyropsin in retina of four-eyed fish, *Anableps anableps*

A RECENT investigation[1] reports the same visual pigments in the dorsal and ventral regions of *Anableps* retina. I present here some previously unpublished studies that demonstrate the existence of porphyropsin as well as rhodopsin in this species. *Anableps* is therefore similar to two related poeciliids, *Belonesox belizanus* and *Mollienesia latipinna*[2]. The *Anableps* used in the present work were examined only 3 days after collection from their native waters in Guiana, whereas the fish used by Avery and Bowmaker[1] originated from a fish supplier in London. Mixed rhodopsin–porphyropsin retinas are highly variable in composition; this variability probably affects the cone system also[3] and often depends on environmental factors[4]. For example, it has been shown that *Belonesox* may lose much of its porphyropsin if kept in unnaturally bright surroundings[5] and that its rhodopsin–porphyropsin balance shifts markedly with season and local habitat[6]. Other species are known to behave similarly[4]. Therefore, Avery and Bowmaker's results do not exclude the possibility that in its natural habitat *Anableps* may have appreciable proportions of porphyropsin that could be segregated in its dorsal retina.

Specimens of *Anableps* were flown directly from Guiana to Miami. A total of 3 days elapsed between the time of netting and delivery (August 1963) to my laboratory in the Bascom Palmer Eye Institute, University of Miami, Florida. After overnight dark-adaptation at 80°F, 11 fish ranging in standard length from 7 to 10 cm were killed by decapitation. The retinas were then dissected out and the photoreceptor outer segments prepared by sucrose flotation[2]. Further procedures used have been described previously[2]. The visual pigment was extracted in three successive 0.5-ml volumes of 2% digitonin (Merck), and each extract was buffered to *p*H 8.8 with sodium borate.

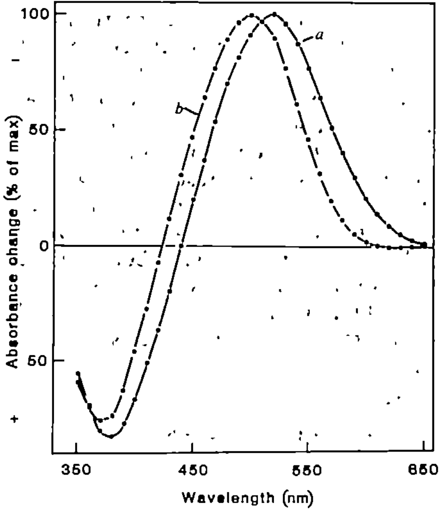

Fig. 1 Analysis of *Anableps* visual pigments. Curve *a* represents the difference spectrum obtained by bleaching a digitonin extract with light of wavelength 660 nm in the equipment described by Bridges[2]: the maximum absorbance loss was 0.077 at 519 nm. After several subsequent exposures to red light (660 and 620 nm), the visual pigment was completely bleached by exposure to yellow light (>440 nm). Curve *b* represents the difference spectrum for this final irradiation: the maximum absorbance loss was 0.0944 at 500 nm (see text for details).

The data presented here are for the first extract from the above procedure, which had a peak absorbance of 0.57 at 507 nm. The extract had more than one visual pigment—this was demonstrated by exposing it to a series of irradiations at wavelengths ranging from 660 to 620 nm, then finally to non-isomerizing yellow light of wavelengths >440 nm. Figure 1 curve (*a*) shows the difference spectrum for an initial exposure to 660 nm light. The amount bleached represents 14% of the total visual pigment, and the difference spectrum has a λ_{max} at 519 nm, close to that of porphyropsin. The difference spectrum for the final exposure to yellow light (representing 16% of the total pigment) had a λ_{max} at 500 nm, typical of rhodopsin. As Fig. 1 shows, the λ_{max} of the bleaching product also shifted to shorter wavelengths. A single fish from this group gave similar results: the digitonin extract had a peak absorbance of 0.12 at 506 nm. As the cone pigments of fishes do not survive digitonin extraction, it seems that the *Anableps* used here contained a mixture of rhodopsin and porphyropsin in their retinas.

The λ_{max} of *Anableps* rhodopsin was calculated[4] to be identical to that reported for *Belonesox*[2] that is, 498 nm, and the proportion of porphyropsin was 25–30%. The presence of porphyropsin may have accounted for the elevated λ_{max} of 506 nm previously assigned to the rhodopsin of this species[7]. The apparent agreement with Avery and Bowmaker's mean rod λ_{max} may be fortuitous, because *in situ* values are often displaced to longer wavelengths[8,9].

Thus, *Anableps* appears to be similar to several of its close relatives in having a mixture of rhodopsin and porphyropsin. Extensive studies of other species have established that such mixtures may vary widely in composition, and that ambient illumination is an important controlling factor[4]. Therefore, further studies of *Anableps* in its natural habitat or in a variety of controlled lighting conditions are needed before a final conclusion on its dorso-ventral distribution of visual pigments can be reached.

This work was supported in part by grants from the NSF and the NIH (National Eye Institute).

AVERY AND BOWMAKER REPLY—Bridges presents data from partial bleaching experiments to show that the rod pigment of *Anableps* (λ_{max} = 506–507 nm) is actually a mixture of rhodopsin (λ_{max} = 498 nm) and a porphyropsin (λ_{max} = 519 nm), and is not a pure rhodopsin as reported by Schwanzara[1]. In our recent investigation of the dorso-ventral distribution of visual pigments in *Anableps*[2], we suggested from the shape of the absorbance spectra of the rods, obtained by microspectrophotometry, that the pigments were probably rhodopsins, but we are not surprised to find that they are rhodopsin–porphyropsin mixtures.

Bridges suggests that we found no difference between the visual pigments of the dorsal and ventral parts of the retina possibly due to a change in the rhodopsin–porphyropsin ratio caused by keeping the fish in artificial light. Our value of the mean λ_{max} of the rods is, however, within 1 nm of the value he and Schwanzara[1] obtained for extracts of the rod pigment, inferring that the rhodopsin–porphyropsin ratio in the rods we measured in both regions of the retina was the same as that of their extracts. If *Anableps* does have higher proportions of porphyropsin in the dorsal retina in its natural habitat, we would have expected the λ_{max} of Bridges' extract to have been longer than our rod mean λ_{max}. Unfortunately, extracts normally contain only rod pigments and give no information about the distribution of pigments across the retina or the nature of the cone pigments. Thus, further microspectrophotometric studies are required.

Multiple realities?

Marie Jahoda

Einstein's Space and Van Gogh's Sky: Physical Reality and Beyond. By Lawrence LeShan and Henry Margenau. Pp.268. ISBN 0-02-570460-5. (Macmillan, New York: 1982.) $14.95. To be published in the United Kingdom in January 1983 by Harvester.

IN THE last quarter of the nineteenth century psychologists, impressed by the advances in the hard sciences, emulated their big brother and issued a unilateral declaration of independence from philosophy. Both, emulation and independence, were powerful motivators; they appeared to work reasonably well in mainstream psychology, even though doubts about the wisdom of either were raised from the beginning.

For a good part of the twentieth century emulation was based on the mechanistic physics of earlier periods. But physics had undergone revolutionary changes. Its new concepts — particularly Heisenberg's principle of uncertainty and the probabilistic nature of knowledge in many areas — gradually permeated the intellectual culture of psychologists, many of whom were all too aware of uncertainties in their methods, concepts and findings. References to Heisenberg increased in the psychological literature, used defensively however, rather than as a stepping stone to further advances, as was the case in physics.

The book under review, written by a research psychologist and a physicist, repeals the declaration of independence from philosophy in both disciplines and searches for a redefinition of their communalities and differences. It is organized in three parts, entitled "The Meanings of Reality", "The Search for Scientific Truth" and "Domains of the Social Sciences". Philosophers of science have dealt with such issues often as outsiders to the practice of science and have, as a rule, concentrated on the hard sciences; the reversed intrusion by practitioners of science into epistemology is largely limited to a specific field. The increase in books, of which this is one, that transcend both these limitations is a welcome sign of efforts to put the human sciences on a more solid base, even those aspects where matters count that cannot be counted; at least not yet.

In crude outline (omitting many interesting asides such as Heisenberg's appreciative comments on Goethe's theory of colours) the rather involved argument of the authors runs thus: the materialistic concept of reality has been shown to be limited by "the works of Heisenberg, Schrödinger, Einstein, Born, Freud, and Jung" (p.1) and needs reformulation. While common sense still regards as real only the external world that can be seen or touched, modern physics constructs as real events in the macro- and in the microcosm that are beyond the sensory competence of the human organism and can be understood only mathematically or through inference from observeable consequences. Newton's formulation of reality was not wrong but insufficient in view of later constructions that left room for his but transcended it. In particle physics and astrophysics visualization is no longer possible, but every physicist regards the regularities established in these areas as real. New constructs of reality have been invented and their correspondence to observation has been discovered.

Physics was for a time erroneously believed by some human scientists to have solved their problems. This is wrong. The aspect to be taken on board from modern physics is the idea that it is legitimate and, for certain areas, necessary to use alternate interpretations of reality, particularly when psychologists go beyond overt behaviour to study the domains of inner life. Here it is unavoidable to assume that purpose and intention are real, even though they can only be inferred (much like the electron), not seen or felt by an observer. This is a construction of psychic reality with which many psychologists have been familiar since the beginning of the century in a systematic way, but even St Augustine knew that psychological time had to be construed differently from measureable time, and accepted both as real.

Just as physics distinguishes between various domains (mechanics, quantum physics and so on) that are based on different constructions of reality, so the human sciences must identify their domains. Those suggested here in addition to molar behaviour are: art, parapsychology, ethics and consciousness. A curious assembly.

Ignoring this idiosyncratic choice of domains, what is one to make of all this? As a non-physicist I learn from this and other expositions of modern physics for the layman one important lesson: I have to take it on credit. As a non-philosopher I can only marvel at the amount of mental energy that has been expended over the centuries on pondering what reality really is: a dream, a unitary or multiple cosmos, a deliberate creation or an evolution by chance and necessity? These eternal ontological questions are metaphysics, not science. As a psychologist, I agree with the authors of this volume, that, whatever one's metaphysical stance ". . . we can never determine the 'true' shape and order of reality. We shall have to give up this dream" (p.24). All we can do *qua* scientists is to invent different ways of thinking about reality (including consciousness as much as the physical world) and check the extent to which concepts correspond to observation.

Two pages later, on p.26, the various constructs have changed into various essences, when the phrase is ". . . multiple, equally valid realities . . .", not constructs of reality. The very chapter title "Alternate Realities" implies the same deviation from p.24, and throughout the book there are other examples of confounding what there is with how we think about it. Surely we must assume that particles performed their indeterminate dance even before modern physics began to look at them as real?

It may seem pedantic to criticize the authors for what might be regarded only as elliptic phrasing, given that the basic position of an unending asymptotic approach to reality was stated clearly early on. But this is not the only case of loose talk about concepts crucial to the entire argument. Another is the concept of purpose, an indispensible concept in much of psychology where it is regarded as a state of consciousness in the here and now. On p.132, however, it is equated with "determination by the future"; on p.157 "future states influence present occurrences". This is magic. Once again, St Augustine and modern psychology know better. It is the present anticipation, not a future event which may or may not occur, that influences experience and action.

There are also some minor flaws: R.F. Bales is consistently misspelled; the index is not very helpful; some of the down-to-earth examples are not convincing; and to usurp art and ethics for psychology seems to me misplaced imperialism. Altogether, an interesting intention has been disappointingly executed. □

Marie Jahoda is Professor Emeritus of Social Psychology and Consultant to the Science Policy Research Unit at the University of Sussex.

What's what in organic chemistry

E.R.H. Jones

Heilbron's Dictionary of Organic Compounds, 5th Edn. Executive editor J. Buckingham. Seven volumes, pp.7,848. ISBN 0-412-17000-0. (Chapman & Hall/Methuen: 1982.) £975, $1,950.

THE number of compounds described in the literature provides a more precise measure of the growth of chemistry than publications or other indicators. Organic chemistry, thanks to the tetravalency of carbon and the stability of its incestuous bonds, is responsible for most of these compounds; even the recent plethora of inorganic compounds is attributable to organic coordinating components. The number is now nearly five million and, resulting from advances in techniques, many recent additions have large and complicated structures. Remarkably, however, this situation is being coped with.

Some 50 years ago Professor Ian Heilbron and H.M. Bunbury recognized the need of chemists for something akin to the *Concise Oxford*, and the first edition of the *Dictionary of Organic Compounds* (1934), a most successful venture, provided a readily accessible source of information. "Heilbron" is the first point of enquiry for many, and this fifth edition (the fourth appeared in 1965) is timely indeed. The need for facile reference to the literature has never been greater.

In the new edition the original policy of encompassing all of interest and importance is more specifically defined; the intention has been to include fundamental compounds of simple structure, the majority of important natural products, compounds of commercial value, and laboratory chemicals and those with special chemical, physical or biological properties. Selection of the 50,000 entries, by deletion as well as addition, which overall results in the mention of about 1 in 30 of known compounds, has been satisfactorily achieved with the assistance of a hundred chemists, including some 20 special editors, all experts.

With this highly organized team and using modern methods of data handling, the selection and compilation of information and production of the books were completed within five years so that the primary literature has been covered to the end of 1980. Although the new edition involves "the most radical revision and modernisation", the traditional format, the generous provision of structural formulae and indeed all the familiar features have been retained. And there are significant changes. Citing only one author's name is a sensible economy and specifying the content of references (e.g., isol, synth, struct, cmr and so on) is a valuable innovation, as is the extensive inclusion of toxicity and hazard indications and references.

Organic chemists think in terms of structural formulae and need assistance to translate these into dictionary entries. Help is abundantly available from the molecular formulae and name indexes. Alternative and recommended names are given, indication of their sources is useful and Chemical Abstracts Registry Numbers provide a nomenclature-independent link to, and from, those printed here and to the other services which are increasingly using Registry Numbers. A heteroatom index, in 62 sections, points to the entries containing elements other than C, H, O, N and halogens. Thus we find amongst the 1,500 organo-metallic compounds 19 of copper and 25 of manganese. Accessibility to the alphabetical entries from the indexes is enormously facilitated by serial numbers for each entry, and will be most helpful with the annual supplements (the first promised for 1983).

By comparison with the cost of periodicals and other books, the seven volumes and 7,800 pages represent excellent value for scarce library money. The *Dictionary* is an essential adjunct wherever organic compounds are used, nowhere more so than in educational establishments where students need training to cope with the population explosion in organic chemistry. □

Sir Ewart Jones is Emeritus Professor of Chemistry at the University of Oxford.

The bones of palaeopathology

D.R. Brothwell

Identification of Pathological Conditions in Human Skeletal Remains. By Donald J. Ortner and Walter G.J. Putschar. Pp.479. (Smithsonian Institution Press/US Government Printing Office: 1982.) Pbk $12.

TWENTY-five years ago, as a young graduate of University College London, I was puzzled and impressed by the near total eclipse of interest in sub-fossil skeletal remains, and especially the evidence of palaeopathology which could be found in them. A quarter of a century earlier, in Egypt and eventually at the same college, Sir Grafton Elliot Smith and colleagues had produced distinguished studies on thousands of skeletons and mummies, paying close attention to the evidence of disease. Yet in my time, bones were a matter of considering the many scraps of fossil hominids or were simply used in the general teaching of comparative vertebrate anatomy.

The balance of interests in the biology of man is ever changing, however, with the result that human disease ecology and even such highly specialized topics as the problems of identifying disease in excavated skeletal remains is receiving renewed attention. Evidence of this, if evidence were needed, is this handsome large-format book by two of the senior names in palaeopathology.

Considering the vast literature on medical diagnosis, one might imagine that there were sufficient references to the differential diagnosis of skeletal disease. What had Elliot Smith, Ruffer, Wood Jones and all the other golden oldies used? The answer is that they made do with rather limited texts and similarly limited dry bone specimens in medical museums, and with a range of clinical experience of bone pathology in those pre-antibiotic times. But museum displays are changing (if not shrinking) and dry bones are no longer priority exhibits. It was thus becoming critical that some detailed stock-taking was undertaken, preferably with an eventual published text and "atlas" of good illustrations in mind.

These changes then, and the growing literature on bone pathology, demanded an up-to-date review of the subject, preferably with a large range of well-selected, high-quality illustrations. Although a number of introductory texts and two symposium proceedings appeared in the 1960s, the definitive reference work of the kind provided by Ortner and Putschar remained a much needed project. This is a well-illustrated, carefully researched collaborative effort providing a comprehensive review of pathological conditions that affect the human skeleton. Having seen the authors in action, scanning the Royal College of Surgeons collection in London, I can vouch for the care with which they have not only surveyed past literature, but personally examined a very wide range of specimens of known diagnosis. There are thus authoritative details of a wide range of diseases affecting the skeleton, from congenital abnormality, trauma and arthropathy, to endocrine and metabolic disturbances, circulatory disorders and the numerous divisions of infectious disease (including less well known bone pathology, the result of mycotic infections, brucellosis, sarcoidosis and echinococcosis).

There is no doubt that this volume is an essential reference work for all those who handle ancient human skeletal material. It should also hold interest for medical historians as well as radiologists, pathologists and orthopaedic specialists. □

Don Brothwell is Reader in Zooarchaeology at the Institute of Archaeology, London.

Plants and biochemical defence

John Friend

Phytoalexins. Edited by John A. Bailey and John W. Mansfield. Pp.334. ISBN 0-216-91162-1. (Blackie/Halsted: 1982.) £28, $79.95.

THE existence of phytoalexins as antifungal compounds actively accumulated by plants was first proposed in 1940 to explain the response of potato tuber tissue to inoculation with avirulent and virulent races of *Phytophthora infestans.* Although the major sesquiterpenoid phytoalexin from potato was not isolated until 1968, in the intervening period phenolic and terpenoid phytoalexins were identified in orchids, sweet potato, carrots, peas and French beans. Many more plants have since been investigated for their ability to produce phytoalexins in response to environmental stress, as well as to challenge not only by fungi by also by bacteria and viruses and by salts of heavy metals.

The aim of the editors of *Phytoalexins* was to review in detail the compass of current research into these compounds; with the aid of a battery of international authorities on the various topics, this is what they have done and excellently so. Broadly the book falls into two parts, the first of which deals mainly with the chemical study of phytoalexins.

Since the majority of such compounds have been isolated from the Leguminosae and the Solanaceae a separate chapter is devoted to each of these families (by J.L. Ingham and J. Kuć, respectively), whereas the phytoalexins from all the other families are covered in a further contribution by D.T. Coxon. Ingham's chapter is particularly valuable in that it includes chromatographic and spectroscopic data which can be used for the separation and identification of phytoalexins. In his comprehensive review of phytoalexin biosynthesis A. Stoessl separates the phytoalexins according to their biosynthetic origin from shikimic acid, acetate-polymalonate and mevalonate; he also emphasizes the value of stressed tissue for biosynthetic studies.

In the remaining contributions, comprising the second part of the book, the accent is on the possible roles of phytoalexins in plant diseases. The reactions involved in the metabolism of phytoalexins both by microorganisms and plants are described by H.D. VanEtten and colleagues, and D.A. Smith discusses the toxicity of phytoalexins and their metabolites. J.W. Mansfield then provides a detailed description of phytoalexin accumulation in the interaction of several leguminous and solanaceous plants with fungi, bacteria, viruses and nematodes. It is clear from these accounts that pathogenicity cannot necessarily be explained by the ability of the invading pathogen to tolerate or metabolize phytoalexins, although in many cases of resistance there is sufficient accumulation of phytoalexins to account for this resistance; nevertheless other factors such as suberization and lignification must be taken into account.

In his review of the mechanisms of phytoalexin accumulation, J.A. Bailey indicates that the underlying mechanisms leading to the build-up of all classes of phytoalexin may be similar. He proposes that host cell death releases an endogenous elicitor which triggers the enzymes involved in phytoalexin biosynthesis, and points out that specificity would involve control of cell death. The final chapter, written by the two editors themselves, is an excellent summary of work on phytoalexin function to date and of possible ways in which it could proceed in the future.

The overall presentation, particularly of the formulae and diagrams, is good and there are very few errors. Moreover there is a comprehensive bibliography with each chapter, and a compound and an organism index at the end of the book (though, unfortunately, no author index). *Phytoalexins* will be the standard work on the subject for some considerable time; as such it is an essential reference volume for all workers in plant disease physiology and phytoalexin biosynthesis. ☐

John Friend is Professor and Head of the Department of Plant Biology at the University of Hull.

Flies in the lab

Michael Ashburner

A Handbook of Drosophila Development. Edited by Robert Ransom. Pp.289. Hbk ISBN 0-444-80366-1; pbk ISBN 0-444-80418-8. (Elsevier Biomedical: 1982.) Hbk Dfl.250, $116; pbk Dfl.100, $46.

THE EDITOR of this collection of reviews on the development of *Drosophila* states his objective as being:

> to provide a useful and practical research aid, which may be kept close at hand on the researcher or students [*sic*] own bookshelf.

This, however, is not a "handbook" in the German tradition; the fact that you can actually pick it up with one hand establishes that. Yet its chapters do provide useful, if not over-scholarly, reviews of the embryonic and imaginal development and structure of *Drosophila.* There is, of course, some overlap with Vol.2 of *The Genetics and Biology of Drosophila* (Academic, 1978) — a work in which I must declare some interest — but except for two

chapters this is minimized by the differences in organization between the two works. I am disappointed, however, that this book has not been truer to its design, restricting itself to hard data and not degrading this information with speculative "noise". In each chapter the worst sections are those with some such heading as "Genetic studies on . . . ". These contribute very little to what is already easily available and are, in general, too superficial to be of any interest or use.

An editor of a "handbook" has a duty to ensure that the factual information is correct. This ideal can never be wholly achieved, yet I cannot but warn the reader of this book that the editor's own chapter, on techniques (and to a lesser extent his contribution on internal organs), is seriously flawed.

Perhaps I should quote one or two errors of fact: "Each female only mates once". Quite untrue. "Sex is determined by X chromosome dosage". Again untrue, it is determined (in *Drosophila*) by the X:autosome ratio. "This phenomenon [mitotic recombination] can be induced spontaneously". No comment.

Finally, I defy any reader to understand the mechanism of mitotic recombination from Fig.6, which shows undivided centromeres as if this were the first division of meiosis; I also do not approve of the illustration of methods to screen for mutations by specialized, rather than more general techniques (i.e. Figs 11 and 12).

Happily, this standard is not maintained in the other chapters. There are one or two annoying features (for example Fig.1 of Chapter 4 and Fig.16 of Chapter 7 are identical), but in general the central eight chapters are solid and competent and make the book a useful addition to the *Drosophila* biologist's laboratory bookshelf. ☐

Michael Ashburner is Reader in Developmental Genetics at the University of Cambridge.

Twenty-five years of cyclic nucleotides

D.G. Hardie

Cyclic Nucleotides, Vols 1 and 2. Edited by J.W. Kebabian and J.A. Nathanson. Vol.1 *Biochemistry*, pp.557, ISBN 3-540-10786-X; Vol.2 *Physiology and Pharmacology*, pp.888, ISBN 3-540-11239-1. (Springer-Verlag: 1982.) Vol.1 DM390, $173.20; Vol.2 DM 560, $248.70.

IT HAS been possible to show that the response of the homogenates to the hormones occurred in two stages. In the first stage, a particulate fraction of homogenates produced a heat-stable factor in the presence of the hormones; in the second stage, this factor stimulated the formation of liver phosphorylase in supernatant fractions of homogenates in which the hormones themselves were inactive [T.W. Rall, E.W. Sutherland and J. Berthet *J. Biol. Chem.* **224**, 463–475, 1957].

This unpretentious announcement of the discovery of a heat-stable factor, later identified as cyclic AMP, quietly heralded the era of the cyclic nucleotides. While the authors no doubt realized that their observations represented a breakthrough, they can hardly have guessed at the impact they would ultimately have. Twenty-five years later it is clear that cyclic AMP has a central role in cellular regulation, equivalent to that of its parent nucleotide ATP in metabolism.

- A second edition of *Germ Cells and Fertilization*, Book 1 in the series *Reproduction in Mammals*, has recently been published by Cambridge University Press. Prices are hbk £15, $24.50, pbk £5.95, $11.95.

Four further volumes in the second edition of the series (which is edited by C.R. Austin and R.V. Short) are scheduled to appear in due course.

These two volumes provide the latest review of the field and are, in the words of the editors, an attempt at a "comprehensive and up-to-date anthology" with contributions by 72 well-known cyclic nucleotide researchers. The books appear in the much-respected *Handbook of Experimental Pharmacology* series, to which all pharmacology departments no doubt subscribe. But do they deserve a wider audience?

The two volumes are to a certain extent independent of each other. Volume 1, *Biochemistry*, covers the enzymology of cyclic nucleotide metabolism and of the protein kinases which form the only known intracellular receptors for the cyclic nucleotides. It also provides ample discussion of the interactions between cyclic nucleotides and that other ubiquitous cellular regulator, the Ca^{2+} ion; calcium, at least in its free cytosolic version, seems now to have almost acquired the status of "honorary cyclic nucleotide". Volume 1 gives a well-balanced and reasonably up-to-date account of these aspects of the field. A notable omission, however, is any discussion of protein phosphatases, which do not even appear in the index. This is regrettable because it is now apparent that some actions of cyclic AMP are mediated through inhibition of protein phosphatase-1 by the heat-stable inhibitor protein which is phosphorylated by cyclic AMP-dependent protein kinase (a topic reviewed recently by Philip Cohen in *Nature* **296**, 613–620; 1982).

Volume 2, *Physiology and Pharmacology*, covers, as it were, the applications of cyclic nucleotides in physiological processes. It gives an idea of their breadth of function, with topics ranging from slime moulds to the mammalian brain.

An interesting contrast emerges from these volumes between our knowledge of the role of cyclic AMP and that of cyclic GMP. Although cyclic GMP was discovered as long ago as 1963, its functions are still largely obscure. The Yin–Yang hypothesis, so delightfully named by Nelson Goldberg, in which cyclic GMP was seen as a messenger opposing the effects of cyclic AMP, now seems untenable. While Murad speculates here that cyclic GMP might be a general feedback regulator of redox state, it seems possible that despite its ubiquitous occurrence it in fact performs only specialized functions (for example in dark adaptation in the retina as discussed by Farber in Vol.II). This would be rather analogous to its parent nucleotide GTP which, in its guise as energy donor rather than nucleic acid precursor, has a small number of rather specialized roles one of which is the regulation of cyclic AMP formation by adenylate cyclase.

In his introduction to the two volumes, Rall states that the 1960s saw a great advance in our understanding of the mechanism of action of cyclic AMP in physiological systems, while in the 1970s the progress has been marginal. This is indeed the overall impression given by Vol.II, with a very few of the systems described being understood in molecular terms. However I believe this view to be misleading. It reflects, in part, an emphasis on systems with relevance to pharmacology where the basic processes themselves are not understood. It also ignores the fact that of the 20 or so physiological substrates for cyclic AMP-dependent protein kinase whose function is known, all but three have been identified since 1970. Given that these substrates are tabulated in the chapter on cyclic AMP-dependent protein kinases in Vol.1, some of the omissions in Vol.2 are very surprising. For example, a chapter on "Regulation of Lipid Metabolism by Cyclic Nucleotides" makes no mention of any of the well-characterized phosphoproteins involved in lipid synthesis, such as acetyl-CoA carboxylase or hydroxymethylglutaryl reductase. And that entitled "The Role of Cyclic Nucleotides in the Vasculature" states that the causal link between cyclic AMP and the relaxation of vascular smooth muscle is unknown — the work of Adelstein and others on relaxation of smooth muscle via phosphorylation of myosin light-chain kinase is not mentioned. Readers who prefer their explanations in molecular terms, or at least in terms of defined proteins, will find Vol.II disappointing, and in my view this need not have been the case. ☐

Where not to put strategic missiles

The Reagan-Weinberger solution to the MX-siting problem is ingenious, probably unworkable and certain to confuse the generals. It points only towards the need for strategic arms control.

The Reagan Administration appears to be capable of thinking not merely the unthinkable but the unworkable. Now, after years of uncertainty, Mr Caspar Weinberger, the US Secretary of Defense, has proposed and President Ronald Reagan has agreed that 100 MX missiles should be based in a narrow tract of land in Wyoming, handy for the short journey over the North Pole to targets in the Soviet Union but also so well advertised in position as to be itself an easy target for Soviet intercontinental missiles. In the bewildering spectrum of solutions to the problem of how the MX missiles should be sited, the Reagan-Weinberger solution is at the other extreme from that to which President Carter appeared to be most attracted — building underground railway systems so that 100 missiles could be distributed more or less at random (so far as outsiders could tell) between more than 2,000 potential launching silos. The Carter solution to the problem of where and how to put the missiles had the obvious advantage that a potential enemy of the United States (supposed for these purposes to be the Soviet Union) could make an effective first strike against the US stock of strategic missiles only by making 2,000 separate attacks on as many holes in the ground, of which fewer than five per cent would be occupied by missiles. The disadvantage, as the people of the western states told Mr Carter clearly enough, was that the whole arrangement would be an infernal nuisance, socially as well as environmentally. His taxpayers were also understandably alarmed at the cost. The Reagan-Weinberger solution has the advantage of avoiding the most obvious difficulties. Its disadvantage, which influential people as different as Professor Charles Townes (see *Nature* 18 November, p.208) and Dr Richard Garwin are pointing out, is that it lacks credibility.

Although intercontinental ballistic missiles are only a little more than a quarter of a century old, they have been with us long enough for the question of where to put them to be recognized as important, crucial and vital (in the sense of life and death). At the outset, when missiles were so inaccurate that their only accessible targets had to be large cities, and when the chance of a missile silo being hit by an attacking missile aimed at it was virtually zero, superpowers could base their intercontinental missiles in silos whose locations were known to potential enemies without fearing that their capacity to retaliate would be impaired by a preemptive strike. For the past decade, however, and especially with the development of techniques for guiding warheads to their targets without continual reference to the launching site (i.e. intelligently), that calculation has gone by the board. The chances now are that it is possible for one side or the other to destroy point targets on the other side with weapons whose yield in terms of the equivalent in conventional explosives is no more than, say, 100,000 tonnes. So the United States is rightly worried that its force of nearly 1,000 Minutemen scattered through the western states has become vulnerable to a first strike, and anxious that it should be replaced by something better or less vulnerable. Even those who disdain entirely the basis on which such calculations are made must acknowledge that a superpower worried about the viability of its striking force is a dangerous superpower, likely to be tempted to fire them off before there is an undeniable need to do so. In other words, so long as superpowers exist, they must be helped to feel confident about the security of their missile forces for otherwise they will become trigger-happy and dangers to the rest of us.

The principal Soviet striking force is no better placed. While missile launchers are able to shuttle along most of the length of the trans-Siberian railway and thus secure a measure of protection from uncertainty, the speed with which they move (slow) and the steady improvement of satellite reconnaissance also makes them vulnerable to a first strike from some other superpower. So there is a case for hoping that both of those superpowers with a legitimate interest in the maintenance of counter-force missile flights should be helped towards a system for their deployment that will be more credible for the generals, more conducive to good nights' sleep by generals' political bosses (and less burdensome for taxpayers). What can this be?

The Reagan-Weinberger solution in Wyoming is a reasonable starting point. The calculation is that a hostile superpower would first attack the southernmost missile silos; otherwise succeeding waves of missiles would necessarily have to travel through electrically and mechanically disturbed atmosphere. So why not build the southernmost silos, but not put missiles in them? With a little luck, it might be possible to get by with only half the force of 100 missiles now planned. But with a little ingenuity, it will be possible to save still more public money and at the same time to reinforce the now shaken confidence of the generals, by leaving all the silos empty but deciding, secretly, to put a few MX missiles in existing holes in the ground, the Minuteman silos soon to be vacated for example. Or it could, with an even greater exercise of ingenuity and intelligence, be recognized by both the superpowers that what the Reagan-Weinberger solution of the MX problem demonstrates is the need for both of them to opt out of the application of a first strike capability.

In retrospect, the 1950s, when the two superpowers were able only to threaten each other with the crudest forms of annihilation, were comparatively comforting times. The gulf between conventional conflict and mutual nuclear annihilation was huge — so huge that nobody ever thought it would be bridged. What technology has made possible, in the MX missile and its Soviet counterparts, is the prospect that the other fellow's strategic force might be destroyed before it can be used, coupled with a haunting anxiety that the missiles that will accomplish that cannot themselves be hidden or protected. The sensible course, therefore, is to agree to give them up, by negotiation at Geneva. For the time being, neither superpower need abandon its force of submarine-launched missiles, the reason why each can say to the other that annihilation of people, not machines, is still within its grasp. But the Reagan-Weinberger solution should, by the fancifulness of its disposition of expensive hardware, point urgently in that direction.

The Reagan-Weinberger solution of this dilemma is ingenious and even daring but may not create the sense of confidence that both generals and taxpayers in the United States are likely to demand. The theory, of course, is simple. If a hostile warhead should attack some missile silo in the proposed "Dense Pack" missile park in Wyoming, destroying that and putting its immediate neighbours out of action, the calculation is that there would still be others (further north?) still capable of reacting, and that these would be invulnerable to attacking warheads because they would be protected by the atmospheric ionization (radio blackout) and turbulence caused by the first attacks. The underlying assumption, of course, is that the attacking warheads

0028-0836/82/480389-02$01.00

would be fashioned as those intended to be packed (ten to a rocket) in the MX missile are designed. The trouble is, for the Reagan-Weinberger solution, that attacking warheads might be differently designed, made so as to make large holes in the ground. But in any case, what the generals in charge of the proposed missile park in Wyoming will know up until the last moment is that there has not and will not have been a practical demonstration of the doctrine of fratricide, the argument that the first attacking warhead will prevent others from doing their job. And in the event, uncertainty in a general's mind is more important than any amount of theoretical calculation by professional people who have studied the effects of nuclear weapons on the atmosphere. The calculations may be right, but if the generals do not accept their implications, they may ask the president of their day (unlikely to be Mr Ronald Reagan) to press the button that will prevent a preemptive attack. And he (or she) will have no choice but to agree.

Tell us about our friends

The President of the Royal Society has made a brave speech on Soviet illiberality.

How should a learned society, or for that matter a national rugby football union, conduct international relations with its counterparts in countries whose governments command little respect? This old dilemma is too little discussed, but Sir Andrew Huxley seems to have enlivened this year's anniversary meeting of the Royal Society (see next page) by an account of how deliberate and even obdurate innocence can triumph where diplomacy dictates mere compromise.

Conventional logic goes like this. By convention, (and United Nations charter) governments do not interfere in each others' internal affairs except in those mercifully rare circumstances in which they go to war with each other. National academies (not to mention rugby football unions) are even less well-equipped to effect political change in any sphere. Their analysis of what needs changing, and how, is certain to be less expert than that of the political professionals, diplomats on the international stage. Their assessment of how change might be accomplished is bound to be amateurish. Their resolution to carry through a recipe for change is bound to be compromised by differences of opinion among their members. This is why the Royal Society has been right, in this presidency and the last (Lord Todd's), to insist that the character of the Soviet government was not part of its concern, and was in any case a question outside its competence. If Soviet citizens are locked up or harassed in other ways because Soviet laws expect and exact more from them than do other people's laws, the fact that those injured happen to be scientists (or rugby footballers) is strictly speaking irrelevant. Indeed, when the going is rough, conventional opinion has it that the preservation of close relationships is all the more important. This is the spirit in which Huxley this week insisted that the pitiful trickle of professional exchanges with the Soviet Union should not be compromised by his decision to complain in public about the Soviet academy's apparently deliberate misunderstanding of questions about the ill-treatment of certain Soviet scientists.

Huxley's predecessor, Lord Todd, maddened much of the British scientific community by his proper repetition of the doctrine that sovereign governments of any kind are autonomous within their legal territory, but then won unexpected friends with his fierce attack on Soviet oppression of scientists at the Hamburg meeting on the Helsinki accords three years ago. Huxley's line has been more guileful. Enquire about your friends. When challenged, put the details down on paper. Then hope for the best but anticipate the worst. And when the weasel answer comes that Sakharov has been dealt with leniently, and when you know that he is still confined in Gork'ii with the third winter closing in, simply say in public that the explanation is insufficient. The doctrine of the autonomy of sovereign states is an essential foundation of orderliness, and should not be undermined, but what is to prevent us asking after our friends?

Adam Smith forgotten

This week's meeting on international trade could have been disastrous but should have been better.

In the nine years since the last formal meeting of the governments that are party to the General Agreement on Tariffs and Trade (GATT), the world for which the agreement was originally negotiated has been transformed out of recognition. Nine years ago, the great increase of the international price of oil had only just begun, and few could guess what the consequences would be. Now, of course, we know: inflation and recession in the industrialized world, inflation and stagnation elsewhere. The rich countries are at best marking time, (but Japan, ironically classified at GATT as a country in the process of industrialization, is an exception); the poor are mostly becoming poorer (but countries such as India may yet be exceptions). The barely hidden agenda for this year's meeting seems to have been the wish of industrialized countries to look each other in the eye so as to discover whether they should hold to the principles of free trade on which GATT is founded (and if so whether their partners could be persuaded to obey the rules) or whether they should follow the politically more prudent course and settle for protectionism instead. Although Monday's formal communique reaffirms the principle that free trade is best, only in the months ahead will it be clear how many of the signatories believe that to be the case. (The government of Australia walked out at the weekend on the grounds that the then promised declaration was too leaky a commitment, generously studded as it was with phrases such as "wherever practicable".)

The trouble with GATT, like any other club, is that its members can and will resign whenever they think the costs of membership outweigh the benefits. And the trouble with a club whose members agree to trade freely with each other is that the costs are the more easily perceived. Most industrialized countries, now struggling with unpalatable and perhaps even unsupportable unemployment, know that measures to keep out imports would have an immediately beneficial effect. Domestic customers now buying efficiently-made goods imported from abroad would instead buy less efficiently manufactured domestic products, creating jobs for fellow-countrymen. Only in the longer run would the snags show up — customers required to support inefficient industries are on that account less prosperous than they might be. Two centuries ago, Adam Smith made the point quite simply: the wealth of nations stems from their capacity to bring about a rational division of labour, domestically and internationally.

This time round, GATT has merely stayed still. The constructive parts of the communique on Monday are those referring to studies to be carried out in the first instance by officials on some of the more contentious issues — should free trade extend not merely to manufactured goods but to invisibles — insurance, shipping and the like? (Yes, whatever Japan says.) Should free trade also extend to agriculture? (Yes, even though the European Community is outwardly united in its opposition.) What should be done about counterfeiting? (It should be penalized.) And the plight of countries in the process of industrialization? Who knows? If GATT hopes to survive, it must answer these questions before too many of its members drift away.

Meanwhile, Adam Smith is an evocative reminder that a rational (market-driven) division of labour cannot be accomplished without upheaval. Even in the best-regulated international communities, in the short run one country's industrial gain is likely to be another's loss. In the heady 1960s, when it seemed as if economic growth (and world trade) would continue without interruption, there was endless talk in places such as GATT of the virtues of adjustment assistance — ways of compensating losers for short-term losses. But that talk has now faded. Yet when the danger that nations will barricade themselves behind their trade barriers is greater than ever, the need for such assistance is ironically more urgent than it has ever been.

London and Moscow in hassle

Huxley attacks Soviets on civil rights

A complaint by the Royal Society about the treatment of Soviet scientists by their government has been delivered to the Academy of Sciences of the USSR, and the reply has fallen "far short" of what was promised, and hoped for. This was the most arresting message in the anniversary address to the Royal Society, delivered by Sir Andrew Huxley, the president, last Tuesday. While Sir Andrew reaffirmed his adherence to the society's view that scientists who break their countries' laws are just as liable to punishment on that account as are other citizens, his decision to make public the Royal Society's dissatisfaction with its enquiries of Soviet scientists is a break with precedent and recent practice.

The exchange between the two academies apparently began in May this year, when a Soviet delegation visited the United Kingdom. Sir Andrew explained this week that while not wishing "to sacrifice international cooperation between individual scientists in the hope of persuading the government of another country to change its internal policies", oppressive treatment of scientists by the Soviet government was already "harming scientific interchange" with Britain.

By way of illustration, Sir Andrew said that the funds available each year for exchanges with the Soviet Union are not fully taken up, partly because British scientists are unwilling "to spend time in the USSR because of the oppression in that country of dissident scientists, the refusal of permission to Jewish scientists to emigrate to Israel and recently the revoking of the academic degrees of certain individuals".

The meeting with the Soviet delegation in May this year seems to have been turbulent. Sir Andrew said this week that "we took this opportunity of putting this point forcefully to them". By his account, the Soviet delegation, emphasizing that the Academy of Sciences was not responsible, offered to investigate any cases the Royal Society cared to specify in detail, and to report. The Royal Society then apparently wrote with details of twenty-one Soviet scientists in trouble — seventeen who were being "subjected to various forms of punishment", five refusniks and three who had been prevented from attending scientific meetings in the United Kingdom. The reply from Moscow appears to have arrived only early in November, and to have been unsatisfactory. "Seventeen of the twenty-one scientists named in our letter are not even mentioned, and I take this as a tacit admission that in most or all of these cases there is no respectable excuse that can be put forward as justification of the treatment they have been given."

Huxley went on to say that he finds it "difficult to accept" the explanation given for the treatment of Alekssander Lerner, who has been refused permission to emigrate to Israel; can "reasons of national security, including knowledge of classified and defence material", apply to one dismissed from his post at the institute of control sciences in Moscow eleven years ago? The Soviet academy also says that V. Kislik is imprisoned for "petty crimes" without saying why he has been deprived of his degrees, and that Y. Orlov is imprisoned for having damaged the Soviet Union politically.

The case of Andrei Sakharov seems, however, to have been the most serious bone of contention. Sir Andrew said that the Royal Society's letter complained that Sakharov was being "persecuted for his work in defence of human rights", and went on to say that nobody denied that he had criticized restrictions of individual freedom in the Soviet Union, published writing abroad and yet been allowed to remain a member of the Soviet academy.

The Soviet academy's reply seems to have been a deliberate misreading of the complaint. Sakharov's exile to Gork'ii is said to be "comparatively mild" in relation to "his actions, which had the aspect of being crimes against the state". Huxley says that the Soviet reply on Sakharov emphasized his dissent from Soviet policies on arms control whereas "most in the West" consider that the "real reason" for his exile is his criticims of "the illiberal internal regime in the USSR".

Huxley concluded his address by saying that his decision "to express publicly my own feelings" is to be taken as a definition of his position, but that he would not wish to curtail the exchange of scientists between the two countries or restrict visas "to *bona fide* scientists wishing to attend international meetings". ●

French university lecturers protest

Hundreds of French university lecturers marched from the Sorbonne in the centre of Paris to the ministry of national education last Friday, in protest against what they see as a complete abandonment by the minister, M. Alain Savary of any serious — and socialist — reform of the university system.

Much had been — and is — expected of Savary's "law for higher education" to be put before parliament by the end of the year, but the higher education trades unions have not been much impressed so far. Hence the strike.

Backing for the union view, however, may not be particularly strong. A few hundred demonstrators are only a small part of the 44,000-strong community of university teachers, and the union demands for a single kind of lecturer (including professor), with promotion by seniority are seen as unrealistic in many quarters.

Nevertheless the outburst of grievances among the unions has a substantial basis — the enormous blockage of posts within the universities, which according to ministry calculations will see only 158 retirements next year, one third of one per cent of the staff. Thus a common international problem among universities is gravely exaggerated in France, because of a peak in the recruitment of staff in the late 1960s, before and after the "troubles" of 1968.

Moreover, this tinder-box situation has been aggravated by some expectation of relief, after the savage activities of the previous, Giscardian, minister of the universities. But Savary is offering little or no relief, and indeed is piling on the pressure with a reduction in part-time teaching allocations, a lengthening of the university year, and an insistence that since university staff are civil servants, they must take no more than five weeks' holiday. The number of students would also increase from its present 800,000 to 1 million, said the minister.

Recently the minister further announced to the unions that their dream of a single category of lecturers was unattainable, and that there would instead be a system much like the present, with effectively lecturers, senior lecturers and professors with appointments between grades determined by peer review. That was the last straw, and led the left-wing unions to the strike.

Now, however, the ministry is suggesting that "new propositions" will be made within a couple of weeks — apparently opening all options once more.

This seems to leave the preparation for a new higher education law, one to replace the somewhat rushed law of 1968, in an utter shambles. So many interest groups are at work that it is little wonder that the French education system is sometimes described as the largest political system outside the Red Army.

Moreover, there is a further muddle ahead: the question of appointments and promotions for 1983, previously fixed in late December and early January by the Conseil Supérieur des Corps Universitaires (CSCU), a giant partially-elected parliament of specialist committees. Savary dissolved the previous CSCU, a product of the previous government, a year ago. But this year, without an election policy, each committee has had to be filled by a lottery. It is hoped that the promotions will not be equally random.

French science

No big deal

Eighteen months after the arrival of the Mitterrand government in France, with its promise of a great new deal for French scientists, reform of the Centre National de la Recherche Scientifique (CNRS) is complete, or almost complete.

Last week the new statute for CNRS was finally agreed at the Council of Ministers, and published along with the appointments to seven top jobs — some of them new — and the budget details for 1983, showing continued growth of about 13 per cent in real terms (outside salaries). What remains are the elections to the Comité National, the CNRS "parliament" which makes detailed decisions on grant allocations, appointments and promotions in CNRS laboratories. The elections on new (reformed) principles are planned for March.

M. Maurice Godelier, the anthropologist whose appointment as director of social sciences was vehemently opposed little more than a year ago, has now slipped into the role without much protest. His far-ranging report on social sciences to the minister of research and industry (see *Nature* 28 October, p.771) appears to have had a calming effect, and he has been appointed jointly with the previous acting director, M. Armand Frémont, to a combined directorate of social sciences and humanities. Frémont is expected to concern himself with regional issues, while Godelier will be concerned with the higher issues of policy.

Two new directorates have been created: one for information and publications, and another for the application of research ("valorization"), which should strengthen the role of the CNRS in innovation, a principal objective of the government.

The director of valorization will be M. Jean-Jacques Duby, a 42-year-old mathematician who has had a distinguished career in IBM research and management. M. Duby will consider offering incentives to research groups in the form of additional grants for basic research in return for time spent on applications, a scheme which works well at the Institut Pasteur. CNRS will also seek an increasing role in the research training of third world scientists.

As for the 1983 budget, the net real increase of 7.3 per cent (including salaries), the 320 new research posts (3.4 per cent) and 220 new technicians (1.5 per cent) will be divided unevenly according to the particular needs of each sector. Thus the social sciences receive a large sum for new buildings, to house the home workers; biotechnology sees a start on a new FF20 million (£1.7 million) laboratory for the molecular biology of plants in Strasbourg (which will take three years to complete); and physics sees an allocation for the construction of a new synchrotron radiation source for Orsay, "Super-ACO".

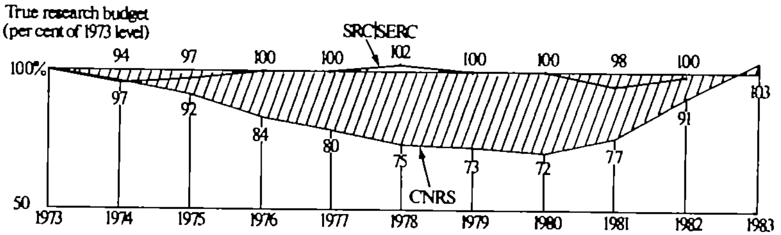
Dividing the budget differently, however, one of the most substantial increases planned for next year comes in medium-sized equipment — instruments costing roughly between FF 1 million and FF 3 million. Here the budget will rise 60 per cent. There is some question, however, whether this sum will survive "regulation" — the mechanism whereby the minister of finance holds back some monies previously promised, subject to good performance of the French economy. This year CNRS did well — losing only FF 50 million in the last analysis, in a budget of FF 6,000 million, but there are fears of worse controls to come — even up to 30 per cent. M. Jean-Pierre Chevènement, the minister for research and industry, is fighting this battle with his ministerial colleagues, in the hope of protecting research from the ravages of the government deficit.

Robert Walgate

Budget trends in Britain and France

For Britain, the graph shows the evolution of the budget of the Science and Engineering Research Council, excepting salaries and corrected for inflation by the retail price index. The figures are given as percentages of the 1973 budget. This indicator of "true money for science" is almost exactly constant over the decade. By contrast, the roughly equivalent Centre National de la Recherche Scientifique in France shows a strong decline in the same quantity over the 1970s, followed by a small rise in 1981 (the last year of the previous government). The strong increase in the past two years indicates the impact of the Mitterrand era. But the 1983 budget will only just pass that of a decade earlier. The continuation of the slope to 1985 is broadly guaranteed by the "law for research" of July this year but may be affected by the uncertain state of the teetering French economy.

Robert Walgate



Professional liability

Biologists at risk

Washington

As biology comes to have commercial implications, biologists need to insure themselves against lawsuits: their professional lives are getting risky. This seems to be the unwritten message of a brochure now being mailed to members of four US scientific societies concerned with biology and biomedicine.

A "professional liability insurance policy" is being offered for $62 per year to members of the Federation of American Societies for Experimental Biology, the American Institute for Biological Sciences, the Society for Neuroscience and the Society for Medical Research. The policy is organized by Maginnis and Associates of Chicago and underwritten by the National Union Fire Insurance Company of Pittsburgh.

The policy covers up to $1 million in costs, in addition to repayment of legal defence costs, for each "occurrence" or incident in which an insured scientist stands accused. It will also pay these costs if the lawsuit arises years after the policy has expired, so long as the events in question took place while the policy was active.

Maginnis officials say the policy covers scientists in situations where they do not normally have insurance cover. An employer such as a university, they note, might be sued for something a faculty member did and then decide the faculty member was negligent and sue him. Or the university might decide that the action in question was outside the faculty member's "scope of employment" and leave him to fight on his own.

The policy would also cover a scientist when consulting outside his regular employment, with a company or individually, whereas his regular employer's insurance would not.

Scientists are covered for advice they give to doctors or nurses about how to treat patients in case the patient later sues the scientist as part of a malpractice suit against his doctors. But the proposed insurance policy does not cover the scientist if he talks to the patient directly, so cancer gene specialists are advised not to hand out free advice to potential patients at cocktail parties.

Arthur C. Gentile, executive director of the American Institute of Biological Sciences, says the policy "covers just about every kind of professional activity". He cites a case where there was an explosion in a laboratory and people who were injured sued. Although the institution that owns the laboratory would probably be liable, the scientist running the laboratory might be named too. "The liability may not be clear and in the meantime you have legal costs" says Gentile.

The policy covers someone charged with libel or slander — such as harming another

0028-0836/82/480392-02$01 00

scientist's reputation by overheated statements in the classroom or in published articles.

In the court fight between Hoffman LaRoche and the University of California at Los Angeles (UCLA) over how Hoffman LaRoche obtained a KG1 cell line belonging to the university, the company also named individually two UCLA scientists, David W. Golde and H. Philip Koeffler. It also named Golde separately and accused him of slandering the company. The university is conducting the entire case, including the parts in which the individuals are named, and carrying the costs.

Golde's view is that he therefore does not need the insurance policy now being offered. (Moreover, the university has a malpractice policy that covers him because he is also a physician.) But he warns that "there is not always a 100 per cent congruence of interests between a faculty member and his university in this kind of situation".

As for the likelihood that a university, after defending one of its faculty, would turn round and sue him, Harvard's general counsel Daniel Steiner says it is "far-fetched".

The brochure does not mention the problem of liability for new organisms created through gene-splicing: would the policy cover, for example, a scientist who invents a bug that eats Manhattan, as one observer phrased it? But the policy would in any case be of only marginal use in that situation. For one thing, the likely damages would exceed the $1 million liability limit. Moreover it does not cover any "punitive" damages — the extra penalties a judge can impose to deter the scientist from, say, turning his bug loose on Chicago.

Deborah Shapley

Soviet technology

Red tape blamed for delay

Soviet bureaucrats — not scientists — should be blamed for persistent delays in the introduction of new technology, Academician Anatolii P. Aleksandrov, president of the Soviet Academy of Sciences, said last week. He was commenting on the recent plenum of the Central Committee of the Communist Party of the Soviet Union, which, in his words, had put "new pressure" on the drive for the more rapid implementation of new technology. This drive was a major issue in the policy of the late President Leonid Brezhnev, and the stress that the plenum put on it seems an intensification rather than a change in policy. Dr Aleksandrov, however, may find his own position under the new administration more vulnerable. It is widely believed that, although he was elected by the academy in a secret ballot in the regular way, his candidacy was known to enjoy the support of Mr Brezhnev, and there has been considerable speculation that with Mr Brezhnev gone, Dr Aleksandrov may now be replaced as president of the academy.

In any case, as president of the academy, Dr Aleksandrov holds considerable responsibility for the technological modernization programme, since, during the last five-year plan, the academy was given a major coordinating role and charged with establishing and strengthening links between researchers and industrial customers. This move followed a wave of criticism of scientists for not pulling their weight with those science centres which had been specially created to serve the needs of local industry singled out for special blame — starting with the relatively small Far Eastern Science Centre, and working up to the prestigious Siberian branch of the Academy of Sciences. The scientists retaliated vocally, blaming the administrators and managers who failed to implement their recommendations.

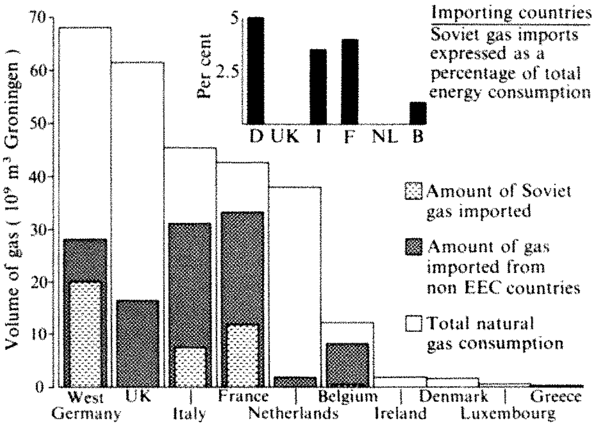
Scientists were again blamed earlier this autumn. On 20 October, *Pravda* carried an article by two senior officials alleging that research potential was being wasted and misapplied in the various institutes of the Academy of Agricultural Sciences. Three days later, in an interview on Moscow radio, Dr Vladimir Shumnyy, deputy director of the Cytology and Genetics Institute of the Siberian branch of the Academy of Sciences, tacitly denied the accusation, citing an impressive list of joint achievements of the Siberian branches of the two academies, from the development of the hardy Novosibirskaya-607 winter wheat and a strain of sheep with a 50 per cent increased wool yield to the hormonal control of plant growth and pig fertility and the protection of grain by irradiation.

Such a media dialogue is a well-known ploy in Soviet journalism; a new drive is launched and backsliders rebuked, and then a selected representative of those under attack states his case. The matter may then be dropped (on the assumption that those who deserved criticism will have profited by the warning), or else may go on to become a full-scale press campaign of criticism, culuminating in a new party and government decree.

What was not routine in this case was, of course, the death of Mr Brezhnev, which necessitated the convening of the Central Committee plenum, and the latter's announcements of, effectively, new party directives. For Dr Aleksandrov, who, only a few days before, had on behalf of Soviet science, made one of the five valedictory speeches at Brezhnev's funeral, it was time to make his position clear. The scientists had produced the designs, he said, and in some cases they were implemented "quite rapidly and effectively". In many ministries, however, the need for updating technology had been discussed for years, but scientists had not yet been able to establish "proper working contacts". The result was waste, inefficiency and delays. The firm reiteration of the problem by the plenum, he hoped, would get things moving again. He stressed, however, that if the scientists' work is not to be wasted, economic managers should be more accountable for their work in implementing new technology.

Vera Rich

EEC dependence on Soviet national gas



The figure shows the dependence of the European Economic Community (EEC) on imports of natural gas with particular reference to the Soviet Union. Natural gas now accounts for 18 per cent of the total energy consumption of the EEC, compared with just 7 per cent in 1970. But fears that demands for imported gas may lead to an increased dependence on Soviet supplies appear to be unfounded, as shown by the situation envisaged for 1990 which is illustrated here. Gas imported from non-EEC countries will account for 44 per cent of the total amount of gas required. Of this, 19 per cent will come from the Soviet Union, accounting for only 4 per cent of the total energy consumption. Other non-EEC suppliers will be Norway (12 per cent of natural gas imports), Algeria (10 per cent) and Libya (1 per cent), and 2 per cent will come from unspecified sources.

Plant breeding

Genetic diversity threatened

Washington

The International Board for Plant Genetics Resources (IBPGR) is in a race against time to preserve the diversity of germplasm needed for future plant breeding programmes, but its success is threatened by cutbacks in support for international agricultural research.

"If the work is not done in the next 5–10 years, we're finished", Dr J. Trevor Williams, executive secretary of IBPGR, said here last week. The spread of a few high-yielding varieties of many crops "forces the time-scale", and these new varieties are quickly replacing the diverse traditional varieties which have evolved over thousands of years and which represent the essential raw material for the development of future strains. Wild varieties, too, are threatened by such changes as forest clearing in the tropics.

IBPGR, which is part of the Consultative Group on International Agricultural Research (CGIAR), has since 1974 been sponsoring expeditions to gather samples of wild and traditional varieties of key crops and has coordinated efforts to provide storage facilities to preserve these germplasms. But, as a recent report from the CGIAR secretariat notes, "germplasm activity can be discontinued at short notice and, over the short term, its lack is not immediately missed. Over the longer term, its lack will be serious."

CGIAR's support for 1982 is expected to fall about $14 million short of even its low-budget option of $166 million for the year; and given the vulnerability of germplasm activities, IBPGR is "questioning whether it can continue to fund collecting missions or equipment for germplasm storage", according to the report.

IBPGR has sponsored some 250 missions, which have collected about 100,000 new seed varieties. The board has also helped to coordinate the various national germplasm programmes, and has been particularly active in the generally overlooked area of tropical fruits and vegetables. According to Dr William Brown of Pioneer Hi-Bred, a seed company in Des Moines (Brown is also chairman of two crop advisory committees to IBPGR), the board has also played an important part in providing "insurance" in the germplasm resource system. "A real effort has been made to have them stored in more than one place."

The importance of the germplasm collection and storage activities has been underlined by several recent developments. A new variety of rice developed by CGIAR's International Rice Research Institute in the Philippines, for example, included a wild variety of rice (*Oryza nivara*) in its breeding to confer resistance to a disease known as grassy stunt. This new variety, called IR36, has been adopted with remarkable speed, displacing traditional varieties. Almost 11 million hectares have been planted with IR36, which now accounts for more than 60 per cent of the rice grown in the Philippines, Indonesia and southern Vietnam. And, as Dr Williams pointed out, once the traditional varieties are gone, "there is no way you can get them back".

Stephen Budiansky

"Creationism" thwarted

Washington

A Louisiana law requiring the teaching of "creation-science" in public schools was struck down last week in the federal district court. Judge Adrian Duplantier ruled that the law, virtually identical to the Arkansas statute that was overturned last year, infringed upon the authority of the state's Board of Elementary and Secondary Education to set school policy.

In contrast to the Arkansas case, the judge made no finding of fact on the validity of "creationism" as science. "We didn't even deal with the facts", said Burt Neuborne, legal director of the American Civil Liberties Union (ACLU), which brought the suit. "We just said the wrong government agency acted."

Under the Louisiana constitution, the education board has authority to "supervise and control" the public schools; the legislature is charged to "establish and maintain" the schools. The judge ruled that in specifying a detailed course of study, the legislature overstepped its authority. The board, which was originally named as a defendant in the suit, joined with ACLU in arguing that its prerogatives were being usurped by the law. The board, composed of professional educators, is unlikely to institute a "creation-science" teaching requirement on its own. Louisiana's attorney general, however, immediately announced that the state would appeal the decision to the federal circuit court of appeals.

Neuborne suggested that similar separation-of-powers arguments could be raised under the constitutions of other states that pass "creation-science" laws. Georgia and Alabama may do so next year. "Separation of powers is an incredible mine of judicial resources", Neuborne said — and may also be an inexpensive one to tap. "The Arkansas case cost us $1.2 million", he said. "This one cost us eight sheets of yellow legal paper."

Stephen Budiansky

Biotechnology

More help

More help for British biotechnology is on the way. Last week, Mr Patrick Jenkin, Secretary of State for Industry, announced that his department will spend £16 million in the next three years to promote innovation and awareness in biotechnology among British companies. The scheme, modelled on an earlier scheme that promoted microprocessor technology, should go some way to answering persistent criticism of the British government for failing to provide effective support in this area.

In July, a House of Commons select committee complained that the government had failed to protect university research in biotechnology against the reduction of support from the University Grants Committee (UGC) in 1981. Although UGC had set aside £1.2 million for selected universities to support research in biotechnology, the select committee feared that much of this would be used to make good deficiencies incurred in earlier cuts. (The final allocation of this sum has yet to be announced.)

The new scheme from the Department of Industry is intended to complement UGC and research council support, and will be coordinated by a new biotechnology unit set up at the Laboratory of the Government Chemist. A graded system of grants will help companies to commission strategic studies, feasibility studies and specific problem-solving studies by independent consultants. There will also be cash grants for innovative demonstration plants as well as for research projects funded jointly with industry at selected centres. The department also promises a "general strengthening of the biotechnology infrastructure", which will include support for an information service and culture collections.

Mr Jenkin explained that the government was introducing the measures because potentially commercial biotechnology investments entailed high risk and long lead-times. Another reason may be growing concern that British scientists, frustrated by lack of opportunities for research, are being lured abroad. Other recent publicly supported initiatives include a biotechnology research centre at the University of Leicester, supported jointly by the Science and Engineering Research Council and several industrial companies.

Mr Jenkin maintained that British support for biotechnology now compares favourably with that in other countries, an assessment that has been challenged by opposition Labour MPs: one described the scheme as "no more than a drop in the ocean". The Confederation of British Industry has cautiously welcomed the new plan, although a spokesman said of the £16 million figure, "obviously we would like to see it higher".

Drugs for developing countries

Uncharitable stance from Oxfam

In the poorer countries of the world, millions of people suffer unnecessary ill health or die because simple drugs such as antibiotics are not available. But to what extent have the marketing methods of the multinational pharmaceutical manufacturers contributed towards the misuse and waste of drugs in the Third World?

According to the British charity Oxfam, the manufacturers have blatantly promoted inappropriate and harmful drugs in developing countries, which lack the tight governmental control on drug sale and distribution now normal in wealthy nations. And last week Oxfam renewed its attack on the industry by publishing a new study, "Bitter Pills" by Dianna Melrose. Despite a rider from the charity's director-general Brian Walker, recognizing the "valuable contribution of the research-based drug industry to world health", the study casts the industry as the villain of the piece.

But the industry, in the shape of the Association of the British Pharmaceutical Industry (ABPI), says that until it proves possible to build up adequate health-care systems in the poorer countries so that appropriate drugs can be properly prescribed and distributed, there is little the industry can do.

Abuses cited by Oxfam fieldworkers include: the maintenance of "high prices" for pharmaceuticals; inaccurate or misleading promotional literature; and aggressive promotion of "non-essential" drugs at the expense of more vital products. A common complaint is that over-prescription is encouraged — so, for instance, an impoverished patient with a bacterial infection might be prescribed a tonic and a multivitamin preparation in addition to the vital antibiotic. Since the antibiotic is likely to be the most expensive of the three, and the patient cannot afford them all, the cheaper, heavily promoted tonic and multivitamins may be preferred.

One of Oxfam's answers to over-prescription is to limit the number of drugs on sale in developing countries. The World Health Organization (WHO) has issued a list of approximately 200 "essential" drugs (many others being deemed "useful") for developing countries, and in June Bangladesh's military government took the dramatic step of banning the sale of more than 1,700 drugs termed "harmful" or "unnecessary" and allowing only 150 "essential" drugs from the WHO list to remain on the market (*Nature* 15 July, p.219). Local and international drug manufacturers objected, but although there have been some additions to the list of permitted drugs after strong protests, the government is to go ahead with its plan.

"IMPOSSIBLE – IT SAYS TAKE THREE TIMES A DAY BEFORE MEALS."
BIRCH

Thus events in Bangladesh over the next few years should show just what can be achieved by severely restricting drug supply in a country where many of the problems of distribution, prescribing and poverty persist.

There seems little doubt that a policy based on greater promotion of WHO's 200 "essential" drugs for the developing world will be of some benefit. About 50 drug companies are already cooperating with WHO by promising favourable prices for listed drugs, although further moves like that in Bangladesh actually to prohibit the sale of products not listed would not be likely to encourage further cooperation.

Oxfam, though, seems likely to remain unconvinced. WHO is seen as well intentioned, but "a toothless tiger", in the words of Oxfam's Dianna Melrose, and there is mutual distrust between Oxfam and the drugs industry. Were the two camps to stress the many views they hold in common rather than relish the differences, the world's developing countries could only benefit.

Distribution problems — penicillin exposed to heat and sunlight for sale in a market in Upper Volta.

British universities

Agony at Aston

The legal quirk that provides security of tenure for full-time academics at British universities is likely to be tested in a forthcoming battle between the University of Aston in Birmingham and the Association of University Teachers (AUT). The outcome will set an important precedent for other universities.

Aston was told in July 1981 by the University Grants Committee (UGC) that its budget would be reduced by 30 per cent in the succeeding three years. A large-scale programme of voluntary redundancies has already been approved, but now the university's council has voted by a narrow margin (19 votes to 17, with one absentee and one abstention) to effect compulsory redundancies under the 1975 Employment Protection Act. It is thought that 41 academics (chiefly in the fields of engineering and mathematics) could be given notice before Christmas.

The union, according to its general secretary, Mr Laurie Sapper, is prepared to fight all the way. An application to the High Court for a writ to prevent the redundancies is being considered. The grounds of the action are that compulsory redundancies would be contrary to the charter and statutes of the university which (like those of most universities in England and Wales) specify that "no member of staff . . . shall be removed from office . . ." except on grounds such as physical or mental incapacity and immoral, scandalous or criminal behaviour; there is no mention of financial circumstances as a cause for dismissal.

AUT has sought access to the university's accounting figures so that it can carry out its own examination of the university's finances, but Mr Sapper says that Professor Frederick Crawford, Aston's vice-chancellor, has failed to respond to AUT's letters. AUT has accordingly applied for access under the Employment Protection Act.

Aston is primarily technology-based, and has forged extensive links with local industry. The university says that the unemployment rate among its graduates is one of the lowest in Britain.

UGC recommended in July 1981 that student numbers in several science subjects should be reduced and that courses in biological science and architecture should be discontinued. Aston has already axed its courses in human communication and behavioural sciences. The number of science students has fallen from 3,100 in 1980-81 to 2,732 now, while arts student numbers have fallen from 1,383 to 1,340, but further reductions have still to be made. Full-time academic staff, of whom there were 522 in August 1981, will have to be reduced to 357 by July 1984.

At the same time, the university plans to recruit extra staff in some subjects, notably

0028-0836/82/480395-02$01.00

for its Management Centre, which received special praise from UGC. It is also determined to maintain a biology presence, possibly by means of a new biotechnology unit. But staff of the existing biology department have refused to examine that plan on the grounds that it would probably involve abandoning the university's established expertise in applied biology and also lead to redundancies.

Dr Richard Etheridge, a senior lecturer in production technology at Aston and a member of the AUT national executive, says that the university staff feel that the vice-chancellor is imposing redundancies with unseemly haste. The Department of Employment was notified of the proposals (as required by employment law) on 18 November, and redundancy notices could be issued as early as 22 December. Several attempts by academic staff at the most recent meeting of the university senate to introduce motions urging reconsideration or delay were blocked by the vice-chancellor on the grounds that these were not procedural matters.

The issue is certain to be raised again at the next meeting of the university council on 14 December. AUT is planning to lobby council members on that day, urging them to reconsider, and has threatened to tell its members elsewhere to boycott the university, depriving it of external examiners and putting existing procedures for the award of degrees in hazard.

Tim Beardsley

Object lesson

Brussels

In an unusual demonstration of its powers, the European Commission has questioned West Germany's second energy research programme, which is suspected of contravening EEC's rules on competition. The West German government has six weeks in which to reply.

The programme in question, which covers the period up to 1985 and costs DM13,465 million (£3,370 million), was in fact approved last year and is already operating. Nevertheless, the Commission complains that it was not informed in due time about either this programme or the last one and points out that the programme is a form of state aid and so is subject to the Commission's approval.

In its letter, the Commission declares that it wants to examine in greater detail the extent to which the programme fits in with the Community's energy policy aims. The fact that much of the money will be set aside for large-scale projects, particularly in fields such as fast-breeder technology, largely carried out in Germany by private companies, leads the Commission to question whether or not the aid is leading to a distortion of competition within the Community. And second, the Commission is concerned about whether only German companies and not, say, the foreign subsidiaries of companies from other parts of EEC, will be able to take advantage of the loans and subsidies.

This is the first time that the Commission has raised objections to a national research programme and its action is being interpreted in Brussels as a sign that research programmes should not be used by national governments as a discreet form of industrial featherbedding. If the Commission is not satisfied with the reply from Bonn, and is successful in pursuing its action, a similar letter might soon be on its way to Paris.

Jasper Becker

Spina bifida

Controversy over tests continues

Heart-searching and a little politicking about the UK Medical Research Council's proposed controlled trial of the utility of folic acid and other vitamin supplements as a prohylactic of spina bifida continues, fanned by the appearance of a blank space in last week's edition (see *Nature* 25 November, pp.302 and 310). What follows is an account of the origin and the course of this controversy.

The immediate stimulus of present interest in a controlled study of folic acid supplementation appears to have been the publication in February 1980 (*Lancet* i, 339) by Professor R.W. Smithells of the University of Leeds and seven collaborators of an article entitled "Possible prevention of neural-tube defects by preconceptional vitamin supplementation". That reported on a study in which women who had previously given birth to a spina bifida child were offered a vitamin preparation containing folic acid. This report appears to have prompted the UK Department of Health to enquire, in 1980, of the Medical Research Council whether a controlled study of the efficacy of folic acid would be feasible and desirable.

Spina bifida results from the incomplete closure of the neural tube in the early stages of embryonic development, and is thought to date from 15 to 20 days after conception. The other principal neural tube defect in human beings is anencephalus. Animal models for the study of neural tube defects, among which the curly tailed mouse stands out, have not so far provided a clear picture of the mechanism by which the neural tube is closed in normal development, although they do clearly show an interaction between genetic and environmental factors in the causation of neural tube defects (see Morriss, G. *Nature* **284**, 121; 1980).

That a dietary deficiency of some kind may be involved in the occurrence of neural tube defects in human births is suggested by the correlation between the incidence of the defects and the social class of the mothers concerned. (The incidence is greater among less prosperous families.) Another pointer of the same kind is the increased incidence of defective births among children conceived in the late winter and early spring.

The geographical variation of the incidence of these defects is, however, harder to account for. In the British Isles, the incidence of both defects is greatest in the west (Ulster and the Republic of Ireland), amounting to 9 per 1,000 in Belfast, 7 per 1,000 in South Wales, 4 per 1,000 in Birmingham (central England) and 2 per 1,000 in south-east England. By contrast, in France the incidence of the defects is less than 1 per 1,000, while the defects are almost unknown among some of the poorest populations of the world. In North America, the incidence of the defects appears to decrease from a maximum on the east coast of about 2 per 1,000 to less than half as much on the west coast. There appears to be a puzzling cyclical variation of incidence in the United Kingdom with a periodicity of twenty years or so.

That genetic factors influence the occurrence of neural tube defects is borne out, for example, by studies in South Wales in the 1960s. In one survey (Carter, C.O. *et al. J. med Genet.* 5, 81; 1968), 5.2 per cent of the siblings of an affected mother were found to produce neural tube defective children, compared with the general incidence of 0.77 per cent in the population as a whole. The risk of neural tube malformations is, puzzlingly, greater among first births and twice as great among females as among male children. One epidemiologist said this week that there can be no other congenital malformation whose incidence provide so many clues but whose causation is still in doubt.

The notion that a deficiency of folic acid may be partly responsible appears to stem from measurements by Smithells and his colleagues suggesting that red-cell folic acid and leukocyte ascorbic acid (vitamin C) might be deficient in mothers giving birth to defective children. These measurements led to Smithells's clinical trial of the efficacy of vitamin supplements including folic acid in the prevention of recurrences of neural-tube defective births.

Women who had previously given birth to spina bifida children were recruited to the study principally from genetic counselling clinics, but also by referral from general practitioners, and were offered a course of treatment with a multivitamin preparation containing folic acid. Among those who accepted, 137 gave birth within the period of the study, as did 187 of those who were found already to have become pregnant again (or who declined). In the first report of the study, among 140 children born to the mothers supplemented with folic acid, there was only one neural tube defect. But there were

0028-0836/82/480396-02$01 00

12 neural tube defects among the 192 infants born to the mothers in the untreated group.

More recently, Smithells and his colleagues have extended their study to include more than 1,000 women with a history of neural-tube defective births, self-selected into two roughly equal groups. They report that the incidence of a second neural-tube defective birth was 0.6 per cent (based on three births) in the group of supplemented mothers, but 4.7 per cent among the children born to untreated mothers.

This seven-fold difference apart, the bearing of the Smithells study on the question of whether vitamins including folic acid were an effective prophylactic of the recurrence of neural tube defects is disputed. First, and most seriously, because the study group is self-selected, the results may be seriously biased, and in the direction reported. For if mothers of higher social class are less likely to decline a course of vitamin supplementation, and are inherently less at risk of producing neural-tube defective children, the results of the trial may partially be explained.

On this point, Smithells argues that the data now accumulated include 44 women with more than one neural-tube defective child who have agreed to accept vitamin supplements and 52 women with two or more defective children who had not joined the trial. (The first group produced one defective child, the second five.) To Smithells, however, the significance of this development is to give the lie to the criticism of his earlier work that mothers accepting vitamin supplementation select themselves in consonance with their tendency to produce neural-tube defective children.

Another difficulty is that the catchment area from which the participants in this study have been drawn includes Ulster, where the natural incidence is large, and the south-east of England, where it is small. Recruitment to the programme of vitamin supplementation seems indeed to have been more successful in the south-east of England (50 per cent) than in Ulster (25 per cent).

It seems also to be agreed that the Smithells trial does not point unambiguously to folic acid rather than some other components of the vitamin preparation used as the putatively effective prophylactic. The preparation used (obtainable in the United Kingdom only on prescription) is manufactured by Beecham Pharmaceuticals Limited, is known as "Pregnavite Forte F" and contains a mixture of vitamins (including ascorbic acid) as well as iron and calcium salts.

During the past year, the Medico-Social Research Board in the Republic of Ireland has mounted a trial initially intended to throw light on this point. With the collaboration of several Dublin maternity hospitals, the board is sponsoring a trial in which three groups of mothers with a history of neural-tube defective children are being offered Pregnavite Forte F, Pregnavite Forte (without folic acid) and folic acid alone. Dr Geoffrey Dean, the board's director, said on the telephone last week that "everybody is convinced that the Smithells theory is not proven". The Dublin study also suffers from the defect that there is no objectively chosen control group with which the effects of vitamin supplementation can be compared.

In Dublin there is some resentment that in the past few months Beechams (which had been supplying the vitamin preparations free of charge) has written to say that it cannot continue this provision (see box). Dr Dean hopes that, nevertheless, it should be possible to recruit enough mothers with a history of neural-tube defective children for a significant result to be available within two years.

In Britain, the interest of the Department of Health in 1980 prompted a seminar in December of that year at which several interested and disinterested parties discussed the conduct of a clinical trial intended to yield significant and decisive results, in which the participants would again be mothers with a history of neural-tube defective births.

Beecham's supplement

The decision of Beecham Pharmaceuticals Ltd to go back on its earlier agreement to supply "Pregnavite Forte F" for the Irish trial free of charge, which has caused some ill-feeling in Dublin, is said to have been prompted by the company's internal ethical committee. According to Mr J. B. Diamond, chairman of Beecham (UK) Ltd, the ethical committee includes "secretaries and people like that".

Mr Diamond explained that his company had supplied material for the trials carried out by Professor R.W. Smithells and his associates over a period of some years, and also for the Irish trials. But "when it became clear that the [proposed] trials raised great ethical problems", the committee had decided that it would be wrong for Beecham to supply a placebo for the MRC trial and, by extension, to supply a vitamin supplement containing folic acid for other trials.

On the question of the safety of folic acid as a dietary supplement, Mr Diamond said on the telephone this week that the company had been marketing Pregnavite Forte F since 1952, before the licensing of drugs became the statutory responsibility of the Department of Health on the advice of the Committee on the Safety of Medicines. As such, the product has a licence "as of right", which may nevertheless be called in question whenever the committee considers that there has been a significant change of usage.

The most controversial feature of this proposal is that there should be a true control group — a group of women selected double-blind to whom only a placebo should be administered. Three other groups would receive respectively a multivitamin preparation, a multivitamin preparation with folic acid, and folic acid without other vitamins (but with minerals). The folic acid dose would be 4 mg a day, roughly ten times the amount of folic acid in the Beechams preparation.

The Medical Research Council, which apparently has indications that 20 per cent of the 3,000 women it would need in a full trail are willing to take part, has run into the following snags.

- Several Members of Parliament have been asking questions of the Department of Health about the conduct of the trials. They include Mr Roger Thomas, Mrs Gwyneth Dunwoodie and Mr Leo Abse. The common thread in their questioning has been to ask why their constituents should be denied an apparently effective treatment.
- On some legal views, informed consent by participants in the trial would not necessarily absolve the physicians concerned from legal action of the birth of damaged children.
- The amounts of folic acid planned for the MRC trials (ten times the amounts included in Pregnavite Forte F) have suggested to some that the procedure could be dangerous. While there is no evidence one way or the other, prudence dictates caution.
- If trials should show that folic acid, alone or in conjunction with other vitamins, should be effective at preventing recurrences of neural-tube defective births, it is by no means clear how that knowledge would be used for the prevention of defective first births.

In the circumstances, the opinion about the proposed trials of scientists working in the field understandably ranges over the whole spectrum. Some hold that the Smithells case, if not fully proven, is sufficiently convincing to make the use of a placebo in the trials unethical. Others would avoid the uncertainties occasioned by the choice of a dose of 4 mg a day by arguing that the amounts used should be smaller until animal tests have been carried out.

On the other hand, there are many who hold that the Smithells investigations raise so many more questions than they answer that a trial with placebo is probably necessary. The ideal would obviously be to ring the changes on all the vitamins administered, but this is probably unpracticable in the short term, which is why some argue for detailed physiological investigations of smaller numbers of women at risk.

Professor R.W. Smithells himself hopes that the Medical Research Council "will decide to carry out a trial" at its next meeting on 7 December. ●

CORRESPONDENCE

Human cancer genes

SIR — In one respect, your News and Views article was startling (*Nature* 11 November, p.103). You have turned upside down the relative values I attach to the different branches of cancer research. You attribute to me the belief that "the prime objective should be to understand the phenomenon of malignancy . . . (rather than to) concentrate on identifying the causes of cancer". This is almost the exact opposite of what I think. In the earlier paper of mine that you cite as evidence of my beliefs (*Nature* **289**, 353-357; 1981), I said that although we know the causes of cancer of the skin and lung, "the preventable causes of the other common cancers are less clear-cut and it may be difficult to identify them until much more is known about mechanism". I go on to say that "eventually the techniques of nucleic acid chemistry should allow us to itemize all the differences in nucleotide sequence and gene expression that distinguish a cancer cell from its normal counterpart, and perhaps at that point the steps involved in carcinogenesis will cease to be in doubt". That was written in 1980, and it still seems a reasonable forecast. Indeed, Logan and I finished the News and Views article that immediately follows your piece with the sentence "But we can at least feel that the technology for studying genes and their patterns of expression are now advancing so fast that the molecular biologist will soon be telling the epidemiologist what to look for".

At the risk of being tediously repetitive, let me say it once again. I believe that the only promising strategy, in the foreseeable future, is to learn what are the causes of cancer and then learn how to avoid them. For, in the absence of prevention, all we are left with is treatment — and that seems, at present, to be an intractable problem.

Cohen–Boyer patent

SIR — In reading the article about Stanford's response on the "second Cohen–Boyer patent" to the US patent office (*Nature* 11 November, p.95), one is struck by the editorializing by the author. The matters brought up by the patent examiner were answered very thoroughly by the patent attorney, and interested readers may obtain the response from the patent office to make their own judgements.

We do, however, wish to respond to the issue raised concerning the possible co-inventorship of Dr Robert Helling, as the article makes it appear the universities have deliberately sought to exclude Dr Helling from being a co-inventor. The facts are these.

Dr Helling has refused to provide evidence supporting his assertion in the press that he is a co-inventor or otherwise communicate with the patent attorney, Mr Rowland, whose professional responsibility it is to determine that the true inventors are indicated on any patent application he files. Under the rules of the patent office, Mr Rowland now is unable to change his original determination of inventorship unless Dr Helling provides the requested information. Issuance of the patent is not affected by this matter of inventorship. If Dr Helling is an inventor, the universities want his name on the patent. Patent office procedures allow for filing of a reissue of a patent to change named inventors.

Lastly, we are disappointed that documents submitted to the patent office regarding inventorship and available to the author of the article were ignored. These would seem to contradict directly statements to *Nature* about Dr Helling's role in the invention.

NIELS J. REIMERS
(Director)

Technology Licensing,
Stanford University,
Stanford, California, USA

Stephen Budiansky responds: The documents Mr Reimers refers to are a short summary by Dr Helling of his research activities, filed with the University of California when he left there in 1973, and submitted to the patent office last month by Mr Rowland. I omitted mention of it because it does not bear on the issue of inventorship. In it Helling states that he "participated in developing a procedure for coupling DNA fragments from any source to bacterial plasmids"; this neither supports nor contradicts his claim that he made a significant contribution to the original conception.

Mr Reimer's assertion that Dr Helling refused to provide information to Stanford's attorney is, I understand, a matter of dispute between the parties, and is in any case academic now that the issue of inventorship is under discussion between Dr Helling, Stanford and the patent office.

Green ecology

SIR — I doubt that I shall be able to dispel the impression gained from the disparaging article "No future for the Greens" (*Nature* 28 October, p.766) but I would like to correct some factual inaccuracies.

The Ecology party conference at Bridlington was not its first public meeting; it has held annual conferences since 1974 and additional policy conferences in 1981 and 1982. All these conferences have been open to outside observers.

Your reporter has also made an error common to ill-informed commentators in suggesting that the Ecology party is solely concerned with environmental issues. As described in its manifesto the Ecology party has policies on all those aspects of life that concern the other British political parties. The difference lies in the application of ecological principles to these concerns in much the same way as the Labour party, for example, would claim to apply socialist principles.

It is correct to suggest that the German Green party (*Die Grünen*) emphasized environmental issues in the recent elections but this does not imply that such issues are the sole concern of the Ecology party. That the Ecology party does not only consider environmental issues may partially explain the greater impact of *Die Grünen*, but the difference between British and German electoral systems is probably more important. The third factor hindering recognition of the Ecology party is the inaccurate reporting in the British media of which the abovementioned article is an example.

Southport, UK R.W. SMALL

Science now and then

SIR — In the course of reviewing Sir Peter Medawar's "Pluto's Republic" (ref.1), Stuart Sutherland commented favourably on the work of K. Popper but less favourably on the work of P. Feyerabend.

Despite Feyerabend's currently anti-Popperian stance Popper[2] has recently drawn a distinction between yesterday's "great science" and today's "big science", indicating that the latter should be attacked along Feyerabendian lines. Popper[3] concluded: "But new ideas should be regarded as precious, and should be carefully nursed; especially if they seem to be a bit wild."

For some of us who were disenchanted[4,5] with the "big science" of the previous decade, Feyerabend was *the* philosopher of science. However, there is evidence that "big chemistry" (at least) is becoming more rational and more tolerant of low status authors[6,7] who publish critical reviews. Thus, Popper's position, strengthened by the recent publication[8] of "Postscript", is becoming increasingly more attractive.

It is currently considered[9-11] that the "chemical revolution" initiated by Lavoisier originated from a Feyerabendian assault rather than from a Popperian "problem situation" or a Kuhnian "crisis". Similar judgements[12,13] are also accorded on Liebig's "biochemical revolution". In both cases the innovators relied on a mixture of empirical evidence and unsupported speculation to justify their theories.

Fruton[14] concludes: "Although most of Liebig's physiological speculations were rejected by several contemporary critics and soon became untenable, there can be little doubt that they stimulated the study of physiological processes from a chemical point of view. The public position that he had won through his achievements in organic chemistry, both as an investigator and as a teacher, assured a respectful hearing for his bold hypothesis. In seeking to prove or disprove Liebig's ideas, his defenders and critics were spurred to examine more closely substances (such as the proteins) present in living organisms . . ."

NEWS AND VIEWS

New lease of life for pulsars?

The discovery of the fastest pulsating radio star so far has surprised observers, and may yet catch out the theorists.

Pulsating stars are becoming fashionable again. That at least is the import of a report in the *New York Times* on Saturday last week, recording the discovery that a well-known but always puzzling radio source, known as 4C21.53, contains as part of its structure a rotating object of some kind spinning at a remarkable 642 times a second. In the past few weeks, most radiotelescopes have been pointed towards the position of the object at Right Ascension 19h 37m 28.72s, Declination 21d 28m 01.3s.

The discovery, made with the help of the radiotelescope strung with wires across the extinct volcanic caldera at Arecibo in Puerto Rico, is credited by the *New York Times* to Dr Carl Heiles of the University of California at Berkeley. The discovery is obviously a landmark in astrophysics because the pulsations of the radio signals are at least twenty times more rapid than those of the most rapidly pulsating star known so far — the supernova remnant more or less at the centre of the Crab nebula. The *New York Times* rightly says that such an object would naturally be taken for a newly formed pulsating star, in which case it might be thought that the radio signals would be accompanied by optical evidence of an expanding shell of matter of the kind supposedly flung off in a supernova explosion and thus travelling through interstellar space at 10,000 km a second or thereabouts.

On the conventional view of the formation of neutron stars as the condensed remnants of roughly one solar mass left over in the explosion of a star perhaps seven or eight times as massive, the rate of rotation of the new pulsating star should also rapidly decay through the conversion of rotational energy into magnetic flux and radiation. The *New York Times* reports that the failure so far to measure such a deceleration is a sign that the pulsating star may not be a now conventional rotating neutron star, but it is probably too soon to jump to that conclusion. The observation of such an object is not child's play, while this particular one has been recognized as a pulsating radio source only since the first half of November (when astronomical observers were informed through the international telegram service) although, with hindsight, it is clear that evidence of pulsation was first obtained during observations in September. The first full account of this discovery, together with a report on what is visible in that patch of sky and a first attempt at an interpretation of these observations will appear in *Nature* before Christmas. On the face of things, the circumstances are even odder than the *New York Times* suggests.

To anticipate what the authors of these discoveries have to say would be unfair to everybody concerned, readers not less than contributors, but just over a decade after the first discoveries of pulsating stars, it is clear that the study of these surprising objects is about to spring to life, and for several different reasons. Not least of all, the mere measurement of a pulsation rate of 642 Hz can be interpreted as the signal from a spinning neutron star only if it is supposed that the object is hovering on the edge of mechanical stability. If such a star has a mass roughly equal to that of the Sun, and a diameter of say 10 km as would be suggested by the equation of state for neutron matter, the velocity of the surface of the star would be a substantial fraction, say 10 per cent, of the speed of light, the rotational energy would be comparable with the energy supposed to be released in supernova explosions and the balance between gravitational attraction and rotational instability would be tenuous, to say the least. It is too soon to know whether some other model than that of the rotating solar-mass neutron star will be necessary to account for the observations now reported.

The other outstanding puzzle about the star itself is the mechanism of its formation. The newly discovered pulsating star, thought to be at a distance of 2500 parsecs, has been radiating for at least twenty years and probably for much longer. It will be crucial to make accurate measurements of the rate of deceleration (reported by the *New York Times* to be negligible). Evidence for radiation elsewhere in the electromagnetic spectrum should also suggest what kinds of processes may have conspired towards the formation of this object (but it is reported that X-ray observations by the Einstein observatory have drawn a blank, which suggests the absence of a recently formed supernova shell). The possibility that the object may have been formed by some process not now considered feasible cannot be discounted, but as yet there is nothing to suggest what that might be.

Puzzles such as these apart, pulsating stars are plainly destined for closer attention because they have proved to be valuable pointers to the characteristics of the galactic environment. So much can be told from the careful measurement of the velocities of 26 pulsating stars measured by A.G. Lyne, B. Anderson and N.J. Salter with the radio-interferometer formed by the antennae at Jodrell Bank and at Defford, 127 kilometres to the south. The sample of radio objects includes those known before 1977, accessible from the Northern Hemisphere and such that a stable reference radio-source could was placed within the working aperture of the interferometer. (See *Mon. Not. Roy. Astron. Soc.*, November 1982.)

The results are important for being the most accurate measurement of the proper motions of pulsating stars, if otherwise unremarkable. So far as can be told from the two-dimensional projection of the velocity vectors on the sky, the motion of this sample of pulsating stars is isotropic. The distribution of speeds differs from a Maxwellian distribution in that there is an excess of high and low speeds — but then there is no reason why pulsating stars at their formation should acquire speeds characteristic of thermal equilibrium. A handful of the objects in the sample have speeds perpendicular to the plane of the galaxy that would be sufficient to carry them beyond the galaxy, while most of the others are destined to oscillate above and below the plane with periods measured in tens or even hundreds of millions of years.

The value of pulsating stars as guides to what the interstellar medium consists of seems also to be destined for fresh appraisal. From the earliest days the rotation of the plane of polarization from a distant radio source (the Faraday effect) has been recognised as a guide to average density of free electrons along the line of sight. Pulsating sources, invariably polarized, are especially convenient sources for this purpose. Now J.A. Roberts and J.G. Ables of the Radiophysics Division of the Australian Commonwealth Scientific and Industrial Research Organisation have formally published (*Mon. Not. Roy. Astron. Soc.*, **201**, 1119-38; 1982) their previously circulated account of how simultaneous records at several frequencies of the variation of the intensity of pulsating stars with time can throw light on the ways in which the radio-energy is scattered in the interplanetary medium. The technique is merely an elaboration of the scintillation measurement that are now customary, but the analysis suggests that it should be possible by a systematic effort to use pulsating stars as a means of keeping track of the gross features of the interstellar radio-scattering material. The only obvious snag is the patience that will be required — and the danger that observers will be dragged away from tasks like these by the discoveries that will succeed the 642 Hz pulsating star.

Self-splicing RNA

from John Abelson

THOMAS CECH and his colleagues in Boulder, Colorado have been studying the transcription and processing of the ribosomal RNA in the protozoan *Tetrahymena thermophila* and have made a surprising and important discovery — the RNA appears to be able to catalyse the splicing out of its own intervening sequence.

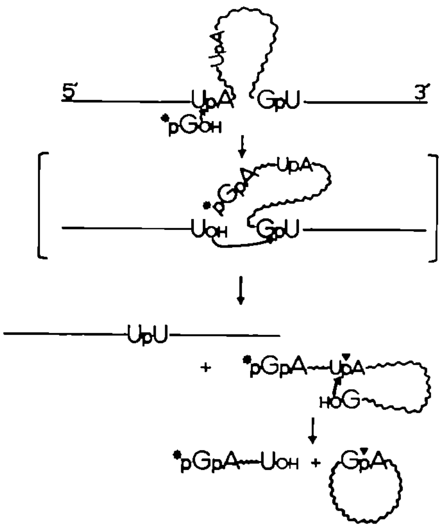
In this species of *Tetrahymena* all of the macronuclear rRNA genes contain an 0.4 kilobase (kb) intervening sequence in the 26S rRNA coding region. Cech found that the excision of the intervening sequence from the precursor RNA, the circularization of the intervening sequence and very likely the covalent joining of the exon sequences are reactions which can take place *in vitro* and do not require either energy (in the form of ATP) or a protein[1].

The conclusion that a protein is not required for the splicing reaction has come from studies on RNA obtained from *in vitro* transcription of a cloned fragment of the 26S rRNA gene from *Tetrahymena.* Earlier studies by Cech and colleagues[2] on the splicing of RNA transcribed in isolated *Tetrahymena* nuclei had suggested that the splicing reaction had unusual properties. The excision of the intervening sequence during *in vitro* transcription depends on monovalent cation concentration. In low salt, transcription of the rRNA genes is optimal and no intervening sequence is excised. At higher salt concentrations, the intervening sequence is released as a linear RNA molecule which is subsequently converted to a circle.

Using precursor RNA synthesized in low salt, the requirements for excision and circularization of the intervening sequence were found to be a monavalent cation (NH_4^+), a divalent cation (Mg^{2+}) and guanosine. The requirement for guanosine can be met by GTP, GDP, GMP or guanosine but not by 2′-deoxyguanosine, 2′-3′-dideoxyguanosine or 3′-GMP. Thus, there is a requirement for the 2′- and 3′-hydroxyls of guanosine but the hydrolysis of nucleotide is apparently not required for energy. When the precursor RNA was deproteinized by a variety of rigorous protocols including SDS–phenol extraction, boiling and protease treatment, it remained active in the excision reaction, requiring only salt, Mg^{2+} and guanosine.

If the G in the reaction is labelled, for example as ^{32}P-GTP, the label is found at the 5′ end of the linear intervening sequence but not in the circular intervening sequence. During excision of the intervening sequence, the guanosine cofactor is linked to the intervening sequence in a 3′–5′ phosphodiester bond[3]. The circularization of purified linear intervening sequence requires only added divalent cation and proceeds better at elevated temperature. The products of the circularization reaction are a covalently closed circle that is 15 bases shorter than the linear intervening sequence and a linear fragment containing 15 bases of the 5′ end.

These studies suggested that the ribosomal RNA was capable of self-splicing but the presence of a peptide with unusual properties was difficult to exclude. To deal with this, Cech and his colleagues[1] have now cloned a fragment of the *T. thermophila* 26S rRNA gene into a plasmid containing the *Escherichia coli lac UV5* promoter. *In vitro* transcription of this DNA with purified *E. coli* RNA polymerase produced a transcript containing 35 bases of *lac* sequence, 261 bases of the 5′ exon, the 413 base intervening sequence and 624 bases of the 3′ exon. This transcript was deproteinized and was shown to undergo self-catalysed excision and circularization of the intervening sequence. In addition, the products of splicing were investigated by nuclease S_1 mapping using a DNA fragment lacking an intron. The results of the study were compatible with precise exon joining.



The splicing reaction mechanism.

These results require a model that by necessity takes us into unfamiliar territory. We have an RNA that is apparently capable of a series of phosphotransfer reactions. The reactions are self-catalysed. The RNA is not an enzyme since there is no evidence that any RNA molecule can do more than catalyse self reaction. Cech and colleagues suggest the new term 'ribozyme'. Whether the reaction is catalysed by an enzyme *in vivo* or not remains an open question but there is no *a priori* requirement for an enzyme. The excision reaction is only 60 times faster *in vivo* than *in vitro* and this difference can easily be explained by factors present in the cell which might stabilize the RNA structure.

In the present working model of the splicing reaction, which will be described in detail in a paper soon to be published in *Nature*[4], the splicing reaction is initiated by the binding of G to a site in the RNA in close proximity to the 5′ splice junction (see the figure). The phosphodiester bond at the 5′ splice junction is broken, perhaps due to strain provided by the tertiary structure of the RNA, and the 5′ phosphate is transferred to G forming a 3′–5′ phosphodiester bond. The 3′ splice junction is similarly opened with transfer to the 3′ hydroxyl of the 5′ exon to form the spliced rRNA. The linear intervening sequence is released. In the subsequent circularization reaction a phosphodiester bond 15 nucleotides from the 5′ end of the intervening sequence is opened. In this case, transfer is to the 3′ end of the intervening sequence to form the circle with the release of the 5′ oligonucleotide. In this mechanism, each of the three cleavage reactions is accompanied by a ligation reaction, that is, the process consists of a series of three phosphotransfer reactions. These reactions are expected to be reversible. Presumably they are driven in the direction of excision by the high concentration of guanosine and perhaps by changes in the structure of the RNA.

The unfamiliar aspect of this mechanism is, of course, that we must assume that the RNA is folded in such a way as to form a guanosine-binding site and to bring the phosphodiester bonds which are to be exchanged into very close proximity. Water must be excluded from the active site to prevent hydrolysis. There are other examples of phosphotransfer reactions which do not require energy, notably the DNA nicking-closing enzymes.

The mechanism of RNA splicing described here is, by its nature, likely to have been a primitive one. One might expect that all RNA splicing would proceed by a similar mechanism; but this is not the case. In the other system where detailed information is known of the mechanism — tRNA splicing in yeast — the reaction proceeds by a totally different mechanism. At least two enzymes catalysing as many as four reactions are required and the ligation step requires two molecules of ATP[5,6]. Little is known about the mechanisms of mRNA splicing but it will not be surprising if that reaction proceeds by yet a third mechanism.

Since intervening sequences have only been found in the genes of eukaryotes, it has been assumed by some that splicing is a reaction which emerged rather late in evolution. The discovery of self-splicing RNA brings that assumption into question.

If an RNA molecule can have the intrinsic property of specifically breaking and rejoining its own bonds and of forming specific binding sites for nucleotides, certainly those properties would have been put to use in early evolution. As Cech and his colleagues point out, the reverse of the excision reaction is integration. This raises the possibility of 'RNA transposons'. Shuffling of RNA sequences by these mechanisms could have been an important factor in the generation of sequence diversity in primordial organisms. ☐

John Abelson is in the Division of Biology, California Institute of Technology, Pasadena, California.

Inserted retroviruses cause embryonic lethal mutation

from Keith R. Willison

EXPERIMENTS in which genes and recombinant DNA molecules have been transferred heritably into the chromosomes of mice have resulted in the identification of a gene whose expression may prove to be essential for a specific stage of embryonic development. Although natural stage-specific embryonic lethal mutants are known, none of the mutant genes has yet been isolated and their mode of action has remained unclear. Rudolf Jaenisch has now used the alternative approach of interfering with the expression of a normal gene through the insertion of retroviral sequence into a mouse chromosome. This has enabled him to produce artificially an embryonic lethal mutation whose site of action he can locate with a retroviral probe.

This experimental approach and its possible applications have been discussed in earlier *News and Views* articles[1,2]. Jaenisch decided, some ten years ago, to try to introduce novel genetic material into the mouse and study its effect on development by infecting early mouse embryos with tumour viruses. Both DNA and RNA tumour viruses were tested and it was quickly found that the Moloney murine leukaemia virus (M-MuLV) was the most promising in the sense that the viruses were able to become integrated in the DNA of the sperm and eggs[4] and could be inherited by later generations of mice. This in itself was an important result at the time (before the advent of gene cloning) because it proved that such events could be made to occur in the laboratory as well in the wild. That this does indeed happen in natural environments has been amply confirmed in cats[5], mice[3,6] and chickens[7]. Some of the mice which carry M-MuLV sequences eventually express them in lymphatic tissues, become full of virus and develop leukaemia.

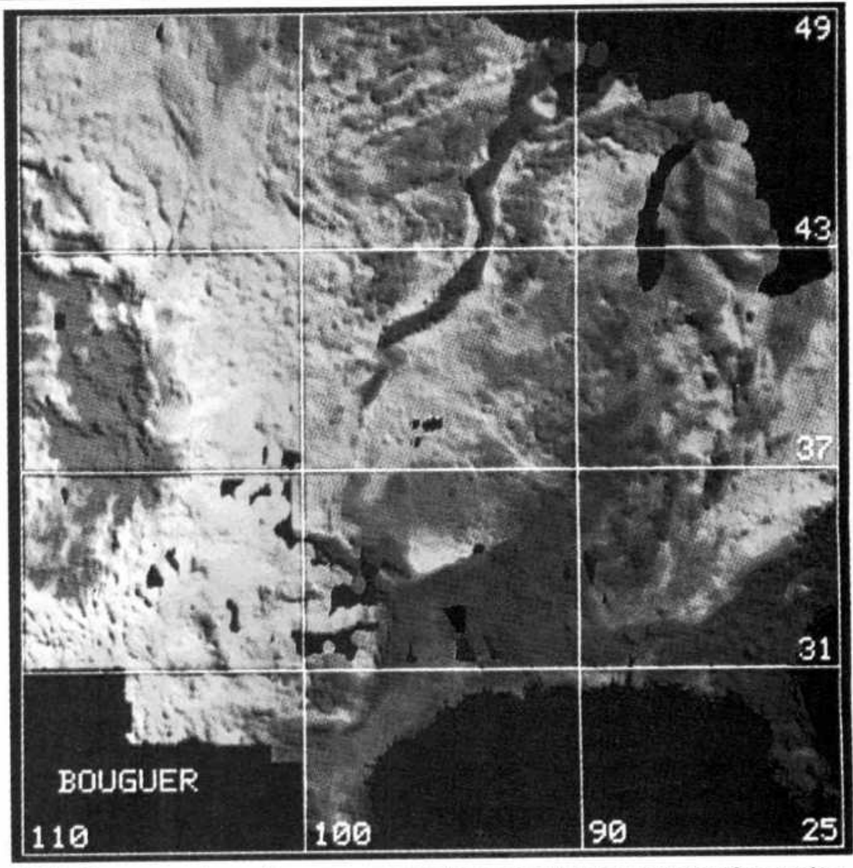
Jaenisch has constructed 13 mouse strains containing integrated M-MuLV sequences called *Mov 1–13*. They were produced by infecting embryos at different stages with virus or purified DNA using microinjection techniques[4,8,9,10] (see also ref. 1 for more detail). The strains are maintained as heterozygous stocks in order to make it easier to breed healthier animals, and the M-MuLV-containing chromosome is followed either by measuring viraemia in the offspring or by Southern blotting with purified M-MuLV probes. The latter technique allows one to distinguish between animals homozygous or heterozygous for the *Mov* allele in cases where the genomic flanking sequences have been cloned, and therefore aids breeding for *Mov*-homozygous mice.

The construction of homozygous strains was described by Jaenisch at a recent meeting* of the Ciba foundation in London and has given an important result. The attempt to produce *Mov-13* homozygotes resulted in consistently smaller than expected litter sizes for the particular inbred genetic background on which it was carried (C57BL/6). This suggested that some of the embryos might be dying, that is, that the *Mov* allele was behaving as an embryonic lethal gene. In fact it turned out that the homozygous embryos (*Mov-13/Mov-13*) were dying at around day 12 of gestation. There appeared to be no specific malformations but rather a total degeneration of the embryo. As the DNA does not quickly break down in dying embryos, it could be isolated and analysed to show that the degenerating embryos are indeed homozygous for *Mov-13*. The lethality of *Mov-13* homozygotes was stage-specific and absolute; 55 embryos surviving beyond day 14 were analysed and none was homozygous for *Mov-13*.

Are there precedents for the production of mutations by retroviruses? It is worth noting that a natural integration of an

---

*The Ciba Foundation meeting on the 'Molecular Biology of Oogenesis' was held 9–12 November. The proceedings will be published as Ciba Symposium 98 (Pitman Books).



Digitally processed gravity measurements have revealed the presence of an ancient rift structure extending across Missouri. In this image the rift extends from the top (centre right) to the middle (centre left). The structure, 120 to 160 km wide and 700 km long, is not discernible from surface topography. E.A. Guiness *et al.* (*J. geophys. Res.* **87**, 8529; 1982) identify the feature as the signature of a Precambrian rifting event that failed to develop into a spreading zone.

Keith R. Willison is in the Chester Beatty Research Institute, Fulham Road, London SW3 6JB.

0028-0836/82/480401-02$01.00

MuLV provirus has also given rise to the dilute (*d*) coat colour mutation of DBA/2J mice[11], and in tissue culture Varmus[13] has used M-MuLV as an insertion mutagen to isolate revertants of a rat cell line transformed by Rous sarcoma virus. In this latter case it was directly shown that the M-MuLV had inserted into the resident RSV provirus sequence in the rat genome and affected the expression of RSV RNA species.

How does the *Mov-13* allele cause embryonic death? Is it just toxicity due to viraemia? No virus can be detected in heterozygotes until day 16 of development and viraemia would certainly be expected to be dominant. Has the M-MuLV DNA integrated into a gene or gene complex essential for embryonic development? It has certainly inserted into actively transcribed DNA, as Jaenisch also reported at the meeting. Furthermore, transcription of DNA at this site normally begins at day 12 of gestation when in normal embryos two abundant transcripts of 4kb and 5kb can be detected in the total RNA. The level of expression of these two transcripts changes during development, maximum expression occurring between days 14 and 18 when at least 10-fold more 4kb and 5kb RNAs can be detected than on either day 12 or day 19 of development. There appears to be no expression of these transcripts in adult tissues, although very small quantities of a 7–8kb transcript are detectable. The relationship to the embryonic 4–5kb RNAs is not yet known. A reasonable interpretation of these data is that an embryonic lethal mutation has been produced by insertion mutagenesis. The affected gene appears to be expressed primarily during embryogenesis and its identification and cell distribution will be awaited with great interest. ☐

Chromatin structure, DNA structure

from Sarah C.R. Elgin

DURING the past few years, specific features of eukaryotic chromatin structure, in particular sites hypersensitive to digestion by DNase I, have been detected and mapped for a variety of genes[1–4]. Frequently (but not always) such sites have been observed at or near the 5′ends of genes transcribed by polymerases I and II (see ref.5 for a brief review). Several studies have noted that 5′DNase I-hypersensitive (DH) sites are present before transcription begins, suggesting they may have some functional role[2,4,6,7]. Now, a number of recent studies is providing evidence that DH sites can play a critical part in the control of gene expression.

A cluster of five DH sites, found only in nuclei where the gene is expressed, has been mapped upstream from the *Drosophila melanogaster* glue protein gene *Sgs4* (ref.8). In a strain that does not express *Sgs4* (ref.9), the DH sites are not observed[8] and sequence data reveal that a small upstream deletion has removed the major DH site of the complex[10] — implying that the loss of this segment both affects the chromatin structure of the surrounding region[8] and eliminates gene expression. A clue to a possible underlying mechanism comes from work on the chick globin locus[11]. Here DNA sequences at or near the previously mapped chromatin DH sites can adopt (at least) two different conformations. When relevant DNA segments are subcloned into pBR322 and the recombinant plasmids are digested with S_1 nuclease, these sites are cleaved in the negatively supercoiled DNA molecule, but not in the linear DNA molecule[11]. We may find that there are switches relevant to gene expression constructed from DNA sequences that can possess alternative structural configurations, the different forms being stabilized and amplified in the chromatin structure. The major DH site of the *Sgs4* locus is a good candidate for such a switch.

The *Sgs4* glue gene of *D. melanogaster* is normally expressed in the salivary gland of the third-instar larva. Differences in mRNA production, observed for different strains, correlate with the presence of small upstream deletions[9,10]. Three Oriental strains (Seto, Hikone-R and Kochi-R) that produce only trace amounts (~2 per cent of levels observed in Oregon-R) of the *Sgs4* mRNA have an upstream restriction fragment that is shorter by about 50 base pairs (bp) than that of five strains (Oregon-R, Chiete V, Urbana-S, Canton-S and D323) that produce significant amounts (~40–100 per cent) of the mRNA. Sequencing of the cloned genes from Hikone-R and Seto flies confirms a deletion (marked ORL on the figure) from –305 to –356 (replaced by the nucleotides CGC) relative to Oregon-R. In the Berkeley-1 (BER-1) strain no *Sgs 4* mRNA has been detected at any larval, pupal or adult stage tested. Here, sequencing of the cloned gene confirms a 95 bp deletion from –392 to –486 (replaced by GAT). Both producer and nonproducer strains have the same TATA box at –22 to –28 and essentially the same loose match with the consensus sequence $5'$-GG$^{C}_{T}$CCAATCT-$3'$ at –66 to –74 (the only change being the substitution of a C for the $3'$-terminal T in BER-1).

In nuclei from embryos or tissue culture cells, three DH sites can be observed $3'$ to the *Sgs4* gene but none near the $5'$ end. The $3'$ sites persist in the chromatin of the third-instar larval salivary gland, but in addition major sites can be mapped to +30, –70, –330, –405 and –480 (with an estimated accuracy of ±30–50 bp) relative to the start of transciption. The most prominent site is that centred at –405 (mapped within ±5 bp). The site mapped to –330, which is lost in the Oriental strains, might play a part in determining the efficiency of transcription. The other DH sites are still apparent in the chromatin of these larvae at the same DNA sequences[8]. In contrast, all the tissue-specific $5'$ DH sites are lost in the nonproducer BER-1 strain[8], even though there are no major differences observed in the DNA sequence other than the deletion[10]. In particular, the sequences from –390 to –250 are identical for Oregon-R and BER-1 flies. This indicates that the DNA sequences at or near the major DH site have a role in determining the chromatin structure of the surrounding region.

That this function may reflect a switch in the underlying DNA structure is suggested by the work on chick globin genes described above. It must be noted, however, that not all sites which are S_1 sensitive in supercoiled plasmids correspond to known DH sites in chromatin[11]. Conversely, it seems likely that not all chromatin DH sites will be S_1 sensitive. Nonetheless, it is apparent that in some instances, specific DNA sequences near the $5'$ ends of globin genes can adopt different conformations dependent on supercoiling of the DNA. That such a switch occurs *in vivo* is indicated by the observation that S_1 nuclease also detects sensitive sites in chromatin, in the region of the previously characterized tissue-specific and developmentally specific DH sites[11]. The same sites are recognized by reagents such as bromoacetaldehyde, which react with unpaired regions of DNA (T. Kohwi and H. Weintraub, personal communication).

What might be the nature of this change? What sequences might be involved? Certainly the most radical suggestion would be

a switch in the form of the DNA double helix, for example from B to Z. This transition can occur in physiological conditions in a segment of d(pCpG)n, the Z form being stabilized by the introduction of negative supercoiling[12,13]. It seems likely that Z-DNA could also be stabilized by protein binding[14]. The B–Z boundary is sensitive to S_1 nuclease[13].

However, a less radical shift in DNA structure seems more likely. No common features of sequence organization have so far been identified for DH sites. It has also been reported that enhancer elements of similar function, such as those of SV40 and of polyoma virus, do not show any obvious sequence homology[15]. It is possible that recognition of such sites will come only with a greater appreciation of the three-dimensional structure of the DNA. That the conformation of the DNA double helix, including the structure of the sugar–phosphate backbone, is variable and sequence dependent, even within the overall B form, is clear both from recent studies of the helical periodicity[16,17] of B-DNA and from the X-ray crystallographic analysis of the B-DNA dodecamer CGCGAATTCGCG[18]. The sequence-dependent conformation is apparently reflected in the sensitivity of the DNA to endonucleases, there being a good correlation between the sites of rapid DNase I cutting in this dodecamer and positions of high local helical twist[19]. The rate of cleavage at a particular site can reflect not only the immediate site but also the 'DNA environment', as illustrated by the fact that the four different *Pst*I sites in pSM1 are cut at very different rates[20]. This effect is not dependent on the degree of supercoiling. It seems, then, that it may be possible to obtain empirical maps of DNA structure by examining site-specificity in the interaction of DNA with enzymes (such as micrococcal nuclease)[21] or with various small DNA-binding compounds (for example intercalators)[22,23]. Structural patterns in the DNA that are invariant to supercoiling might be related to relatively stable features of chromatin structure, while those that are altered might be candidates for potential switch regions as discussed above. Clearly a more detailed appreciation of DNA structure is required to understand the code that directs protein-DNA interactions in eukaryotic chromatin. □

Chromosomes and cancer

from David Forman and Janet Rowley

THE analysis of chromosomes in relation to cancer is a field of research which has gone through successive periods of excitement and frustration. The enthusiasm in the early 1960s arising from the discovery that chronic myeloid leukaemia is strongly associated with a specific marker (the Philadelphia chromosome Ph^1; see also Logan, J. & Cairns, J. *Nature* **300**, 104; 1982) diminished when it was realized that few other cancers exhibit such clear-cut abnormalities. Since then there have been critical developments in technique which have brought the chromosome back to the centre of cancer science.

These technical developments have been of two types. First came consistent improvements in the banding of human chromosomes, which revealed several translocations and deletions, beginning with the discovery that the Ph^1 chromosome results from a translocation usually involving chromosomes 9 and 22. Second, and more recently, has come the application of recombinant DNA technology to the human genome. As was emphasized at a recent meeting on chromosomes and cancer*, the result of these changes has been a narrowing of the gap between molecular biology, dealing with units of around 10^3 nucleotides upwards, and cytogenetics, dealing with around 10^6 nucleotides downwards. Although the gap is not yet closed, communication between the two fields is becoming intense and vigorous. Not only are more cancers being related to consistent non-random chromosome changes but important clues are also being found as to how these alterations affect function.

The most exciting advances reported at the meeting came from Croce (Wistar Institute) and Taub and Leder (Harvard Medical School) concerning Burkitt's lymphoma — already known to be closely associated with an (8;14) translocation. Chromosome 14 contains the immunoglobulin heavy-chain gene cluster which is active in Burkitt's lymphoma cells. Both groups showed that the break in chromosome 14 occurs within the cluster and that the break in chromosome 8 is at the site of the *c-myc* oncogene. Croce and co-workers at the Wistar Institute found the heavy-chain gene regions from several independently derived Burkitt's lymphoma cell lines hybridized with *c-myc* probes. The Harvard group, using a probe derived from a mouse plasmacytoma, isolated a homologous segment of DNA from 12 Burkitt's lymphoma cell lines. In two cases a single restriction fragment contained both a portion of the heavy-chain gene and the cellular *c-myc* gene. Both groups found that about a third of all lines tested contained rearrangements of the immunoglobulin heavy-chain region caused by the integration of the *c-myc* region. Croce suggested that in these cases the genes are aligned in a 5′ to 5′ head-to head fashion. The suggestion is therefore that the level of expression of the transforming *c-myc* gene after translocation is affected by the neighbouring active immunoglobulin genes and normal regulatory control is lost. It is not without significance that the other chromosomes involved with chromosome 8 in translocation events in Burkitt's lymphoma are numbers 2 and 22, containing the sites for the immunoglobulin κ and λ light-chain genes respectively, and that the lymphomas express κ chains in the case of (8;2) translocations and λ in the case of (8;22) translocations.

An animal B-cell tumour, the mouse plasmacytoma, also involves an homologous translocation — a (12;15) or occasionally a (6;15) translocation (Spira, Karolinska Institute). Again chromosome 12 contains the mouse immunoglobulin heavy-chain gene and chromosome 6 the κ light-chain gene. The *c-myc* gene is known to be located on chromosome 15 in mouse

and several investigators, as well as the group at Harvard, have shown that it is translocated adjacent to the immunoglobulin locus.

If *c-onc* genes in aberrant positions are critical to tumour development, what is their normal function? Lane and Cooper (Sidney Farber Cancer Institute) have identified five different stage-specific transforming genes active in lymphocytic leukaemias and lymphomas. Tumours which share a common phenotype, representative of a discrete stage in normal lymphoid differentiation, appear also to share a common transforming gene, suggesting that the altered genes may normally be involved in growth regulation during cellular differentiation. The investigators have gone on to examine a series of African and American Burkitt's lymphomas by transfection of NIH 3T3 cells and have identified a common transforming gene activated in these tumours which is not analogous to genes from the Epstein–Barr virus genome or indeed to *c-myc*. Thus different genes may be involved at different stages of the neoplastic process and in the world outside NIH 3T3 cells, tumour development may depend on the activity of more than a single oncogene.

In this respect it is interesting that the oncogene isolated from a bladder carcinoma cell line and which is homologous to the *ras*^{H} gene maps to the exact region of chromosome 11 that is deleted in the Wilms tumour–aniridia syndrome (11 p13; Francke, Yale University). Thus here there is an association between one particular oncogene and two quite different tumours. It is also apparent that particular translocations may be associated with variable but related tumour phenotypes. The (9;22) translocation is involved in certain cases of acute lymphocytic and non-lymphocytic leukaemias as well as in established chronic myeloid leukaemia. High-resolution banding techniques have shown that the break point on chromosome 22 is very similar in all three diseases (Yunis, University of Minnesota). If there were an oncogene associated with either chromosome 9 or chromosome 22, additional factors must determine which type of phenotype is expressed.

In general, these new advances emphasize the contribution made by cytogeneticists in providing an expanding data base which allows molecular biologists to decide which areas of the genome to concentrate on. Yunis and co-workers can now distinguish several thousand chromosome bands in the human genome so that previously masked small chromosome defects can now be visualized. Certainly it is clear that chromosomal abnormalities are the rule rather than the exception in haematological malignant diseases, with over 90 per cent of all types of acute leukaemia exhibiting some form of defect.

A computerized cancer chromosome registry has now been established (Metelman, University of Lund) and is revealing that although most leukaemias are associated with several types of defect, there are distinct patterns in these associations. First, the abnormalities usually only involve a limited number of chromosomes. In the case of acute myeloid leukaemia, although there is not an association with one specific change, there is a strongly preferential involvement of chromosomes 5,7,8,15,17 and 21. Second, it is usually the case that specific segments of the chromosomes are involved in the aberrations (for example, bands q33–36 on chromosome 7). Third, detailed analyses are making possible the beginnings of a cancer chromosome epidemiology. For example, the incidence or frequency of chromosome changes associated with acute non-lymphocytic leukaemia (ANLL) that arise from chemotherapy or irradiation following a previous malignancy are different from the changes that take place when the disease occurs *de novo* or in childhood (Rowley, University of Chicago). In childhood an (8;21) translocation or an 11q deletion is often seen in ANLL. With increasing age and with exposure to chemicals, either occupationally or as a result of cytotoxic therapy, deletions of part or all of chromosomes 5 or 7 become much more prevalent and the (8;21) or 11q effects very rare. The specific type and degree of abnormality can often have clinical implications in terms of both diagnosis and prognosis (Golumb, University of Chicago).

Further technical develpments will soon be ready to be profitably employed in research into chromosome neoplasia. Flow cytometry can now individually separate most human chromosomes and has already been used for mapping studies (Carrano, Lawrence Livermore, National Labs) and the preparations of single chromosome DNA libraries (Young, Beatson Research Institute). Ward (Yale University) described the *in situ* hybridization of as little as 20–30 pg of biotin-labelled DNA to the chromosome with subsequent detection and visualization using the protein avidin and alkaline phosphatase. It should soon be possible to rapidly screen individual chromosomes with probes for specific genes and build up a much more detailed account of the structure of the chromosome in neoplastic cells.

The increasing fund of knowledge at both the cytological and molecular levels, together with the arrival of new techniques, should lead to rapid advances in our understanding of the role of chromosomes in cancer and, hopefully, to much improved therapy. □

Sex reversal and sex determination

from Elizabeth Simpson

THAT mammals having the XX sex chromosome constitution are generally female, while those with XY constitution are generally male has often been interpreted as showing that a gene (or genes) on the Y chromosome controls primary sex determination. When a Y chromosome is present the foetal gonad, which has the potential to become either ovary or testis, differentiates into a testes and, when absent, into an ovary — the first and crucial event in a series of changes that determines whether the organism has a male or female phenotype. Recent genetic analysis shows that this first step is not as simple as first thought and appears to be controlled by an interaction between autosomal genes and a gene(s) on the Y chromosome, for normal male differentiation.

Insight into sex determination has been provided by exceptions to the rule that the presence of the Y chromosome leads to a male phenotype. In mice, which provide the most readily examined examples, sex reversal can be partial or complete, and is characterised by XX individuals that have testes (rarely ovotestes) and are apparently normal phenotypic males, and XY individuals that have ovotestes or ovaries, and are apparently normal or near normal phenotypic females.

The *Sxr* (sex reversed) gene, originally described by Cattanach, causes XX mice inheriting it to develop as phenotypic males. It was at first thought to be a dominant, autosomal gene, probably derived by translocation from the Y-chromosome. However, it proved impossible to map the *Sxr* gene to any of the autosomes — a mystery that has only recently been solved by the finding that *Sxr* is located on the distal arm of the X chromosome in XX sex-reversed mice.

The mapping of the *Sxr* gene on the X chromosome comes from two independent lines of evidence. First, experiments described in this issue of *Nature* by McLaren and Monk (p.446) and Cattanach and colleagues (p.443 & p.445) show that some *Sxr* XX mice develop as females or hermaphrodites rather than males if the

0028-0836/82/480404-02$01 00

paternally inherited X chromosome is preferentially inactivated (paternal X inactivation was ensured by introducing Searle's translocation (T[X;16]16H[3]) through the mother). Second, *Sxr* has been mapped to the X chromosome by Singh and Jones[4] using hybridization *in situ* of Y chromosome specific DNA sequences (Bkm) to the distal end of the X chromosome in XX *Sxr* mice. From these findings Eicher[5] and Burgoyne[6] have gone on to propose that the Y chromosome contains two regions of Bkm positive sequences, one in the normal centromeric position and the other at the distal end of the chromosome. This makes it possible to explain why sex reversal is inherited in a pattern characteristic of an autosomal dominant gene, with half the XX progeny being sex reversed and half the XY progeny carrying the *Sxr* gene. During meiosis, when haploid sperm are generated by a carrier male, crossing over between X and Y chromosomes creates four types of sperm (i) an X carrying the translocated Bkm sequences from Y, (ii) a normal X, (iii) Y carrying both Bkm sequences, and (iv) a normal Y; created by the transfer of the distal Bkm sequence bearing end of the carrier Y to the X. Assuming that each sperm type has an equal chance to fertilize ova, this would produce the observed 1:1:1:1 ratio of *Sxr* XX males, XX females, XY *Sxr* carrier males, and XY noncarrier males. This interpretation of the transmission of *Sxr* is supported by recent cytogenetic data (Evans, Burtenshaw & Cattanach, this issue of *Nature*, p.443).

Burgoyne[6] has also argued that there may be a whole class of 'pseudo-autosomally' inherited genes located distal to the crossover point on the pairing segment of the X and Y chromosomes. These genes normally escape X inactivation and like *Sxr* would show the same pattern of apparently autosomal inheritance. Some of these genes, in addition to the normal Y specific Bkm related sequences present in the non-pairing part of the Y chromosome, may be involved in sex determination.

Recent work of Eicher and her colleagues[5] with a series of XY sex reversed mice have indicated that the testis determing gene *Tdy* which is probably closely linked to the Bkm sequences, and maps near the centromere on the Y chromosome, cannot be the only primary sex determining gene: it needs to interact with other genes, perhaps in appropriate sequence for normal sex determination. One set of Eicher's sex reversed mice show inheritance of abnormal sex determination through a Y chromosome derived from *Mus poschiavinus*, a subspecies of *Mus domesticus*. An inbred strain of mice with this Y chromosome, designated Y^{pos}, breeds normally, and produces normal F_1 hybrids when mated with the C57BL/6 laboratory strain. However, when these hybrid males are backcrossed with C57BL/6 females half of the XY progeny are hermaphrodite (one gonad being an ovotestis). In subsequent backcross generations the proportion of abnormal XY individuals increases until a high proportion of them are completely sex reversed, phenotypic females with two ovaries, and the rest were males with ovotestes, most of which are fertile[7].

That there is a 1:1 ratio between males and hermaphrodites among the XY progeny of the first backcross generation argues for an effect of a dominant autosomal or pseudoautosomal gene (named *Tda-1*[5]) in addition to the abnormal testis determining gene *Tdy* transmitted by Y^{pos}. The increasing incidence of complete sex reversal in XY individuals in sequential backcross generations argues for the involvement of additional autosomal gene(s). Thus it would appear that in the original Y^{pos} carrying strain, the testis determining gene, *Tdy*, on Y^{pos} could interact normally with a dominant autosomal gene, *Tda-1*, and with additional autosomal gene(s) perhaps in carefully timed sequence, to determine primary sex (testis or ovary). However, when *Tdy* POS was isolated by backcrossing onto the C57BL/6 inbred genome, it could not interact normally with the corresponding genes of C57BL/6.

Three other examples of the type of sex reversal seen with Y^{pos}, have now been found in wild mice captured in Northern, Central and Southern Italy respectively. Each is inherited via the Y chromosome of a male *Mus domesticus*, and produces XY hermaphrodites on back-crossing to C57BL/6[7].

That autosomal genes are involved in primary sex determination is also shown by the effects of an inherited dominant autosomal gene on chromosome 17, causing partial or complete sex reversal in XY individuals (Washburn and Eicher, in preparation; quoted in Eicher[5]).

Sex reversal may also be brought about by another Y-chromosome abnormality; an apparent rearrangement of the Y chromosome that leads in each generation to translocation of *Tdy* from the Y to the X chromosome during meiosis, in a manner probably analogous to that of *Sxr* transmission. However, in this case the translocation involves a very large piece of the Y, readily visible on karyotyping. XX individuals carrying one such translocated X chromosome are phenotypic males, whilst the reciprocal translocation gives rise to females with one normal X and a tiny translocation product lacking the *Tdy* gene[5].

It would appear that normal primary sex determination involves the *Tdy* gene located on the Y chromosome near the centromere, interacting with autosomal and perhaps pseudoautosomal (that is, X/Y linked) genes. Problems can arise through translocations of *Tdy* to other sites on the Y chromosome, especially to the distal sites which pair with the X chromosome during meiosis, since then transfer to the X chromosome is possible. *Sxr* and the translocation described by Eicher (see previous paragraph) probably arose in this way, and both result in the production of a normal X and an X that bears part of the Y. The autosomal genes that necessarily act in concert with *Tdy* also make possible abnormal sex determination due to improper timing of events which take place in the bipotential gonad (see Eicher[5]). Mutations, deletions and inappropriate alleles of such autosomal (and/or pseudoautosomal) genes might be involved.

It is still an open question as to how *Tdy* operates in this sequence of events, and whether its gene product is the male specific antigen which has been proposed as the differentiation antigen that causes testis differentiation. To complicate the matter further, it appears that there are two male specific antigens, one identified by T cells (the transplantation antigen, H-Y) and the serologically detected male (SDM) antigen. These two have been separated by testing mice with the sex chromosome constitution XO. These females, although H-Y negative[8] are SDM positive (ref 9, Koo, G. and Müller, U., personal communications). It has been argued[10] that neither of the two male specific antigens are candidates for the role of sole determinant of sex differentiation, since XO female mice are SDM positive but have ovaries, whilst XY^{pos} females are H-Y positive but have ovaries. The H-Y typing, using skin grafting and/or cytotoxic T cells, of a variety of mice whose karyotype is abnormal or unexpected, for example, XO (H-Y negative, female[8]), XX *Sxr* (H-Y positive, male[11,12]), XY^{pos} (H-Y positive, female[13]) is consistent with H-Y being tightly linked to *Tdy*, which is clearly not the sole testis determining gene. SDM typing is more problematical: from the XO data[9] the structural gene for SDM cannot be on the Y chromosome and is not *Tdy*. Moreover, SDM typing is difficult to reproduce and none of the SDM monoclonals tested so far have shown male specific binding (see ref.14 and Simpson & Goodfellow, unpublished).

By other less direct tests they are reported to have male specific activity[15],

although at titers many orders of magnitude lower than that shown by monoclonals to other cell surface determinants that readily stimulate antibody production (for example, H-2, Thy-1, Ly antigens)[16].

In conclusion then, it appears that the differentiation of testis from the bipotential gonad, the key step that leads to the development of the male phenotype, is controlled by an interaction between autosomal genes and genes on the sex chromosome. Whether sex specific antigens are involved, and if so, how, is still a matter of speculation. □

Distant planetary satellites more accurately measured

from Ian Gatley

A BASIC step in the exploration of the Solar System is the determination of the sizes of planets, satellites and asteroids. Most of these objects are far too small for direct-imaging techniques from ground-based telescopes, but the cost of spacecraft makes size determinations from the ground extremely desirable. Fortunately, a simple and elegant method which combines the results of optical and IR observations is available, and two papers in this issue of *Nature* give new results for four of the uranian satellites (Uranus is to be visited by Voyager 2 in 1986), Neptune's largest satellite Triton and the most distant planet, Pluto.

The principle is this. Sunlight falling on the target is either absorbed or reflected; the energy absorbed is subsequently re-radiated in the thermal IR. Visual photometry measures the reflected component of the solar radiation and IR radiometry measures the absorbed component and the sum of these is equal to the total incident energy. One can therefore solve simultaneously for the albedo (reflectivity) and the size of the object under study (Morrison *Icarus* **19**, 1; 1973).

The principle is simple but its application is not, for two reasons: the IR signals are weak, and the atmosphere transmits poorly at the relevant IR wavelengths (around 20 μm) because of the presence of water vapour. These problems can be overcome by the use of a large IR telescope on a high dry site, such as the newly commissioned 3 metre NASA Infrared Telescope Facility on the 14,000 foot summit of Mauna Kea in Hawaii. This telescope was constructed primarily for the study of the Solar System, and its early results in this area are fascinating.

R. Hamilton Brown, Dale Cruikshank and David Morrison have measured the diameters and albedos of four satellites of Uranus — Ariel, Umbriel, Titania and Oberon, and find lower albedos and larger diameters than previous, less reliable estimates. Having made accurate size measurements, these workers now stress the importance of experiments to determine masses, for knowledge of the densities of the satellites will provide important insights into the origin and subsequent evolution of the uranian system. The albedo measurements give information on the surface composition of the satellites. Ariel, Umbriel, Titania and Oberon all have sizes similar to the large icy saturnian satellites, particularly Rhea, but they have significantly lower albedos, more like those found for Hyperion. It is noteworthy that Voyager images of Hyperion show it to be a reddish colour, suggestive of surface impurities.

Recently, further progress on surface composition has come from IR spectroscopy. Observations of Hyperion by Cruikshank and Brown (*Icarus* **50**, 82; 1982) have revealed the presence of water ice bands, which differ in detail from those seen on Rhea. Measurements of the dark side of Iapetus by L. Lebofsky, M. Feierberg and A. Tokunaga (*Icarus* **49**, 382; 1982) show an absorption feature thought to result from a hydrated silicate mixed with a small amount of water frost.

Stretching the capabilities of the size determination measurement to the outer Solar System, Morrison, Cruikshank and Brown have placed significant upper limits on the sizes of Triton, the major satellite of Neptune, and of Pluto. The results are consistent with icy objects of sub-lunar size, and with the hypothesis that the two objects are physically similar. The possibility that Triton is the largest planetary satellite can now be excluded as it is certainly smaller than the giant satellites Ganymede, Callisto and Titan. An improvement of only a factor of two in the quality of the IR measurements is likely to lead to positive detections, and hence definitive size measurements, for both Triton and Pluto.

The scientific value and cost-effectiveness of these Solar System studies are self-evident, and it is gratifying that NASA has reversed its earlier decision to stop funding for the Infrared Telescope Facility. The importance of IR astronomy for targets outside the Solar System is also gradually being realized in the study of star formation, galactic nuclei and many other dusty interstellar environments. It is to be hoped that the facility will long continue to exploit the special advantages of Mauna Kea, where, as well as University of Hawaii telescopes, there are now two international observatories in operation; the Canada-France–Hawaii Telescope (CFHT) and the United Kingdom Infrared Telescope (UKIRT). More telescopes are planned for the future, including the SERC Millimetre Wave Telescope. □

POLLUTION OF THE ATMOSPHERE

THERE was a letter in *Nature* some time since, calling attention to the pollution of the atmosphere by the burning of coal; and it was calculated that in the year 1900, all animal life would cease, from the amount of carbonic dioxide; but the author had overlooked the fact that the rain is continually cleansing the atmosphere of this, and the fall of this rain on the ground, and the combination of this with various salts; besides the oceans alone would absorb their own bulk at normal pressure, but at an increased pressure of, say half a mile deep, would dissolve more than we are likely to need for hundreds of years.

But there are other products of combustion, or rather of incomplete combustion, that are not brought down in this manner by rain, as hydrogen and the hydrocarbons, chiefly marsh-gas and ethylene.

Since the year 1854 (as near as I can estimate) there has been burnt 10,000 million tons of coal; and if we say (in its consumption by household grates, leakage by gas-pipes, etc.) 1-100th escapes, then 100 million tons of hydrogen and hydrocarbons are floating in the atmosphere or 1-10,000,000 part in bulk; if we say the average proportion of hydrogen to be ·45, and of marsh gas ·35, and of ethylene ·4, we have ·84 per cent of gases that are lighter than air, and it is more than probable that the law of diffusion of gases, as demonstrated with jars, does not apply to the atmosphere. The cases are not parallel: in the air we have unconfined space, pressure, and temperature diminishing infinitely, conditions favourable to the lighter and the gas with the greater amount of specific heat rising and maintaining its elevation, especially as we know that in *large* halls carbonic dioxide is found in larger quantitites on the floor. According to Prof. Tyndall's researches, hydrogen, marsh gas, and ethylene have the property in a very high degree of absorbing and radiating heat, and so much so that a very small proportion, of only one thousandth part, had very great effect. From this we will have a marked influence on the climate of the world. The mountainous regions will be colder, the Arctic regions will be colder, the tropics will be warmer, and throughout the world the nights will be colder, and the days warmer. In the Temperate Zone winter will be colder, and generally differences will be greater, winds, storms, rainfall greater.

Giant voids in the Universe

Ya. B. Zeldovich*, J. Einasto†‡ & S. F. Shandarin*

Recent observations indicate that most galaxies are concentrated in superclusters consisting of galaxies, and clusters of galaxies, aligned along strings. Giant volumes exist between superclusters which are almost empty of visible objects. Theories of galaxy formation predict the formation of non-spherical superclusters and giant voids. Large-scale structure changes very slowly, so the currently observed structure reflects the whole history of galaxy formation and structural evolution.

OBSERVATIONS reveal that galaxies are distributed more or less randomly, showing a moderate tendency towards clustering which statistically can be expressed in terms of the galaxy correlation function[1]. It has usually been assumed that field galaxies and clusters of galaxies are pretty well isolated from each other (island universes), and the correlation function was thought to reflect the size of clusters and the deviation from a purely random distribution.

Modern detectors have made it possible to determine the redshifts of many galaxies. The redshift, interpreted as the expansion speed of the Universe, is proportional to the distance of the galaxy from the observer. Combined with the apparent position in the sky, it is therefore possible to derive a three-dimensional distribution of galaxies in space.

The results of recent studies of the three-dimensional distribution of galaxies are surprising. Most (90%) galaxies are concentrated in strings, groups and clusters of galaxies[2–6]. Neighbouring strings form a connected network which can be called superclusters[3]. Superclusters are often flattened and fill only a small fraction of the total space (<10%), the remaining space between strings and superclusters contains almost no luminous matter[3,6]. The diameter of voids between superclusters reaches 100 h^{-1} Mpc, where h is the Hubble constant in units of 100 km s^{-1} Mpc^{-1} (refs 3, 7), and such voids appear to make up >90% of the total volume of the Universe.

This picture, particularly the presence of giant voids, differs completely from earlier expectations and raises several questions. First, is a revision needed of the fundamental cosmology, the Friedmann–Lemaitre model of the Universe? Second, what does the observed structure tell us about the process of galaxy formation and about the very early Universe?

Observed random velocities of groups and clusters relative to the neighbouring string network seem to be small, of the order of 100 km s^{-1} (ref. 6). During the whole Hubble time a galaxy with such a small velocity could travel a distance <1 Mpc. Although the cluster network as a whole may have larger anomalous velocities[1,8,9], this does not alter the conclusion that the structure of the Universe changes slowly. Thus the present structure reflects the history of its formation and evolution.

We now review new observational data, and pay special attention to quantitative methods of analysing this data. Thereafter a scenario explaining the structure formation is outlined and competing scenarios are discussed.

All current theories of the formation of the structure are essentially gravitational clustering theories based on the theories of the expansion of the Universe[10] and of density fluctuations[11]. Both theories were first formulated in the framework of general relativity. Their essentially newtonian content was understood much later[12].

Geometry of galaxy distribution

To a first approximation the clumpiness of galaxy distribution can be expressed in terms of a correlation function[1]. The most popular two-point correlation function says, however, practically nothing about the characteristic pattern of galaxy distribution.

So far galaxy systems have been described only qualitatively. Our conviction that systems of galaxies of various types (groups, clusters, cluster chains) do exist is based on visual inspection of photographs and on galaxy counts. To build up quantitative theories of how the structure of the Universe formed, its structure must also be described quantitatively.

One possible way to do this is to use the so called 'cluster analysis' (see, for example, ref. 13). Draw a sphere (in the two-dimensional case a circle) of radius r around each dot representing galaxies. If the radius r is small enough, encircled regions are well separated from each other and the whole space is divided into isolated 'islands' containing galaxies and a continuous 'ocean' of empty space. When we take a larger radius, several neighbouring 'islands' join to form connected systems of galaxies. With an even larger radius, most galaxies join to form large connected systems. At a very large radius practically all galaxies join to form a single connected system.

The neighbourhood radius r at which galaxies form connected systems depend on the density of galaxies in space. With a small radius only the densest systems, cores of groups and clusters of galaxies, are picked up. Then, with increasing radius r neighbouring groups and clusters join to form elongated double or multiple clusters, thereafter still larger and less denser aggregates of galaxies will form connected systems.

The form and orientation of connected systems, their length, total volume and other properties depend on the pattern of the galaxy distribution.

Distribution of galaxies in space

Our analysis of the three-dimensional distribution of galaxies in space is based on a catalogue of all available redshifts of galaxies compiled by J. Huchra (Harvard-Smithsonian Center for Astrophysics). In the northern sky the catalogue is complete up to apparent magnitude 14.5, in the southern sky up to apparent magnitude 13.0. For galaxies brighter than the knee-point of the luminosity function (−21.0 absolute magnitude)

0028–0836/82/480407—07$01 00

the catalogue is complete up to distances 130 and 65 Mpc (northern and southern sky, respectively). Throughout this review we use the Hubble constant $H = 50\ \mathrm{km\ s^{-1}\ Mpc^{-1}}$. Due to strong galactic absorption it is difficult or impossible to observe external galaxies in areas close to the Milky Way. Here, of course, data are not complete.

Several slices through the local supercluster are shown in Fig. 1, where supergalactic rectangular coordinates are also indicated and long galaxy strings between the Virgo and Coma clusters and regions void of galaxies can be seen.

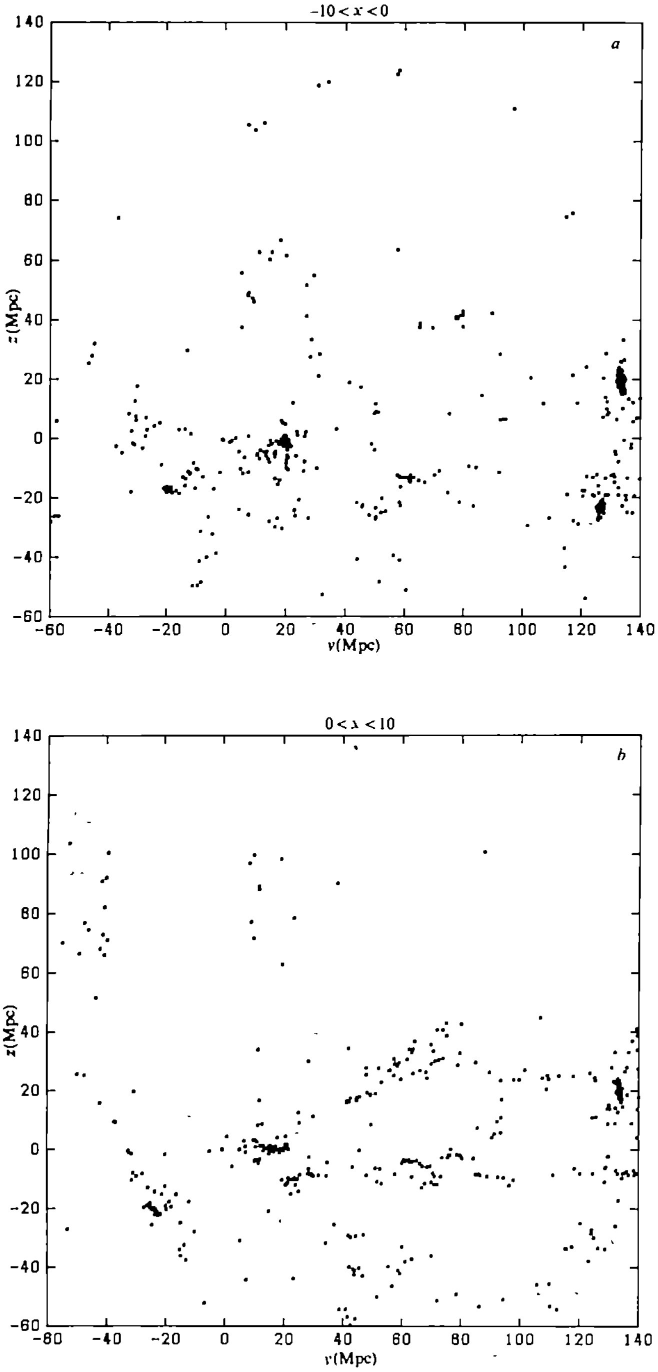

Fig. 1 Slices through the Local supercluster. Supergalactic rectangular coordinates are shown: the x and y axes lie in the supergalactic plane. The Galaxy is at the centre, the Virgo cluster lies in the y axis direction at $y = 20$ Mpc. Bright clusters of galactics at $y = 130$ Mpc are the Coma cluster ($z = 20$ Mpc) and A1367 ($z = -10$ Mpc). Galaxies brighter than −19.5 absolute magnitude have been plotted.

Properties of systems of galaxies have been studied using the cluster analysis. For comparison, identical analysis was carried out for several model catalogues. One model was calculated following the method of Soneira and Peebles[14]. The second model was generated for a full random (Poisson) distribution of galaxies. The third model was taken from a N-body experiment, based on the adiabatic scenario of structure formation[15]. These model catalogues H, P, and A have approximately equal number and mean density of objects. The two-point correlation function was calculated for all model catalogues and for the observed (O) catalogue (the region centred at the Virgo cluster, cube side of 80 Mpc, limiting absolute magnitude −19.5, total number of galaxies 866). The correlation function is plotted in Fig. 2. Functions are close to each other and only for the random P-distribution do we have zero correlation, as expected.

The maximal length of connected regions as a function of neighbourhood radius r is plotted in Fig. 3 for the observed and model distributions. At small r all curves corresponding to catalogues with normal correlation function have similar slopes. Connected regions are round or slightly elongated. Most regions found from the observational data correspond to know groups and clusters of galaxies.

At a certain critical radius (~1 Mpc) the slope of O and A curves abruptly increases. This corresponds to the transition from single to multiple clusters and cluster chains. With growing radius the length of chains rapidly increases and at some other critical radius (~5 Mpc in our case) it exceeds the size of the cube under study.

For the hierarchical H-catalogue the length increases slowly over the whole neighbourhood radius interval studied. For the P-catalogue the length increases at small r very slowly (the catalogue contains no built in systems), but then the slope gradually increases.

Figure 4 shows the distribution of the number of galaxies in systems of different multiplicity for the observed and model catalogues. All histograms correspond to an neighbourhood radius $r = 5$ Mpc.

At this radius about half of all galaxies in the O and A catalogues form a single connected system. H and P catalogues have no large single connected systems. Galaxy systems, not connected to a single supersystem, have multiplicity <64. In the case of the O catalogue these galaxies are more or less evenly distributed among systems of different multiplicity. The H catalogue has too few singles and pairs (in comparison with the O catalogue). The distribution of small systems in the A and P catalogues is similar, peaking at singles.

Figures 3 and 4 can be interpreted as follows. Both random catalogues, H and P, behave completely differently from the observed O catalogue. Thus the observed distribution cannot be considered as a simple hierarchical one. In general, the A distribution has similar properties to the observed one. But we note two important differences.

First, in the A catalogue test particles that are not connected to the single large connected system, are distributed evenly like the particles in the P catalogue which can be considered as a field population. The O catalogue has no appreciable field population. Thus in regions of lower than the average matter density no galaxy formation takes place. The comparison of respective numbers of test particles suggests that about half of primordial matter can still be found in low density regions in some pre-galactic form.

The second difference lies in the fact that the A catalogue has no systems of intermediate size and mass. The observed catalogue has at this neighbourhood radius one large system (containing half the galaxies) and about 10 systems containing galaxies of multiplicity between 8 and 64 with length from 10 to 35 Mpc (mean value 20 Mpc). These systems are strings of galaxies and groups of galaxies, they contain some poor Zwicky[16] clusters but no rich Abell[17] clusters. The presence of systems of intermediate scale demonstrates that the Universe has some fine structure, which is lacking in the A model.

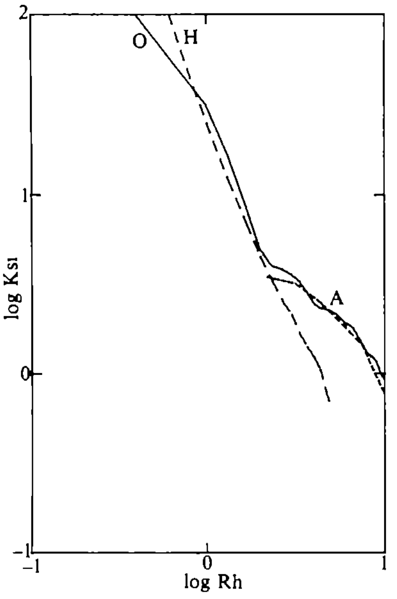

Fig. 2 Correlation function for the observed catalogue (O) around the Virgo cluster (cube of side 80 Mpc), for the catalogue generated by Soneira and Peebles method (H) and for the adiabatic model (A) (ref. 61).

The status of galaxies, not connected to systems of large or intermediate scale at this neighbourhood radius, is not clear. There are two possibilities, either these galaxies and small groups are outlying members of larger systems, or they constitute a true field population. To check these possibilities we have studied galaxies in a smaller and more complete region around the Virgo cluster. It is a cube of side 40 Mpc, has a limiting absolute magnitude of −16.5, and contains 1,009 galaxies. We have calculated the distribution of galaxies among systems of various multiplicity for several values of the neighbourhood radii (1–5 Mpc). The results indicate that the relative number of singles and small systems quickly decreases with increasing radius, for $r = 3$ and 4 Mpc only 10 and 5% of all galaxies are located in systems of multiplicity <8, respectively. This test emphasizes that most small systems are outlying members of larger systems. The field population, if it exists, does not exceed 5–10% of the total number of galaxies.

Let us now estimate the volume occupied by systems of galaxies. Galaxy strings can be approximated by cylinders of length, found from the previous study of connected systems, and of radius, equal to the characteristic radius of galaxy groups and clusters. Nearby rich clusters of galaxies have following radii: Virgo, 2.2 Mpc; Perseus, 2.9 Mpc; Coma, 2.5 Mpc. The radius of groups found in our study of connected systems lies between 0.5 and 2 Mpc, the r.m.s. radius being 1.0 Mpc. We adopt as a mean outer radius of the cylinder $r = 2$ Mpc. The total length of galaxy strings in cubes around the Virgo cluster is 140 Mpc and 380 Mpc (smaller and larger cube respectively), so we found that within these cubes galaxy strings occupy 0.110 and 0.037 of the total volume.

To estimate the volume filled with galaxy systems in a larger region, only data on the distribution of bright galaxies (absolute magnitude <−21) can be used. For this we have divided the region under study into cubic cells of various size. We note that at cell size 5 Mpc relative volume of cells occupied by bright galaxies is approximately equal to the relative volume occupied by galaxy systems. Using this method we have found that the filling factor of a cube of side 200 Mpc centred on the Virgo cluster is only 0.01. Thus the density of galaxies outside superclusters should be very small.

Where are the low density areas? Figure 1 shows that at high supergalactic z coordinates the galaxy density is much lower than near the supergalactic plane $z = 0$. The almost complete absence of galaxies in front of the Hercules supercluster is well known[5]. To study the galaxy distribution in vertical supergalactic direction we have found the number of bright galaxies in rectangular sheets of sizes 200×200×20 Mpc. One sheet is centred at the Virgo cluster, others lie upwards and downwards. The distribution of numbers of galaxies in these sheets as a function of z is given in Fig. 5. We see that the number of galaxies rapidly decreases with increasing distance from the supergalactic plane. A similar distribution in the x and y directions shows no systematic trend.

The rapid decrease of the number of galaxies in the z direction is partly due to the galactic absorption: the zone of avoidance crosses the sky near supergalactic poles. A rough estimate shows that the number of galaxies at extreme z values may be underestimated by a factor of three. The corrected distribution is also plotted in Fig. 5, as well as the distribution of rich clusters of galaxies having redshift <7,000 km s^{-1}. Nearby clusters of galaxies are very strongly concentrated towards the supergalactic plane and belong to three well studied superclusters: the Local, Coma, and Perseus, as well as to several other previously unrecognized superclusters.

This sheet of superclusters can be considered as a wall shared by two local cells of the Universe, the northern and the southern[18]. The Hercules supercluster, the supercluster around Abell cluster A539 and several southern superclusters form side walls of these cells. The far side of the local cells can be located only approximately, due to the lack of observations near the galactic plane. Both local cells have a diameter of ~200 Mpc.

Available data suggest that the interior of local cells contains no rich clusters of galaxies. In this respect they are similar to cells found by Jõeveer *et al.*[2] behind the Perseus supercluster and by Kirschner *et al.*[7]. However, there are also some poor Zwicky[16] clusters here[19]. Our study confirms the results obtained by Balzano and Weedman[20] indicating that Kirshner's void is not completely empty. Zwicky clusters as well as galaxies located in cell interiors are not randomly spaced. As in superclusters, galaxies and clusters form long strings here. The basic differences between galaxy strings in superclusters and in cell interiors lie in the population and the spacing: in cell interiors

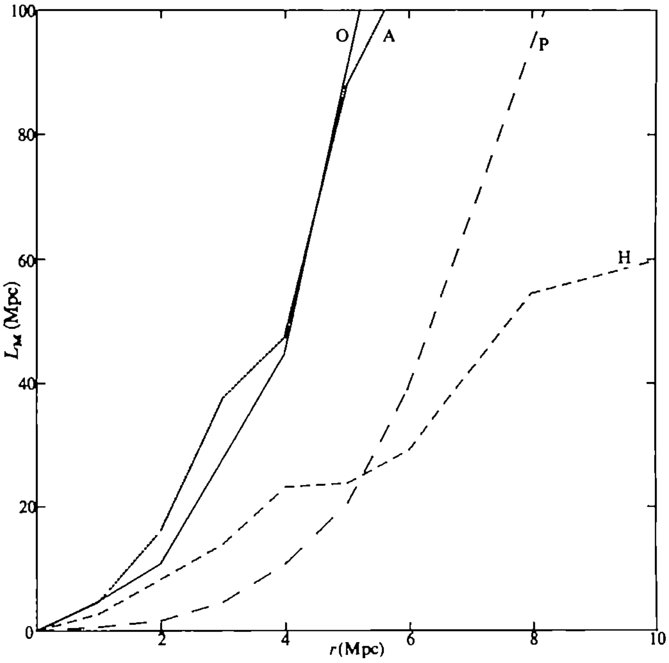

Fig. 3 Maximal length L_M of connected regions as a function of neighbourhood radius r for four catalogues[61].

the string population is smaller and the spacing between neighbouring strings is larger.

From available data the luminosity density in different structures can be calculated. As luminosity indicators we use bright galaxies. The total luminosity in solar units for standard luminosity functions is

$$L = n^* \times 3.6 \times 10^{11} L_\odot$$

where n^* is the number of galaxies brighter than $M = -21.0$ (ref. 2). We found that for the average luminosity density $5 \times 10^7 L_\odot \mathrm{Mpc}^{-3}$, the mean density in cell interiors is about 3 times lower, but in galaxy strings about 70 times higher. An upper limit for the luminosity density outside connected regions is 10 times lower than the average luminosity density. Thus the luminosity density contrast between galaxy strings and 'empty' space is at least three orders of magnitudes.

Cluster analysis gives us the possibility of picking up and studying individual connected systems. This study demonstrates that most systems are elongated and look like cluster strings in the Perseus supercluster[2,3]. In some cases, however, small sheets of galaxies have been found; one such sheet is connected with the Virgo cluster. Three orthogonal views of this system are given in Fig. 6. The interpretation of sheets of this type is still open. No large sheets of galaxies have been found so far.

Compatibility of the observed structure with the Friedmann–Lemaitre model

Large voids between superclusters have a volume of $\sim 10^6 \mathrm{Mpc}^3$ (refs 3, 7). In an expanding Universe the diameter of voids expressed in redshift units remains approximately constant (exactly constant in the case of a non-decelerating Universe), thus we can adopt as a first approximation $\Delta z = 0.05$. Let us assume that the cellular structure was formed at $z = 3$–10, as indicated by a comparison of densities in various structural elements and by the cutoff of quasar redshifts at $z = 3.5$ (refs 3, 21). If this is the case, then within the horizon our Universe should contain $\sim 10^6$ cells.

There is little or no evidence for the presence of still larger structural units in the Universe. Cell dimensions in comparison with the Universe as a whole are still small, thus we see no need for a revision of the fundamental principles of cosmology. Our confidence in the classical model is strengthened by small temperature fluctuations of the microwave radiation, indicating small density fluctuations at the epoch of decoupling of radiation and matter ($z \approx 1{,}300$) (refs 22, 23).

How the structure of the Universe formed

At present it is difficult to infer the type, the spectrum and the amplitude of initial perturbations from general physical principles. So theorists consider all possibilities. The most developed scenarios of the formation of the large-scale structure are based on two different assumptions about the character of perturbations in the pre-decoupling era[24].

First, at an early stage both matter and radiation density were perturbed so that their ratio was constant in space and time. Because this ratio is conserved in adiabatic processes such perturbations are termed adiabatic.

Second, it is supposed that the matter density was perturbed but the radiation density was not. These perturbations are known as isothermal since in this case temperature is assumed to be the same everywhere.

Both scenarios have important features in common: the initial perturbations on scales larger than galaxy ones are small, the large density contrast and the large-scale structure develops due to the gravitational forces. In an expanding Universe small density fluctuations can grow only if gravitation amplifies them. In this sense both the adiabatic and the isothermal scenarios are gravitational clustering theories, however, the principal differences between them lie in the scale of post-decoupling perturbations.

Adiabatic scenario

Adiabatic fluctuations on scales smaller than a characteristic mass $M_c \approx 10^{13}$–$10^{15} M_\odot$ were damped before decoupling due to photon viscosity[25]; after decoupling one finds practically no fluctuations on scales smaller than this limit. Perturbations of the scale M_c had the largest amplitude, thus under- and overdensities of this scale developed first. Galaxies and clusters of galaxies formed in dense regions after the gas collapsed and cooled. The formation of dense regions and galaxies started at a relatively late epoch $z = 3$–10.

The principal feature of the adiabatic scenario lies in the fact that the formation of large-scale units occurs in a cold environment. The gas pressure is negligible until the final stages of formation of large-scale structures. Numerically this fact is expressed in terms of the ratio of the Jeans mass of the neutral gas after decoupling, $M_J \approx 10^6 M_\odot$, to the characteristic mass of adiabatic perturbations, $M_c \approx 10^{13}$–$10^{15} M_\odot$: $M_J/M_C \approx 10^{-7}$–10^{-9}. In the first approximation we can neglect the temperature and gas pressure, assuming $M_J/M_C = 0$.

The evolution of perturbations in a pressureless environment is now well established. Before giving more details on the formation of the large-scale structure let us outline the main processes leading to galaxy formation in the adiabatic scenario[24,26,27].

Very flattened clouds—'pancakes'—with masses about $M_C \approx 10^{13}$–$10^{15} M_\odot$ were formed first[28]. At its arrival to a pancake the gas is heated and compressed in the shock wave, which represents the boundary of the pancake. Inner parts of pancakes cool quickly due to radiative losses of their thermal energy causing an increase in density[29]. So in inner parts of pancakes the conditions become favourable for galaxy formation[26,27]. Shock waves on the boundaries of pancakes favour the generation of rotation, thus spiral galaxies could form easily[30]. The general trend in the evolution on galaxy scales after pancake

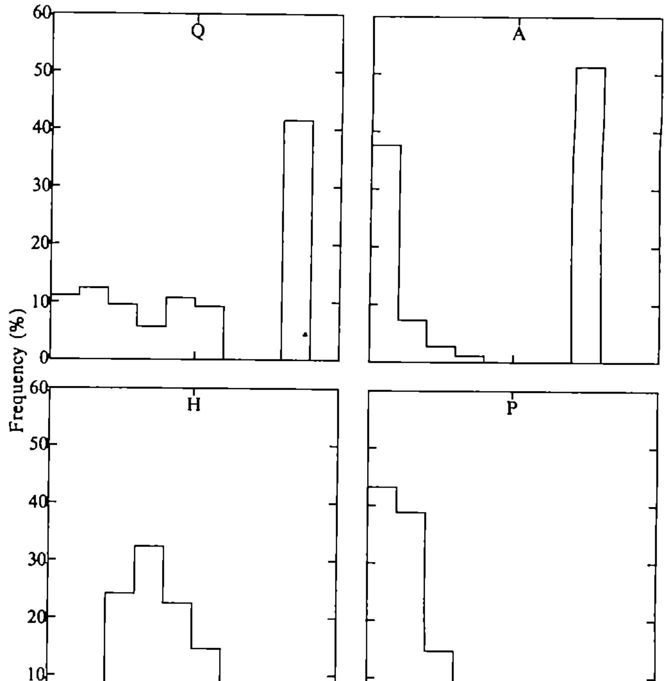

Fig. 4 Distribution of galaxies according to the multiplicity of the system. Neighbourhood radius $r = 5$ Mpc. Multiplicity is expressed in powers of 2 (5 corresponds to $2^5 = 32$ and so on)[61]

formation is the fragmentation of pancakes into smaller units. Thus the adiabatic theory is often called the fragmentation scenario.

Large-scale structure and the catastrophe theory

We now consider the formation of larger-scale objects. We believe that the processes of galaxy formation do not have a major influence on the motion of matter on scales of rich clusters and superclusters. As noted earlier, the growth of adiabatic perturbations has one important property: the evolution proceeds at low temperature of self-gravitating medium. This evolution has a simple approximate analytical solution[28]. As the smooth initial perturbations develop into the nonlinear stage, dense regions will be built up by the concentration of matter into caustics—the intersection of particle trajectories.

The formation of caustics in a swarm of dust particles has been demonstrated by Lifshitz and Khalatnikov[31] and later studied by Grishtshuk[32]. Initially it was thought that this case is physically not realistic because an arbitrarily small pressure removes sharp caustics. However, the idealized case is a very good approximation to the actual situation. The geometry of dense regions is closely related to that of caustics in a pressureless medium.

Geometrical properties of caustics can be studied mathematically using the catastrophe theory[33,34]. Because adiabatic perturbations are potential (rot $\vec{v} = 0$), the study of singularities in the potential flows is of great interest.

As shown by Arnold and co-workers[35] following an early suggestion by Zeldovich[28], pancake-like singularities known in the catastrophe theory as lips formed first. At a later epoch pancakes grew, intersected and formed a fairly pronounced cellular structure[36]. Matter continued to flow towards and within pancakes, so that some time later higher-order singularities, lines and knots, formed. All this happened in a similar way both in gaseous medium and in some collisionless cold (neutrino) medium. This phase ended with a cellular structure of high density sheets, strings in sheets and knots connected by strings. At this stage dense regions fill $<10\%$ of the total volume of the Universe, while isolated low density regions (cell interiors) fill the remaining major part of the volume of the Universe.

Numerical experiments demonstrate[15,37] that the density is highest in knots (zero-dimensional structures), high in strings (one-dimensional structures) but much lower in sheets (two-dimensional structures). Subsequent evolution of the structure depends on three processes, the formation of galaxies, the gravitational redistribution (clustering) of galaxies, and the expansion of the Universe.

One comment is necessary here: galaxies are easier born in dense and cold gas. Thus it is natural to expect that no galaxies will be formed in cell interiors and that an intensive galaxy formation would occur along the lines and in the knots. It is not evident whether the density in all sheets is sufficient for galaxy formation or not. Perhaps some gaseous sheets remain in gaseous form and can be seen as absorption lines in quasar spectra[38,39].

Later gravitational clustering tries to destroy the cellular structure, the rate of which depends on the mean density of the Universe. In a low density Universe cellular structure is maintained for a long time, in a closed Universe this structure disappears in a time scale comparable with the Hubble time, thereafter galaxies clump to clusters of very high mass[15,37].

Neutrino dominated Universe

Perhaps the weakest point in the adiabatic scenario is its need for too large an amplitude of density perturbations at the decoupling era: $\delta\rho/\rho \approx 10^{-3}$ if $\Omega = 1$ and $\delta\rho/\rho \approx 10^{-1}$ if $\Omega = 0.02$ (ref. 40). As noted already by Silk[23], density fluctuations at the epoch of decoupling correspond to similar angular fluctuations of the temperature of the microwave background, $\delta T/T \sim 1/3\delta\rho/\rho$. On the other hand, observations give an upper limit of temperature fluctuations of the order 10^{-4} (refs 22, 23).

In an open Universe density fluctuations grow extremely slowly. To obtain the observed density contrast, it is also necessary to have at the epoch of decoupling high-density perturbations in contrast to small temperature fluctuations of the microwave background.

One can infer from these arguments that $\Omega = 1$ is necessary for the adiabatic scenario. However, the data on helium and deuterium abundances strongly support the model of a low baryon density. Deuterium cannot be produced in stars like heavy elements, the whole deuterium observed now must have originated during the primordial fireball stage of the Universe. Deuterium production rate is extremely sensitive to the density of baryons in the Universe. Observed deuterium abundance suggests the baryon density 0.01–0.1 of the closure density[41], that is the Universe should be open by a large margin.

Last but not least, flat rotation curves of galaxies, the dynamics of double galaxies and of clusters of galaxies indicates that giant galaxies and clusters of galaxies are embedded in huge invisible coronas[42,43]. The mass of the coronas exceeds the mass of visible galactic populations by a factor of 10 or more.

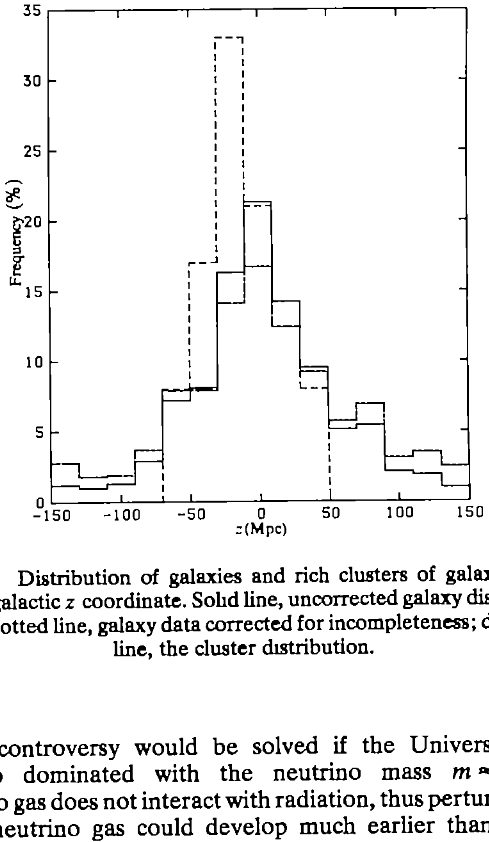

Fig. 5 Distribution of galaxies and rich clusters of galaxies in supergalactic z coordinate. Solid line, uncorrected galaxy distribution; dotted line, galaxy data corrected for incompleteness; dashed line, the cluster distribution.

This controversy would be solved if the Universe were neutrino dominated with the neutrino mass $m \approx 10$ eV. Neutrino gas does not interact with radiation, thus perturbations in the neutrino gas could develop much earlier than in the baryon dominated Universe and could have the necessary amplitude. Baryon gas is bound to radiation and has smaller density fluctuations, after decoupling it simply flows to gravitational wells formed in the neutrino gas.

Thus in the neutrino dominated Universe one has low baryon density $\Omega_b \approx 0.01$–0.1 while the total density is close to the closure once $\Omega_t \approx \Omega_\nu \approx 1$.

The formation of the structure in a neutrino dominated Universe is, essentially, an adiabatic scenario[44–51]. The initial ratio of baryons to neutrinos is the same everywhere (the entropy is constant), small-scale fluctuations are damped, the characteristic mass of objects to form first is $10^{15} M_\odot$ as in the conventional adiabatic scenario.

However, the structure of pancakes is more complicated: inside a neutrino pancake there is a pancake made of baryons which is similar to that described earlier.

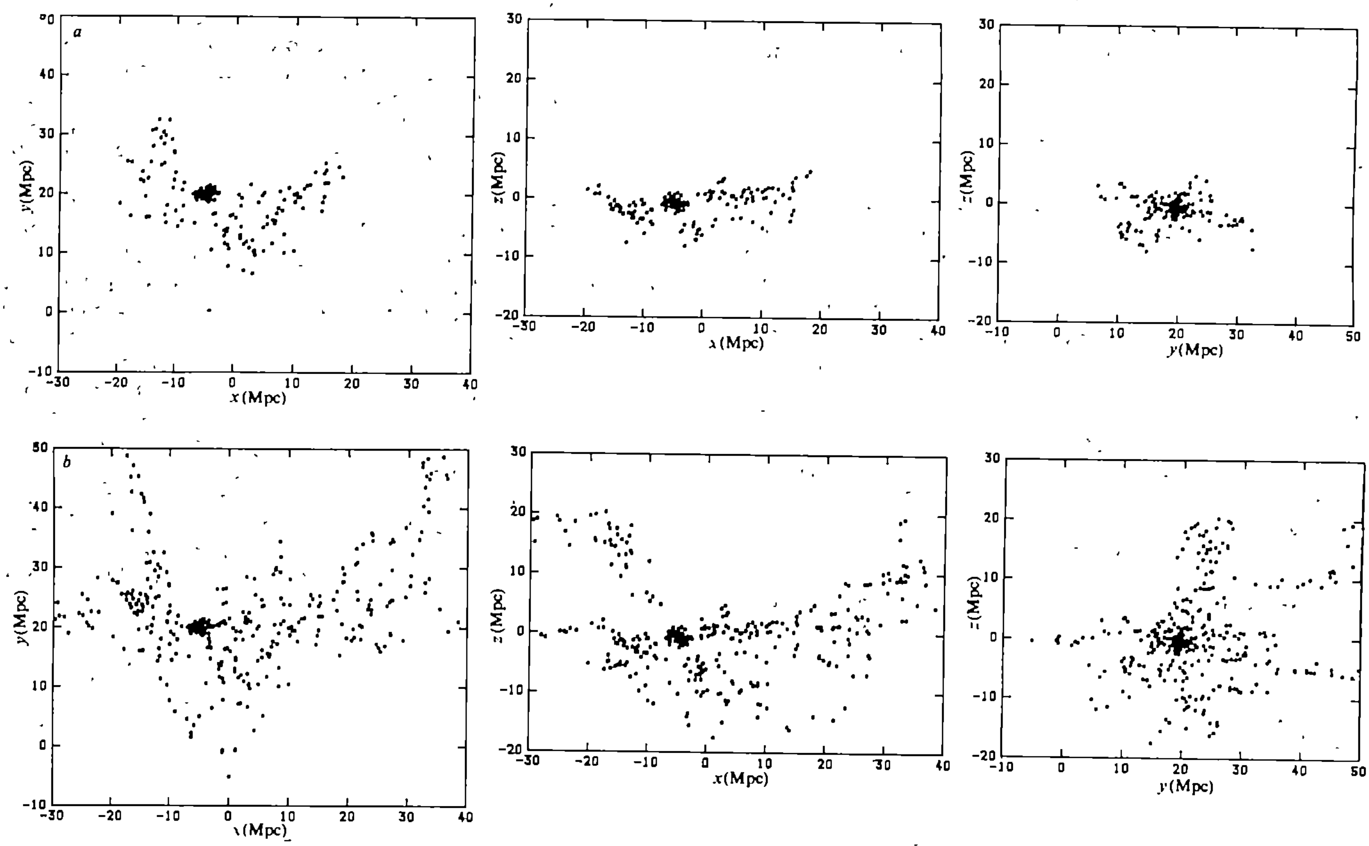

Fig. 6 Three views of a connected system around the Virgo cluster[61]: *a* corresponds to the neighbourhood radius $r \simeq 4$ Mpc; *b* to the radius $r = 5$ Mpc. *a* shows two sheets of galaxies in both sides of the Virgo cluster, *b* demonstrates the presence of a string network around the cluster.

Isothermal scenario

According to the isothermal scenario, small-scale density fluctuations were not damped. Thus, it is natural to think that the mass of the first objects to be formed was limited by the gas pressure—by the respective Jeans mass after decoupling 10^5–$10^6 M_\odot$ (refs 49, 52). Thus globular cluster-sized objects were the first primordial building units formed soon after decoupling, $z \simeq 10^3$. During the subsequent evolution larger building blocks, galaxies and clusters of galaxies, were built up step-by-step by gravitational clustering.

The formation of the first bound objects of mass $10^6 M_\odot$ takes place in the environment when one cannot neglect the influence of pressure. Therefore they must have a shape that is almost spherical. Part of gravitational energy liberated during their formation transforms into chaotic motion, having the role of 'temperature' of the 'gas' of these primordial objects. Hence, according to the isothermal scenario, the formation of large-scale structural units proceeds in a high-temperature 'gaseous' environment. The 'gas' pressure was active during the whole process of the formation of the structure so that it is difficult to build up strongly anisotropic structures.

Extensive series[53–55] of three-dimensional N-body calculations in the framework of the isothermal model reproduced the observational correlation function. The general appearance of particle distribution was claimed to be similar to the observational distribution of galaxies. However, it seems that in details the calculated distribution is more amorphous than the observational one.

Tepid and other cosmological models

Another scenario of the formation of the large-scale structure is suggested by Ostriker and Cowie[56]. They argued that the formation of large-scale second generation objects (superclusters around voids) may be due to the nuclear energy released during the explosions of first generation objects. These explosions can give rise to expanding shock wave shells which ignite star and galaxy formation in the remaining gas.

Earlier it was recognized that total energy released during explosions of primordial objects is comparable with the energy contained in the microwave background radiation. This point has led Rees (refs 57, 58 and references therein) to the hypothesis that microwave radiation can be of nuclear origin and thus that there is no need for a hot Big Bang.

Both scenarios predict many dead remnants of first generation stars, therefore, they easily solve the problem of missing mass.

Observable differences expected in different formation scenarios

In the isothermal case dominant post-decoupling perturbations had a scale corresponding to a mass of $10^6 M_\odot$. Star cluster like objects formed very quickly after decoupling and most of the primordial gas went into stars at an early stage. Large-scale structures, such as superclusters and large voids, were due to large-scale perturbations, which needed more time to develop and formed gradually. Galaxies should have a tendency towards clustering, but could be found everywhere between clusters and strings. Strings should be short and not connected with other structural elements, voids should have moderate sizes. These expectations have been confirmed by numerical simulations[53,54].

In the adiabatic case small-scale perturbations were damped. The Universe evolved slowly and was gaseous for a long time. In contrast to the isothermal scenario, clusters and groups of galaxies formed at a later epoch along the initially continuous pre-existing network of gaseous strings and knots. The density of gas outside this network was small, thus no galaxies should have been formed there[36,59]. Some ionized gas and dark matter is still in 'empty' areas, because it is difficult to evacuate these large regions completely[60]. This gas should have had primoridal abundance.

In the Ostriker and Cowie[56] version one expects to have rather empty cell interiors, also filled with some ionized gas that should have a normal chemical composition.

The expected differences are of two types: (1) the composition of the gas outside superclusters; and (2) the fine structure of superclusters and 'empty' areas.

Gas layers in cell walls can be studied using absorption line spectra of distant quasars as suggested by Oort[38] (see also ref. 39). Here not only the presence of gas but also its chemical composition is important. Geometrical properties of alignment of galaxies and clusters of galaxies can be best studied in the vicinity of our own Galaxy.

Problems

The history of the formation of large-scale structure critically depends on basic cosmological constants, the time scale available (Hubble constant H), the overall density of matter (the ratio of density to the closure density $\Omega=\rho/\rho c$), and last but not least, on the nature of the dark matter (is it baryon matter or neutrino gas?).

A very important observational constraint is the temperature fluctuation of the microwave background radiation. Here not only the upper limit but also the actual fluctuations and their angular size are needed.

Conventionally observational studies in cosmology are based on data of objects located at high 'cosmological' redshifts. The study of superclusters in our vicinity has shown that important cosmological information can be received also by studying the distribution of nearby galaxies. Here we can study the distribution in greater detail.

To build up a quantitative theory of the formation of the structure in the Universe, the structure itself must be characterized quantitatively. Some weak points of principal structure formation scenarios that are already known are now considered.

The adiabatic scenario predicts the formation of structures of three types: surfaces, lines and dots. Numerical experiments suggest that the density is highest in dots, relatively high in lines, much lower in surfaces and very low in regions outside these singularities. Were galaxies formed in all of dense regions? If so, should we expect to observe all three kinds of galaxy system: pancakes, strings and clusters? The tests carried out so far demonstrate the presence of strings and clusters, the evidence for pancakes is controversial. Does this indicate that galaxy formation occurs basically at the structures having highest densities—in lines and dots?

The adiabatic scenario also predicts the formation of a simple cellular structure[36]. Observations indicate that the real distribution is much more complex. Rich clusters of galaxies (of the type included in the Abell catalogue) and connecting cluster chains surround regions, which are void of rich cluster. Voids of this type have a diameter of 200 Mpc. These voids are not completely empty, they are intertwined by a lattice of galaxy strings. Near the rich cluster the network of galaxy strings is much more closely spaced. How can we explain this hierarchical structure? Why do the properties of the fine structure (small galaxy strings) depend on the large-scale environment (proximity to rich clusters)?

The severest problem encountered by the isothermal scenario is the amorphous character of the calculated structure. This conclusion is based on the visual inspection of the results of N-body calculations. To draw more quantitative conclusions, one must await objective checks.

Another weak point in the isothermal scenario is the galaxy formation. As Silk has pointed out[46], there are several arguments (such as high central concentration demanding dissipation of extra energy, and radial gradient of chemical composition favouring *in situ* formation of heavy elements) demanding that galaxies have been formed directly from gas, not by clustering of ready stellar systems of lower mass.

Astronomers usually question which formation scenario is right. But both basic scenarios have weak points—perhaps it would be more correct to ask, which physical processes have led to the formation of structure in the Universe?

To answer this question, more observational data are needed. In particular, the study of 'empty' regions is important. So far astronomers have concentrated on rich clusters and other prominent features. The study of empty regions requires the coverage of large areas in the sky up to a fairly faint apparent magnitude, and thus much observing time. The first line of attack should be the study of the central regions of local cells. This can be done using telescopes of moderate size (of the 1.5–2 m class).

We thank many colleagues, in particular Professors V. I. Arnold, R. H. Miller, J. H. Oort and M. J. Rees, and Drs A. G. Doroshkevich, J. E. Hartley, E. Saar and R. A. Sunyaev for helpful discussions, also Drs J. Huchra and H. Rood for unpublished redshift compilations, and Professor R. H. Miller and Dr A. Klypin for permission to use preprint material. J. E. benefited from the hospitality of the European Southern Observatory, where a considerable part of this paper was written.

Absolute age of formation of chondrites studied by the ^{87}Rb–^{87}Sr method

J-F. Minster, J-L. Birck & C. J. Allègre

Laboratoire de Géochimie et de Cosmochimie, Département des Sciences de la Terre, Institut de Physique du Globe de Paris,
Universités Pierre et Marie Curie et Paris-VII, 4, Place Jussieu-75230 Paris Cedex 05, France

The ^{87}Rb–^{87}Sr isochrons for H-, E- and LL-, chondrites are undistinguishable from each other. The joint isochron yields an age of 4,498 ± 15 Myr if the rubidium decay constant $\lambda\ ^{87}Rb = 1.42\times10^{-11}\ yr^{-1}$, and a strontium initial ratio $^{87}Rb/^{87}Sr = 0.69885 \pm 0.00010$. For the age to agree with U–Th–Pb data, $\lambda\ ^{87}Rb$ would have to be changed to $1.402 \pm 0.008\times10^{-11}\ yr^{-1}$.

DATING of meteorites helps to decipher the mode of formation and the history of these extraterrestrial objects. This also provides constraints—mainly as a starting point—for the evolution of the terrestrial planets. In this respect, chondrites are particularly useful because they are chemically undifferentiated relative to the solar abundances and have had a fairly simple history. Thus it is thought that their age of formation corresponds to that of the Solar System. An absolute value for this age can in principle be obtained from the radioactive chronometers and we aim here to give a 'best' ^{87}Rb–^{87}Sr age of chondrites and discuss its interpretation.

In this method, the ^{87}Sr/^{86}Sr isotopic ratio of a series of objects is plotted against their ^{87}Rb/^{86}Sr atomic ratio. If these objects have been formed simultaneously with the same ^{87}Sr/^{86}Sr initial isotopic composition, and if they evolved since as closed systems (without external exchange of Rb and Sr), they should define a straight line in such a diagram. This line is called an isochron; its slope yields the age of the objects and its intercept gives the strontium initial ratio (Fig. 1). Besides the uncertainties introduced by the analytical determination of ^{87}Sr/^{86}Sr and ^{87}Rb/^{86}Sr, the only source of error is that of the decay constant of the parent nuclide ^{87}Rb. Because its decay energy is very low, its direct determination is relatively unprecise. The current value is λ^{87}Rb $1.42\pm0.01\times10^{-11}$ yr^{-1} (refs 1, 2). Another way to obtain this constant is to compare ages obtained by the ^{87}Rb–^{87}Sr method with those obtained by the U–Pb method[1,3]. Indeed, as the decay constant of ^{235}U is much larger than that of ^{87}Rb, it is easier to measure and its uncertainty is $<0.3\%$ (ref. 4). We now compare ^{87}Rb–^{87}Sr and U–Th–Pb ages for chondrites and indicate that, in order for the ages to agree, the ^{87}Rb decay constant would have to be changed.

Compared with dating terrestrial or lunar samples, dating of meteorites presents a major difficulty: because their origin is uncertain, it is impossible to know in advance whether they are genetically related. The best approach is therefore to analyse a set of meteorites and, if an isochron is obtained, to infer that they are genetically related, or at least formed within a short interval of time compared with the uncertainty of the dating. In the early works on ^{87}Rb–^{87}Sr dating of meteorites, objects of widely varying compositions, including chondrites and basaltic achondrites, were analysed[5–9]. As the latter are differentiated objects, largely deficient in Rb compared with chondrites, fairly well-defined 'isochrons' were obtained which gave an age of 4,560 Myr, with an error limit of the order of 150 Myr.

Clearly, however, such drastically different objects cannot be genetically related in a simple way. A 'primitive' ^{87}Rb–^{87}Sr isochron should use only chondrites. Moreover, chondrites can be classified into chemical groups[10]. Oxygen isotopes studies have recently provided some evidence in favour of this classification: indeed, the chondrites from a given group tend to have similar oxygen isotopic composition[11]. Though this result is not systematic, it indicates that the chondrites from a given group originated from a single reservoir of the solar nebula. It is thus preferable to date chondrites group by group. The first attempt of such an analysis[12] has been followed by a systematic study by Wetherill and his co-workers[13,14]. This resulted in a set of isochrons for carbonaceous, ordinary and enstatite chondrites which were grouped by Wetherill[15] into a

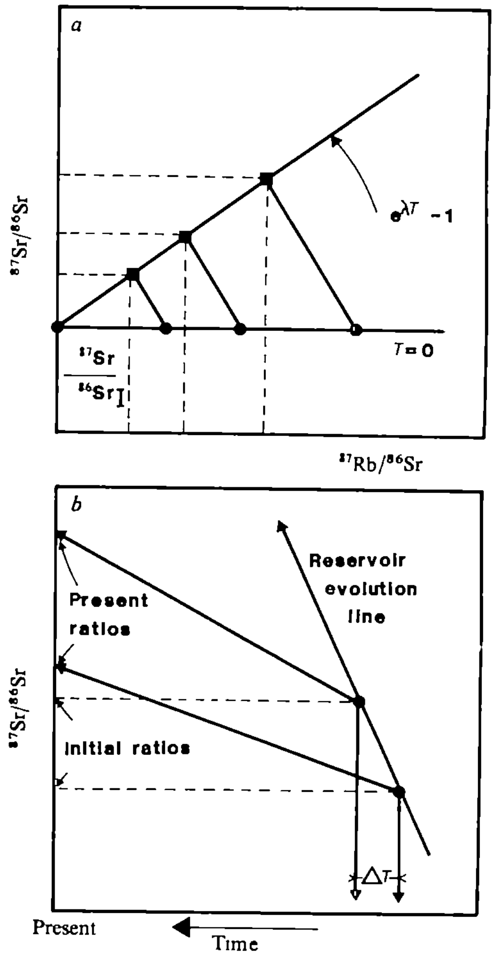

Fig. 1 *a*, Schematic evolution of the ^{87}Sr/^{86}Sr isotopic compositions of a series of objects formed simultaneously with different Rb/Sr ratios. Such objects plot on a straight line called isochron whose slope yields the 'age' of the objects. *b*, Evolution with time of the ^{87}Sr/^{86}Sr ratio in a reservoir. The higher the Rb/Sr ratio in the reservoir, the faster this evolution. The difference between the initial ratio of two objects formed from a single reservoir can be used to calculate an age difference.

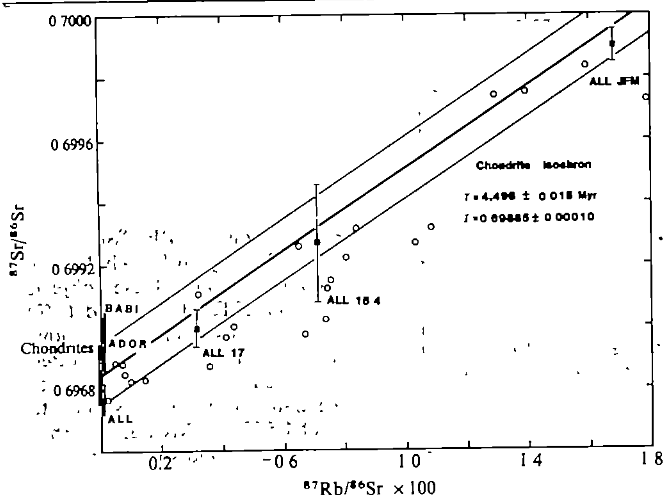

Fig. 2 Plots of $^{87}Rb/^{86}Sr$ against $^{87}Sr/^{86}Sr$ for some Allende refractory inclusions. ■, New values (see ref. 45): ALL 17 – $^{87}Rb/^{86}Sr = 0.00316$ – $^{87}Sr/^{86}Sr = 0.69900 \pm 0.0006$; ALL 15.4 – $^{87}Rb/^{86}Sr = 0.00714$ – $^{87}Sr/^{86}Sr = 0.69927 \pm 0.00014$; ALL JFM – $^{87}Rb/^{86}Sr = 0.0168$ – $^{87}Sr/^{86}Sr = 0.69990 \pm 0.00006$. ○, Data from the literature (refs 19–23). Since Allende refractory inclusions have been disturbed, extrapolation from the actual data points to an initial ratio can be meaningless. The Allende initial ratio (ALL) is obtained from a measured value. The $^{87}Sr/^{86}Sr$ initial values BABI[17,18] and ADOR[41] are indicated as well the error envelope of the isochron from Fig. 4.

single isochron of age (4,520±40) Myr and strontium initial ratio 0.7003±0.0004.

At the same time, Wasserburg and his co-workers demonstrated that it was possible to measure the isotopic composition of strontium at a precision of better than 10^{-4} (ref. 16) and obtained a very well-defined strontium initial ratio for basaltic achondrites of $^{87}Sr/^{86}Sr_{BABI} = 0.69899 \pm 0.00005$ (ref. 17, see also ref. 18). They have also proposed the use of the strontium initial ratio as a cosmochronometer. The principle of this technique is (Fig. 1): due to the decay of ^{87}Rb, the $^{87}Sr/^{86}Sr$ isotopic ratio increases with time in any reservoir. The larger the Rb/Sr ratio of the reservoir, the faster this increase. The difference between the strontium initial ratio of two objects formed from a same reservoir gives the time elapsed between their formation, provided the Rb/Sr ratio of the reservoir is known. Basaltic achondrites are differentiated, that is, have suffered magmatic events after their formation; thus it could be expected that their initial ratio should be higher than that for chondrites. Indeed, that ratio for the refractory inclusions of the carbonaceous chondrite Allende was found to be $^{87}Sr/^{86}Sr_{ALL} = 0.69877 \pm 0.00005$ (refs 19–21; also refs 22, 23 and Fig. 2). Yet the chondrite isochron of Wetherill[15], some precise data for low-radiogenic chondrites[20] as well as an internal isochron for the chondrite Guareña[24] indicated strontium initial ratios higher than BABI. Clearly more data with an improved accuracy were needed.

Since chondrites are radiogenic (the mean $^{87}Sr/^{86}Sr$ ratio for chondrites is about 0.75), the error on chondrite isochrons is dominated by that on the abscissa $^{87}Rb/^{86}Sr$. We developed a technique for measuring the rubidium isotopic composition with a reproductibility of better than 0.2% allowing a precision of ±0.5% for the $^{87}Rb/^{86}Sr$ ratio[25]. This represented an increase of the precision for this ratio by a factor of 2–4 compared with the previous studies; joined with a better than 10^{-4} precision for the strontium isotopic composition[18], this allowed a re-analysis of the problem. Specifically, we wanted to answer the following questions:

(1) Do chondrites still define ^{87}Rb–^{87}Sr isochrons with this increased precision?

(2) Are there differences between the different groups of chondrites?

(3) What is the strontium initial ratio for chondrites?

(4) What is the ^{87}Rb–^{87}Sr age for chondrites?

The results for the whole rock and mineral studies of the different groups of ordinary and enstatite chondrites have been published recently[25–27]. However, the joint results of these group studies as well as their discussion have not yet been presented and are given here, with a new set of analyses for Allende white inclusions, carried out in our laboratory. Most of the recent results from other laboratories on ^{87}Rb–^{87}Sr dating of chondrites will be incorporated into this discussion.

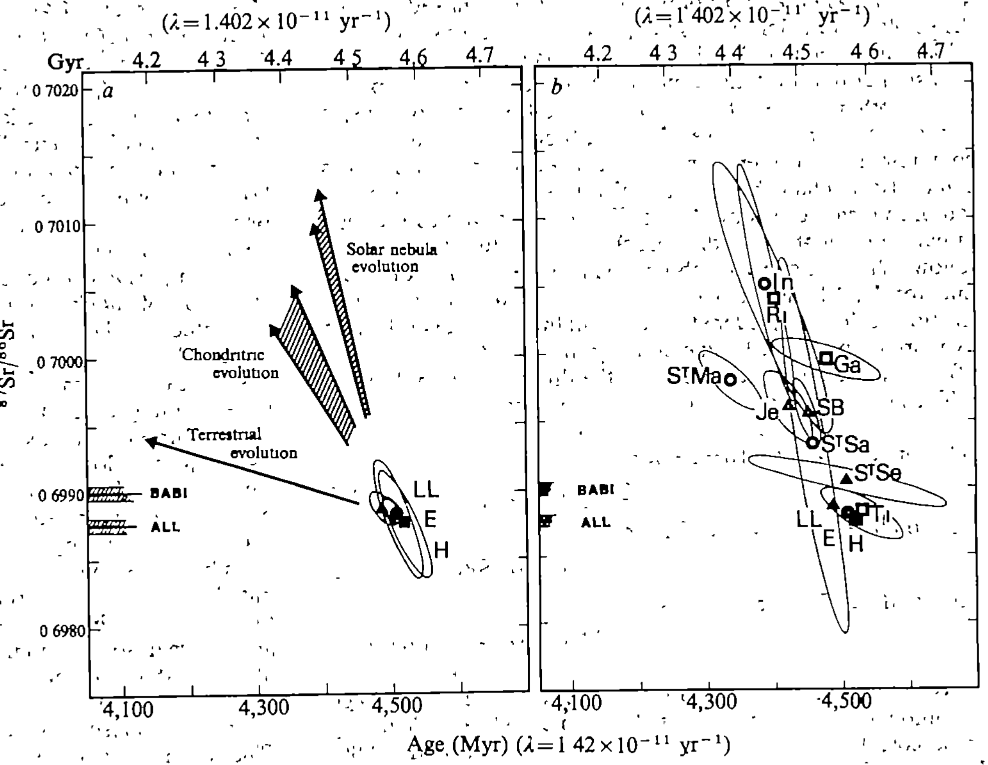

Fig. 3 *a*, Plot of age against strontium initial ratio for the chondrite whole-rock isochrons. The ellipse representation is justified in ref. 26. The smaller ellipse corresponds to the 'chondrite isochron' of Fig. 4. The strontium initial ratios ALL and BABI are also shown. The arrows indicate the direction of evolution of the $^{87}Sr/^{86}Sr$ ratio with time in reservoirs of solar (Rb/Sr = 0.5 to 0.6), chondritic (Rb/Sr = 0.2 to 0.3) and terrestrial (Rb/Sr = 0.04) composition. *b*, Age against strontium initial ratio for internal isochrons of chondrites. Ti, Tieschitz (H3 – 4,530±60 Myr; $I = 0.69880 \pm 0.00024$)[25]; Ri, Richardton (H5 – 4,400±90 Myr; $I = 0.7004 \pm 0.0010$)[30]; Ga, Guareña (H6 – 4,480±80 Myr; $I = 0.69995 \pm 0.00015$)[24]; SB, Soko Banja (LL4 – 4,420±20 Myr; $I = 0.69954 \pm 0.00024$)[25]; St Se, Saint Severin (LL6 – 4,510±150 Myr; $I = 0.69903 \pm 0.00020$)[27]; Je, Jelica (LL6 – 4,423±41 Myr; $I = 0.69959 \pm 0.00029$)[25]; In, Indarch (E4 – 4,393±43 Myr; $I = 0.7005 \pm 0.0009$)[26]; St Ma, Saints Marks (E5 – 4,335±50 Myr; $I = 0.69979 \pm 0.0022$)[26]; St Sa, Saint Sauveur (E5 – 4,457+47 Myr; $I = 0.6993 \pm 0.0014$)[26]. Within error limits, these isochrons can be interpreted as closed system internal isotopic re-equilibration of the meteorites.

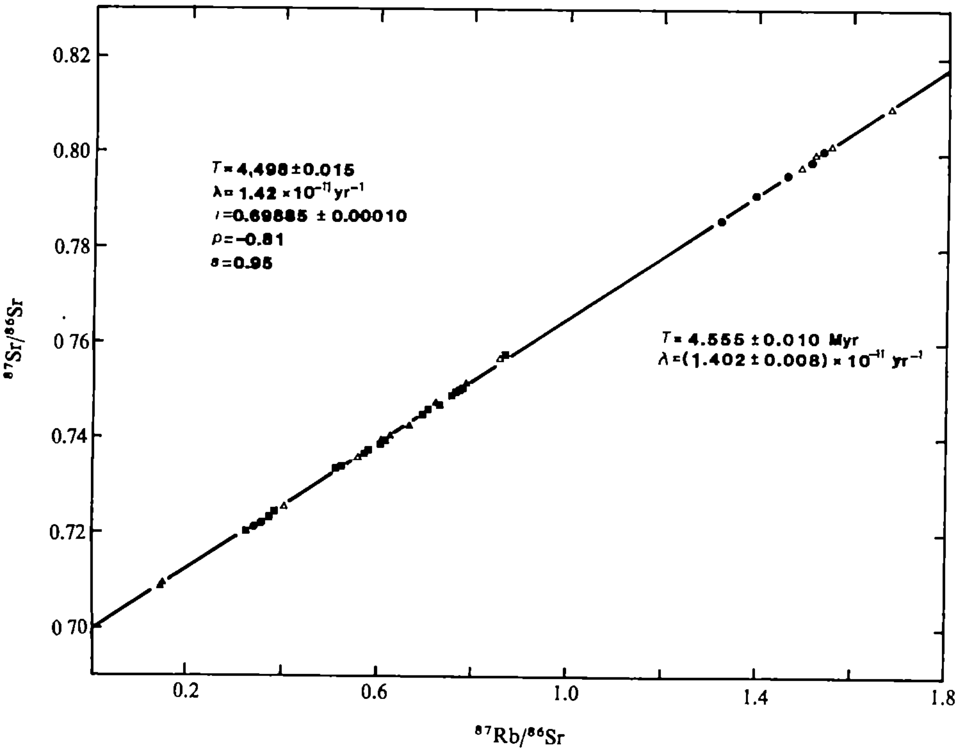

Fig. 4 Plots of $^{87}Rb/^{86}Sr$ against $^{87}Sr/^{86}Sr$ diagram for whole rock chondrites. Only these objects from the H(■), LL(△) and E(●) chondrites used in the previous isochron calculations are plotted and used in the least-squares regression. If the age is assumed to be of 4,555±10 Myr, then $^{87}Rb = 1.402 \pm 0.008 \times 10^{-11}\ yr^{-1}$.

Comparative chronology of chondrites

(1) Do chondrites still define whole-rock isochrons when the precision of the measurements is increased?

The answer to this question is positive: with a few exceptions, H, LL, and E-type chondrites define very precise isochrons. On the other hand, L chondrites scatter in the $^{87}Rb/^{86}Sr$ against $^{87}Sr/^{86}Sr$ diagram[25]. Our preferred interpretation is that Rb has been lost by volatilization from these meteorites during the severe shocks which affected most of them: those which are unshocked tend to plot close to a reference isochron of age 4,500 Myr, whereas most of the shocked and degassed L chondrites plot on the left of this line, possibly indicating a lowered Rb/Sr ratio compared with their initial one.

A similar interpretation could explain most of the exceptions for the other groups of chondrites: for all of these objects, it is possible to find evidence of shock, brecciation or terrestrial contamination or alteration[25–27]. Such secondary disturbances could also explain the high initial ratios found for some low radiogenic chondrites by Wetherill *et al.*[20], as well as the high initial ratio for the chondrite isochron of Wetherill[15]. In what follows these 'disturbed' objects will be rejected. Note here that for H, LL and E chondrites, these amount to a small fraction of the analysed meteorites, and that they generally plot by more than 3σ off the line defining the others.

(2) Are there differences between the different groups?

The ages for the other groups were respectively:

H chondrites $T = 4{,}518 \pm 39$ Myr:

$$^{87}Sr/^{86}Sr_I = 0.69876 \pm 0.00040$$

LL chondrites $T = 4{,}486 \pm 20$ Myr:

$$^{87}Sr/^{86}Sr_I = 0.69887 \pm 0.00012$$

E chondrites $T = 4{,}508 \pm 37$ Myr:

$$^{87}Sr/^{86}Sr_I = 0.69880 \pm 0.00044$$

As noted by Sanz and Wasserburg[28], the errors on the age and initial ratio are anticorrelated. Our method[26] of calculating these correlation coefficients, gives −0.96, −0.73 and −0.80. We have also shown that, in a diagram where one plots the initial ratio against the age, an ellipse is always a reasonable representation of the error limits. The error ellipses for the above isochrons are represented in Fig. 3. They are clearly undistinguishable from each other; in other words, the ^{87}Rb–^{87}Sr age of all chondrites is identical within error limits.

(3) What are the internal isochrons of chondrites with respect to those for whole rocks?

It might be argued that to be sure that the different analysed objects be cogenetic, the best method is to analyse separate mineral phases of a given meteorite. Quite a few ^{87}Rb–^{87}Sr internal studies of chondrites have now been achieved. These are Allende (CV)[19–23] (and this work), Tieschitz (H3)[25], Lost City (H5)[29], Richardton (H5)[30], Guareña (H6)[24], Mező Madaras (L3)[25], Bjürbole (L4)[31], Orvinio (L6)[13], Farmington (L6)[13], Bruderheim (L6)[32], Chainpur (LL3)[25], Soko Banja (LL4)[25], Olivenza (LL5)[28], Guidder (LL5)[25], Krähenberg (LL5)[33], Peace River (LL6)[32,19], Saint Séverin (LL6)[27], Saint Mesmin (LL5)[25], Ensisheim (LL6)[25], Jelica (LL6)[25], Abee (E4)[32,26], Indarch (E4)[13,26], Saint Sauveur (E5)[26], Saint Mark's (E5)[26].

For some, the data obviously present analytical difficulties. Some do not have the necessary precision, number of analyses or range of the values in the ^{87}Rb–^{86}Sr, ^{87}Sr–^{86}Sr diagram, to be useful for comparative chronology. In addition, most of the remaining results do not define an isochron. In most cases, this can result of shock resetting or terrestrial alteration. We have presented in Fig. 3 the few which we consider reliable and useful. The obvious result is that only the H3 chondrite Tieschitz has the same internal age as that for whole rocks. All others have a younger age and a higher $^{87}Sr/^{86}Sr$ initial ratio. Note that within error limits, all these internal isochrons are consistent with a closed system reequilibration of the meteorites. Because Tieschitz is an unequilibrated object, whereas most others are equilibrated, this is interpreted as being due to the cooling or metamorphism history of the latter[25–27]. As for E-chondrite, this could reveal shock effects[26]. From the $^{87}Sr/^{86}Sr$ initial ratio of these internal isochrons, it is possible to estimate the interval of time elapsed between the chondrite formation and internal isotopic homogenization[17]. For the type 6 objects of Fig. 3, this interval is of the order of 100 Myr. It is shorter, of the order of 40 Myr, for the type 4 object Soko Banja.

The internal isochron for Tieschitz is a 'chondrule isochron'. This means that it has not been obtained by analysing pure mineral phases, but whole chondrules[25]. This result shows that, at the precision limits of the method, chondrules were formed simultaneously with whole rock chondrites.

The whole rock best isochron for chondrites

Comparison of the ages of the various chondrite classes shows that they are undistinguishable within error limits. It is thus justified to use all data together and determine a $^{87}Rb-^{87}Sr$ 'best' age for chondrites. The results are shown in Figs 4 and 5: the best age for chondrites is 4,498±15 Myr for $\lambda\ ^{87}Rb = 1.42\times10^{-11}\ yr^{-1}$.

Let us consider the consequences of this result.

The precision for this age is the 'best' ever obtained for a $^{87}Rb-^{87}Sr$ isochron; it is comparable to that for extinct radioactivities such as $^{129}I-^{129}Xe$ (see ref. 34), but relates to an absolute age. Since the scatter of the data points around the isochron is small (the reduced X^2 is 0.95), this error limit is probably significant. On Fig. 5, we have represented the $^{87}Rb-^{87}Sr$ model age of the various chondrites relative to the $^{87}Sr/^{86}Sr$ initial ratio of the isochron from Fig. 4. Most results indeed agree with the best fit line within error limits: 95% of the data points plot within an interval of ±50 Myr. More than 80% plot within an interval of ±30 Myr. This result confirms the idea of a 'sharp isochronism' of formation of chondrites, on a time scale of a few million years as deduced from I–Xe chronology[34].

The question is then to relate this age to the processes of formation of the Solar System. The isochron is based on variations of the Rb/Sr ratio among chondrites. As the Sr concentration for the objects of a given group is constant[35] (Fig. 6), the variations are due to variations of the Rb concentration. It is generally believed that the latter is either the result of fractionation of moderately volatile elements during condensation–accretion, or of volatilization and loss during the reheating and metamorphic events which affected most chondrites (see ref. 36). $^{87}Rb-^{87}Sr$ dating does not help to decipher which process is being dated. However, in order not to perturb the whole rock isochron, the latter process should have occurred during the first few million years of the chondrites. In particular it is unlikely that Rb was lost some 100 Myr after the formation of these meteorites, at the time dated by internal $^{87}Rb-^{87}Sr$ isochrons of equilibrated chondrites. Rb is also fractionated among various clasts of a given chondrite and it is not generally known when such clasts assembled. If it could be demonstrated that their assembly occurred before metamorphism, this would be a strong evidence in favour of Rb fractionation during condensation–accretion.

It is known that Rb is highly fractionated in the Earth compared with ordinary chondrites: from the Sr–Nd isotopic correlation in terrestrial basalts, it is estimated that the 'bulk Earth' $^{87}Rb/^{86}Sr$ ratio is 0.098 (refs 37, 38). Not that only Ensisheim presents such a low value. It is not certain whether the fractionation processes which affected moderately volatile elements were the same inside the chondrite parent bodies as they were in a whole terrestrial planet. Yet the present results indicate that fractionation could attain the same efficiency on very small to very large distance scales. Identification of these processes could result in very strong constraints for the chronology of formation of the Earth.

The best age for chondrites is different from the most recent $^{206}Pb-^{207}Pb$ ages for meteorites. The latter can be very precise because they rely on isotopic ratios only. However, their actual values are very sensitive to small disturbances[39]. If one selects the data for which the U–Pb or U–Th–Pb ages are concordant, which means that the ages deduced from the independent chronometers $^{235}U-^{207}Pb$, $^{238}U-^{206}Pb$ and $^{232}Th-^{208}Pb$ are equal, the corresponding $^{206}Pb-^{207}Pb$ ages fall around 4,555±10 Myr, whether for whole rocks chondrites[39], for chondritic minerals[27], or for achondrites[41]. We do not intend to discuss the problems of U–Pb dating of chondrites fully here but it is possible that the actual U–Pb age of some chondrites is as old as 4,580 Myr (ref. 39). In any case, even the 4,555 Myr value is 1% older than our $^{87}Rb-^{87}Sr$ age. It seems unrealistic that such a difference is real, and that Pb–Sr and U–Th–Pb fractionations occurred independently on a time scale of about 50 Myr.

As all our measurements were made using the same method, and the same spike solution[25–27], such a difference could be due to a systematic bias in our technique. The main possible source for such a bias would be the spike calibration. However, our spike has been repetitively calibrated against different normal solutions and the results agreed within 0.2%. In addition, these spike solutions were used to analyse the Rb and Sr concentrations in NBS glass wafers and our results agreed within 0.2% of the certified values. Finally, our values agree very well with those obtained by others[30].

On the whole, we believe that a 1% bias in our measurements is unreasonably large. A possible alternative is that the ^{87}Rb decay constant is still incorrectly estimated. Our results compared with the $^{206}Pb-^{207}Pb$ ages would indicate that $\lambda^{87}Rb = (1.402\pm0.008)\times10^{-11}\ yr^{-1}$. Compared with the value of $1.42\times10^{-11}\ yr^{-1}$, this would change $^{87}Rb-^{87}Sr$ ages by a factor of 1.013. This should be verified by comparison of other simultaneous Rb–Sr, Sm–Nd and Pb–Pb measurements; however, such studies should attain a better than 1% precision for eventual differences to be significant.

Note that K–Ar ages of chondites are also younger than U–Th–Pb ages: Turner *et al.*[40] found an average $^{39}Ar-^{40}Ar$ plateau age of 4,480±30 Myr for such objects, the older one being of 4,520 Myr. Their interpretation is that the K–Ar system of the bulk meteorites has been reset during metamorphism on a time scale of 100 Myr. If such was the case, one would expect that Rb should also be redistributed simultaneously during this process but, as discussed above, this seems difficult. In addition, no systematics of $^{39}Ar-^{40}Ar$ ages against the degree of metamorphism is found. Alternatively, a bias in the ^{40}K decay constant joined by larger than estimated error limits would render the problem simpler to understand. Again, these questions warrant more data (see the discussion in ref. 25).

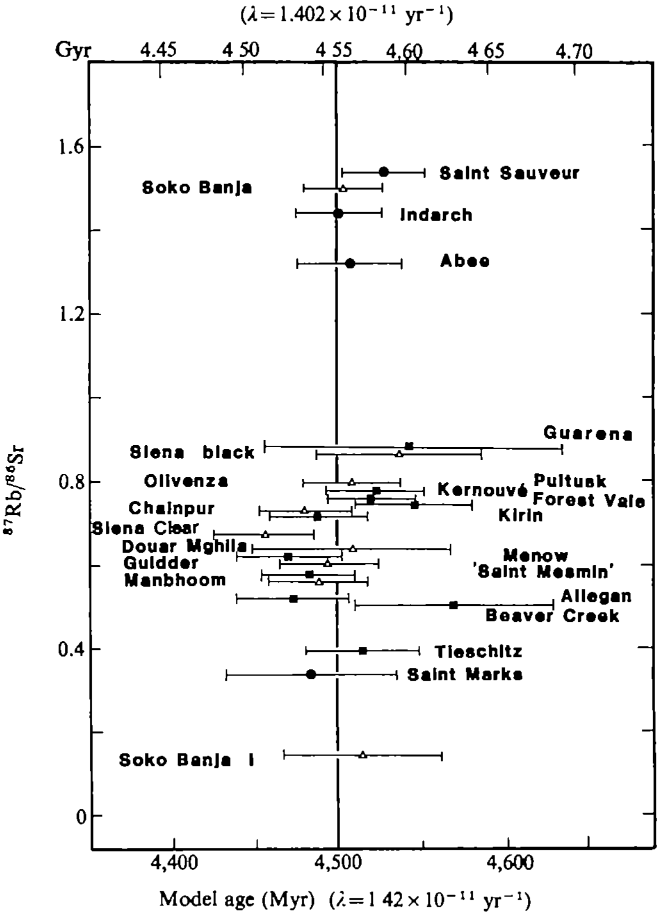

Fig. 5 Model $^{87}Rb-^{87}Sr$ ages of chondrites. The $^{87}Sr/^{86}Sr$ initial ratio is assumed to be that of our best fit isochron (Fig. 4). The different analyses for a given object have been averaged. All ordinary and enstatite chondrites have undistinguishable ages.

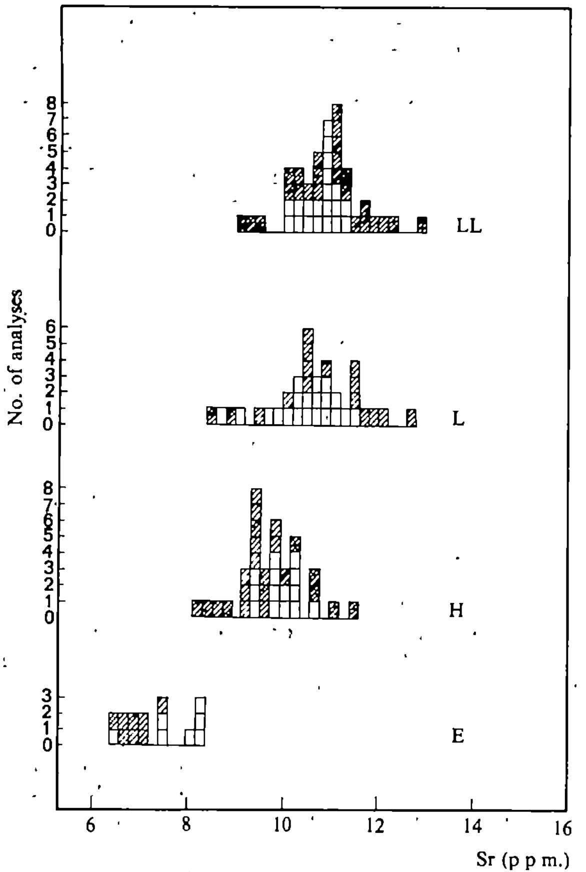

Fig. 6 Sr concentration in ordinary and enstatite chondrites. Our data[25,26] (▨) and these of Gopalan and Wetherill[35] (☐) are included. Only objects which plot close to the Rb–Sr isochron have been considered. Much of the scatter is probably due to the non-representativity of the samples. The Sr concentration within each group is constant.

The $^{87}Sr/^{86}Sr$ initial ratio for chondrites is 0.69885 ± 0.00010. Figures 2 and 3 also show $^{87}Sr/^{86}Sr_{BABI}$ and $^{87}Sr/^{86}Sr_{ALL}$, where $^{87}Sr/^{86}Sr_{BABI}$ is the initial ratio for basaltic achondrites[17], and $^{87}Sr/^{86}Sr_{ALL}$ is that for Allende white inclusions[19]. The value for basaltic achondrites has been confirmed in our laboratory[18]. We also show in Fig. 2 a few data on Allende white inclusions. We assume that no interlaboratory bias has been introduced in the strontium initial ratios for meteorites, and that for the 'chondrite isochron' is significantly lower than BABI and undistinguishable from ALL. Thus, the expected result that the differentiated achondrites have a strontium initial ratio higher than that of chondrites is confirmed.

Yet, from Figs 2 and 3, it might appear that ALL is slightly lower than the chondrite initial ratio. The actual value for chondrites is very close to that observed in the differentiated meteorite Angra Dos Reis (Ador, see for example ref. 41). Such a difference could be due to a time delay in the chondritic fractionation of Rb relative to the formation of the Allende refractory inclusions. Assuming that both formed directly from the solar nebula, the Rb/Sr ratio of which is 0.6 to 0.5 (ref. 42), the time delay would be 3.0 ± 5.6 Myr to 3.9 ± 7.3 Myr. If the Rb fractionation which is being dated by the chondrite isochrons occurred during chondrite metamorphism, these objects would have evolved in a reservoir of chondritic composition (Rb/Sr = 0.3 to 0.2) and the time delay would be 7.0 ± 13.2 to 9.4 ± 17.6 Myr. Thus, chondrites and Allende refractory inclusions are 'synchronous' on a time scale of 10 Myr. This time scale is comparable with that deduced from I–Xe chronology[34]. Unfortunately, it is not precise enough for constraining the models of formation of planetesimals (see ref. 43), since all these models deal with time scales shorter than 10 Myr.

Another indirect result of the existence of an isochron is that there was no large anomaly for the ^{87}Sr and ^{86}Sr isotopic abundances at the time of formation of chondrites in the areas of the solar nebula where these meteorites formed. Evidence has been found for isotopic abundance anomalies of ^{84}Sr in some rare refractory inclusions of the Allende carbonaceous chondrite[44]. It is not clear whether there were some anomalies for ^{87}Sr and ^{86}Sr in this material. For whole rock chondrites, the present evidence is that isotopic anomalies for these isotopes were small enough for the ^{87}Rb–^{87}Sr dating technique to be fully useable.

Conclusions

The major conclusion of our study is that all chondrites formed simultaneously from a solar nebula where the $^{87}Sr/^{86}Sr$ ratio was homogeneous; the $^{87}Sr/^{86}Sr$ initial ratio for chondrites is undistinguishable from that for carbonaceous chondrites.

This ratio is significantly lower than BABI, the initial ratio for basaltic achondrites[17,18]. This can be interpreted as a later differentiation of the parent body of these latter objects. However, the matter is complicated by the fact that there exists at least one differentiated object with an initial ratio lower than BABI and undistinguishable from that for chondrites (ADOR, ref. 41). In addition, ^{87}Rb–^{87}Sr dating does not give any information about the predifferentiation history of these bodies (see ref. 18). The same applies for the Earth and the Moon. Yet, our results indicate that use of the ALL value of 0.69877 ± 0.00005 (ref. 19) as a starting value for the history of all these planets is not unplausible.

Using the ^{87}Rb decay constant of $\lambda = 1.42 \times 10^{-11}$ yr^{-1}, the ^{87}Rb–^{87}Sr age for chondrites is 4,498 ± 15 Myr. For the Rb–Sr and U–Th–Pb chronometers to agree with each other at 4,555 Myr, this decay constant would be $1.402 \pm 0.008 \times 10^{-11}$ yr^{-1}. This result calls for further simultaneous precise Rb–Sr, Sm–Nd and U–Th–Pb analyses of selected samples. It should certainly be considered in the comparison of precise ages obtained by different chronometers.

^{87}Rb–^{87}Sr dating of chondrites relates to Rb fractionation in the early Solar System. This occurred either during condensation–accretion or at an early stage of metamorphism of chondrites. The ^{87}Rb–^{87}Sr internal system has been perturbed in most chondrites, probably due to shock and thermal metamorphism: type 3 unequilibrated chondrites are an exception and can be considered unique.

We thank G. Manhes and all our colleagues for discussions, the technicians of the laboratory for maintenance of machines, P. Pellas and numerous curators for providing the samples, and D. Unruh and G. Wetherill for helpful criticisms.

Human chorionic gonadotropin β-subunit is encoded by at least eight genes arranged in tandem and inverted pairs

William R. Boorstein*, Nikos C. Vamvakopoulos* & John C. Fiddes

Cold Spring Harbor Laboratory, PO Box 100, Cold Spring Harbor, New York 11724, USA

The β-subunit of the human placental glycoprotein hormone, chorionic gonadotropin (HCG), is coded for by at least eight different genes or pseudogenes, four of which are arranged in inverted pairs while the other four are arranged in tandem pairs. The genes are each 1.45 kilobases (kb) long and have two short introns located in identical positions.

THE placental hormone, human chorionic gonadotropin (HCG), together with the three pituitary hormones, luteinizing hormone (LH), follicle-stimulating hormone (FSH) and thyroid-stimulating hormone (TSH), comprise the glycoprotein hormone family. All four hormones are dimeric with two different subunits, α and β, which are associated noncovalently (for review see ref. 1).

Amino acid sequence analysis has shown that the α-subunit seems to be common to the four hormones, while the β-subunits are unique and confer biological specificity on the individual hormones. Varying degrees of amino acid sequence homology exist between the four β-subunits, which led to the proposal that they evolved from a common ancestral gene[1].

We have previously isolated and characterized cDNA clones encoding the α-(ref. 2) and β-(ref. 3) subunits of the placental hormone, HCG. The α-subunit cDNA was then used as a hybridization probe to purify the corresponding genomic fragment[4]. Comparison of the structure of the cloned α-subunit gene with the hybridizing restriction enzyme fragments in human DNA led to the conclusion that there is only a single α-subunit gene which is transcribed to make the α-subunit mRNA for all four hormones[4]. A similar conclusion was also reached by Boothby *et al.*[5], who used an α-subunit cDNA to probe uncloned human DNA.

Here we show that the gene structure for the β-subunit of HCG is much more complex than that of the single α-subunit gene. At least eight distinct β-HCG or β-HCG-like genes have been identified by a combination of filter hybridization of genomic DNA and isolation of bacteriophage λ genomic recombinants. These genes, which are structurally very similar, form a family of sequences which are probably all linked.

Isolation of β-HCG genomic recombinants

The β-HCG cDNA was used to isolate genomic recombinants from two independent human chromosomal libraries, one in bacteriophage λ Charon 4A (ref. 6) and one in bacteriophage λ Charon 28 (E. Fritsch and C. Sabourin, unpublished results). We purified 16 hybridizing phage, 9 from the Charon 4A library and 7 from the Charon 28 library. Restriction enzyme maps for these phage DNAs were determined by analysing a combination of single and double restriction enzyme digests using the filter hybridization method of Southern[7]. We thus identified three different groups of overlapping recombinants (the restriction enzyme maps for these three groups, *a*, *b* and *c*, are shown in Fig. 1).

β-HCG genes are arranged in both inverted and tandem pairs

Eight separate β-HCG, or β-HCG-like, genes or pseudogenes have been identified by hybridization in the three groups, *a*, *b*, and *c*; the location and polarity of these genes, termed β-HCG 1–8, are shown in Fig. 1.

Four of the genes, β-HCG 1 and 2 and β-HCG 5 and 6, are found in inverted pairs. A detailed map of the region containing the gene pair β-HCG 5 and 6 is shown in Fig. 2; DNA sequencing of the subcloned fragments identified in this figure confirmed the inverted orientation of the genes. Similarities between the restriction enzyme patterns of these β-HCG 5 and 6 subclones with similar subclones containing β-HCG 1 and 2 showed that these two genes also form an inverted pair.

In contrast to these four genes, β-HCG 3 and 4 and β-HCG 7 and 8 form tandem gene pairs. We have shown this again by comparing restriction enzyme digestion patterns of subcloned fragments and, in the case of β-HCG 3, by DNA sequencing.

β-HCG genes contain two introns in identical positions

DNA sequencing of four of the eight β-HCG genes (β-HCG 2, 3, 5 and 6; K. Talmadge, N.C.V., W.R.B. and J.C.F., unpublished results) reveals that they all have two introns that separate codon -16 of the signal peptide from codon -15, and codon 41 of the mature protein from codon 42. The two introns,

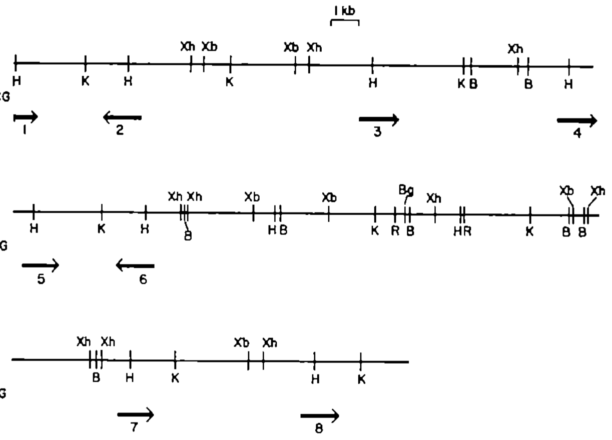

Fig. 1 Restriction enzyme maps of the three goups of β-HCG genomic isolates (*a*, *b* and *c*). H = *Hin*dIII, K = *Kpn*I, Xh = *Xho*I, Xb = *Xba*I, B = *Bam*HI, Bg = *Bgl*II and R = *Eco*RI. The map for group *a* (21.5 kb long) was constructed from 10 overlapping phage isolates, that for group *b* (22.0 kb) from 5 isolates and that for *c* (14.7 kb) from a single isolate. The positions of the eight β-HCG genes (1–8) are indicated by arrows which point in the proposed direction of transcription. Each gene spans ~1.45 kb from the cap site to the poly(A)site. These phage isolates were obtained either from a genomic library made from human fetal liver DNA, partially digested with *Hae*III and *Alu*I, and cloned with *Eco*RI linkers into bacteriophage λ Charon 4A (a gift from T. Maniatis[6]) or from a second library, made from DNA isolated from the chemically transformed human fibroblast cell line, HAI, and cloned as an *Mbo*I partial digest in the vector bacteriophage λ Charon 28 (a gift from E. Fritsch). These libraries, and the individual bacteriophage isolates, were propagated in *E. coli* K803 in P1 conditions in accordance wth the NIH Guidelines for Recombinant DNA Research. The 579-base pair (bp) *Hin*dIII fragment containing the cloned β-HCG cDNA isolated previously[3] was ^{32}P-labelled either by nick-translation[12] or by priming with calf thymus DNA oligonucleotides[13]. Recombinant phage plaques were screened on Schleicher and Schuell 0.45-μm nitrocellulose filters by the method of Benton and Davis[14] as described elsewhere[4]. Restriction endonucleases were from New England Biolabs. Digests of DNA isolated from recombinant bacteriophage were analysed by electrophoresis on 1.0% agarose gels, followed by transfer to nitrocellulose filters and hybridization by the method of Southern[7] as described elsewhere[4]. The sizes of fragments less than 2 kb long were estimated on 3% acrylamide gels.

named A and B, are ~350 and 230 nucleotides long, respectively. Figure 3 shows a composite structure for these genes. As the other genes, β-HCG 1, 4, 7 and 8, have restriction enzyme patterns very similar to the partially sequenced β-HCG genes, we expect them also to have two introns at the same positions.

The *Hin*dIII site in intron A (Fig. 3) is the *Hin*dIII site at the end of the 2.6- and 1.6-kb *Hin*dIII-*Kpn*I fragments identified in Fig. 2. These fragments, which contain β-HCG 5 and 6 respectively, were subcloned into plasmid vectors. The 5′ exon and the promoter region for β-HCG 5 and 6 are contained on a 0.8-kb *Hin*dIII to *Eco*RI fragment and a 1.4-kb *Hin*dIII to *Bam*HI fragment, respectively (Fig. 2). These fragments were also isolated from a phage λ recombinant and subcloned into plasmids. The DNA sequencing used to generate the composite map in Fig. 3 was obtained from these subclones.

The 0.8-kb *Hin*dIII to *Eco*RI fragment of Fig. 2 was also used as a hybridization probe in filter hybridization analysis of all the phage λ clones. This fragment, which contains the 5′ end of β-HCG 5, hybridizes strongly to the region upstream from the *Hin*dIII site observed in all the β-HCG genes. This information, together with the detailed restriction enzyme analysis of the region upstream from these *Hin*dIII sites, further supports our conclusion that all eight β-HCG genes have the same general structure with two intervening sequences in identical positions. Small differences between the genes, and the possibility that there may be pseudogenes, cannot be excluded until the DNA sequence analysis is completed.

Correlation of cloned fragments with those in total genomic DNA

To determine whether the cloned β-HCG genes correlate with the hybridizing fragments seen in total genomic DNA and to estimate the number of β-HCG hybridizing genes or pseudogenes, we digested human placental DNA with several restriction endonucleases, followed by filter hybridization analysis[7]. Two separate probes were used: the β-HCG cDNA specific for the region to the 3′ side of the *Hin*dIII site located in intron A (Fig. 3), and the 0.8-kb *Hin*dIII to *Eco*RI fragment specific for the region to the 5′ side of this site (Fig. 2). An autoradiograph of a filter hybridization of genomic DNA with the 3′ probe is shown in Fig. 4 while one with the 5′ probe is shown in Fig. 5. Both of these probes identify a fairly complex pattern of hybridizing fragments. This is consistent with the conclusion, drawn from the analysis of the phage λ recombinants, that there are multiple regions hybridizing to the β-HCG cDNA. The intensity differences among the hybridizing bands make it difficult to estimate accurately the number of β-HCG sequences.

Examination of the restriction enzyme maps of Fig. 1 suggests that in a *Kpn*I digest of genomic DNA, each gene should be contained in a unique fragment that is recognized by both the 5′ and the 3′ probes. Similarly, in a combined *Hin*dIII-*Kpn*I digest, the genes should be separated into two parts that are recognized exclusively by either probe. The hybridization patterns observed in the filter hybridizations of human genomic DNA are consistent with these expectations. With *Kpn*I alone, both probes (Figs 4, 5) identify the same set of bands, but, as a result of intensity differences, it is hard to estimate the number of genes represented by these bands. With the combined *Hin*dIII–*Kpn*I digests, both probes (Figs 4, 5) give different, but rather simpler, patterns. For example, in the case of the 3′ probe with a *Hin*dIII–*Kpn*I digest (Fig. 4), four bands of 3.5, 2.6, 2.2 and 1.6 kb are identified. Examination of restriction enzyme maps of the cloned genes (Fig. 1) reveals that β-HCG genes 1 and 5 are both on 2.6-kb *Hin*dIII–*Kpn*I fragments, β-HCG 2, 6, 7 and 8 are on 1.6-kb fragments, β-HCG 3 is on

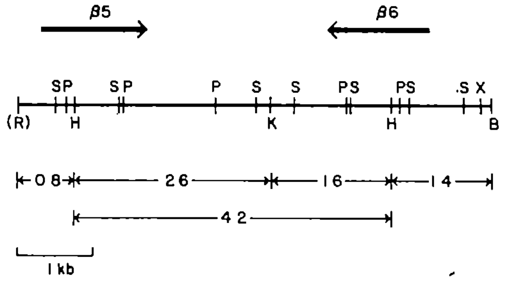

Fig. 2 Detailed restriction enzyme map for the region of group *b* containing the symmetrical pair of genes β5 and β6. The polarity of these genes is indicated by arrows. Restriction enzyme sites are shown for *Eco*RI (R), *Hin*dIII (H), *Kpn*I (K), *Bam*HI (B), *Sac*I (S), *Xho*I (X) and *Pst*I (P). The *Eco*RI site shown in parentheses is the result of linker ligation in the construction of the Charon 4A library. This map was obtained from an analysis of the following subcloned fragments whose positions are indicated: *Eco*RI–*Hin*dIII, 0.8 kb; *Hin*dIII–*Kpn*I, 1.6 and 2.6 kb; *Bam*HI–*Hin*dIII, 1.4 kb; and *Hin*dIII–*Hin*dIII, 4.2 kb. Double cut *Hin*dIII/*Eco*RI and *Hin*dIII/*Bam*HI vectors were prepared from pBR322 while a *Hin*dIII/*Kpn*I vector was prepared from pSM804, a pBR322 derivative containing a unique *Kpn*I site (obtained from E. Stavnezer). Subcloning of the λ DNA fragments was by standard methods using *E. coli* DH1 (D. Hanahan, unpublished results) as the host strain.

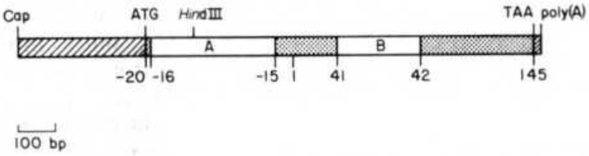

Fig. 3 Composite structure of β-HCG gene. Dotted areas represent coding regions while the cross-hatched areas represent the 5′ and 3′ untranslated regions. The positions of the two introns (A and B) are shown. The locations of the predicted cap site (Cap), the initiation codon (ATG), termination codon (TAA) and the polyadenylation site [poly (A)] are marked. Numbers at the bottom of the diagram refer to amino acids (negative numbers refer to the signal peptide). The location of the single *Hin*dIII site referred to in the text is shown. DNA fragments were labelled at their 3′ termini by DNA polymerase I (Klenow fragment; New England Biolabs) with [α-^{32}P]-labelled dNTPs (Amersham). The sequencing method of Maxam and Gilbert[5] was used.

a 3.5-kb fragment, while β-HCG 4 is on a fragment of unknown size as it is at the end of a phage λ clone. There is no evidence in the cloned isolates of the hybridizing 2.2-kb fragment seen in the filter hybridizations of genomic DNA.

Similarly, with the 5′ probe (Fig. 5) there are *Hin*dIII–*Kpn*I bands at 5.0, 4.0 and 3.7 kb. Again this correlates well with the map of the cloned genes. The 5′ ends of β-HCG genes, 2 and 4 are on 3.7-kb fragments, those of β-HCG 3, 6 and 8 are on 5.0-kb fragments, while those of β-HCG 1, 5 and 7 are on fragments of unknown size. As with the 2.2-kb fragment seen with the 3′ probe, there is no evidence in the cloned isolates of a 4.0-kb fragment hybridizing to the 5′ probe. Both of these missing fragments are seen in the filter hybridization of genomic DNA as weakly hybridizing bands and are thus good candidates for containing β-LH sequences which have not yet been detected in the phage library screening (see below).

The apparent simplicity of the filter hybridization of genomic DNA with the combined *Hin*dIII–*Kpn*I digests when compared with *Kpn*I alone is a reflection of the duplication of sequences observed in the β-HCG locus. For example, the 1.6-kb *Hin*dIII–*Kpn*I band which hybridizes strongly to the 3′ probe (Fig. 4) is known from the analysis of the bacteriophage recombinants, to contain at least four genes—β-HCG, 2, 6, 7 and 8.

The symmetrical organization of the β-HCG genes presents additional problems in correlating the cloned fragments with the bands observed in the genomic filter hybridizations. For example, after hybridization of the 3′ probe to a *Hin*dIII digest (Fig. 4), the expected 4.2-kb band is observed but at a much lower intensity than expected, as we have identified two distinct 4.2-kb fragments each of which contain two genes. In other filter hybridizations of genomic DNA (data not shown), we observed variability in the intensity of this band and attribute this to the ability of the 4.2-kb inverted fragments to form snap-back structures on renaturation during the transfer procedure. This would reduce the availability of sequences for hybridizing to the β-HCG cDNA probe and would therefore reduce the observed level of hybridization.

Because the DNA being used for the filter hybridization analysis and for the construction of the two genomic libraries came from different individuals, it is possible that the correlation of the filter hybridization data with the cloned fragments is confused by polymorphism. We have, however, found no evidence for this as the *Kpn*I and *Hin*dIII–*Kpn*I fragments that hybridize β-HCG from 10 different sources, including the DNA used to make the Charon 28 library (data not shown), are identical.

While all these factors make it difficult to determine the precise number of β-HCG-related sequences in the human genome, we believe that a reasonable estimate, based mainly on the bacteriophage λ clones we have isolated and on the *Kpn*I and *Hin*dIII digests of human DNA, is nine, of which eight have been isolated and characterized.

Are all the β-HCG genes physically linked?

Although it is not known to which chromosome the β-subunit of HCG maps, we have some evidence for the linkage of all the β-HCG hybridizing fragments. A single hybridizing band is observed in filter hybridizations of human DNA digested with either *Eco*RI or *Sal*I (our unpublished results). In the case of *Eco*RI, this fragment is between 50 and 60 kb long. Although we are unable to exclude the possibility that a band of this size contains several hybridizing fragments, which were not resolved by electrophoresis, it suggests that the β-HCG genes may all be linked. Consistent with a single hybridizing fragment is the fact that in the phage λ recombinants there are no *Sal*I sites and the only *Eco*RI sites are those two observed upstream from the 5′ end of β-HCG 6 (Fig. 1). The first of these sites may represent one end of a large *Eco*RI fragment which defines the β-HCG locus.

Despite evidence suggesting that the genes are all linked, extensive screening of two distinct genomic libraries with a β-HCG cDNA hybridization probe resulted in the isolation of 16 phage recombinants, yet failed to produce an overlapping series of sequences linking all the β-HCG genes. In fact, the isolates in the two groups *a* and *b* (Fig. 1) are remarkably similar, with clustered end points. It is possible that as there are repeats and symmetries in this locus, certain regions are unstable when cloned in *Escherichia coli*. This explanation is supported by the fact that the coding sequences tend to be found close to the ends of the phage isolates. A random distribution of DNA around the hybridizing regions would normally be expected as there are 16 independently isolated phage recombinants from two separate libraries generated by different restriction enzymes. This positioning of coding sequences at the ends of the recombinants also makes it difficult to isolate a suitable fragment for use as a probe to 'walk' along the chromosome.

One potential region of overlap between the sequences shown in Fig. 1 should be considered; it is possible that β-HCG 4 and 5 are identical and provide an overlap of ~1.5 kb between groups *a* and *b*. Some evidence in support of this overlap comes from the filter hybridizations of genomic DNA. With *Bam*HI, both probes (Figs 4, 5) identify two bands, one of ~7 kb and the other >30 kb. Linkage of the two families as proposed above would generate a 7.2-kb *Bam*HI fragment containing β-HCG 4/5 and 6. The other genes would be contained on

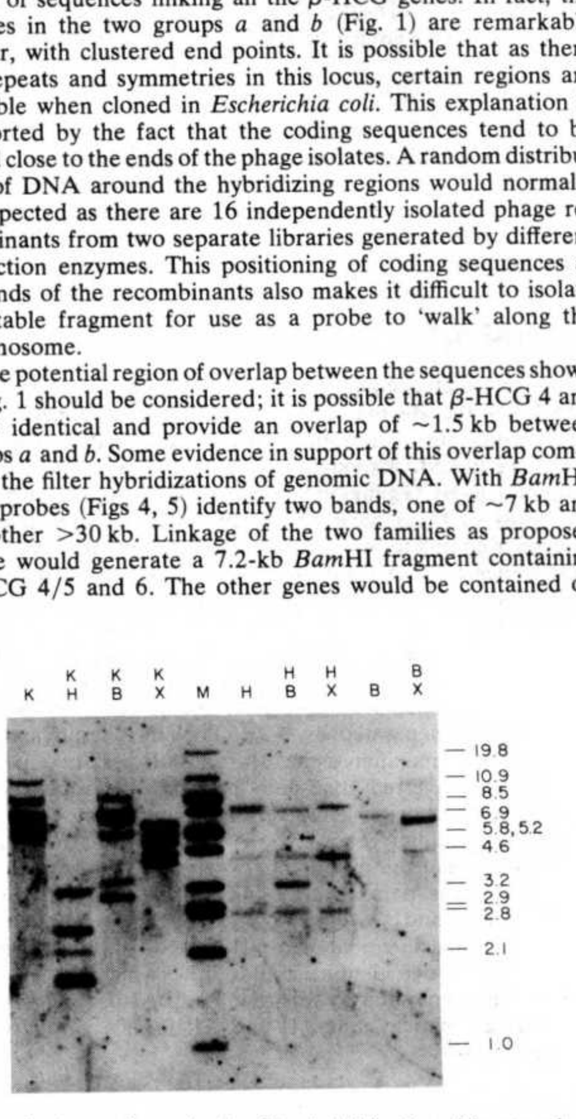

Fig. 4 Autoradiograph of a filter hybridization of human placental DNA; 10 μg of DNA were digested with various restriction enzymes, electrophoresed through a 1.0% agarose gel and transferred to nitrocellulose sheets (Schleicher and Schuell) by the method of Southern[7] as described previously[4]. The ^{32}P-labelled hybridization probe was the cloned β-HCG cDNA fragment (specific activity $1\text{–}2\times10^8$ c.p.m. μg^{-1}; ref. 3) which is specific for the region of the gene(s) to the 3′ side of the *Hin*dIII site (Fig. 3). K = *Kpn*I, H = *Hin*dIII, B = *Bam*HI, X = *Xba*I, M = markers whose sizes are given in kb at the right-hand side.

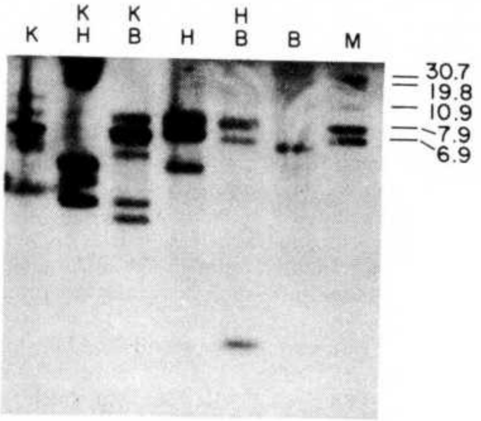

Fig. 5 Autoradiograph of a filter hybridization of human placental DNA digested with various restriction enzymes as in Fig. 4. The ^{32}P-labelled hybridization probe was a subcloned 0.8-kb *Eco*RI–*Hin*dIII fragment (Fig. 2). This probe is specific for the region of the gene(s) to the 5′ side of the *Hin*dIII site (Fig. 3). K = *Kpn*I, H = *Hin*dIII, B = *Bam*HI, M = markers whose sizes are given in kb at the right-hand side.

the large *Bam*HI fragment, which is consistent with the distribution of *Bam*HI sites in the recombinants. However, in view of the fact that the β-HCG genes and surrounding regions are repeated, this is insufficient to establish an overlap, although it is suggestive.

Discussion

We have isolated eight separate genes that hybridize to the cDNA for the β-subunit of human chorionic gonadotropin. These genes have very similar structures and, at least in some cases, are linked. Although it is difficult to estimate the total number of β-HCG genes in the human chromosome, we believe that most of them have now been isolated. Until sequence analysis is complete, we cannot exclude the possibility that the eight genes include some pseudogenes or the related gene, β-LH (see below).

Four of the β-HCG genes (1, 2 and 5, 6) have been shown to exist as inverted pairs. In both cases the genes are arranged in the order 5′–3′, space, 3′–5′ so that, assuming both genes are active, transcription would be convergent. The 3′ ends of the two genes are separated by ~2.25 kb. DNA sequencing and restriction enzyme analysis has shown that these two pairs are very similar. Inverted gene pairs have also been observed in the silk moth chorion genes, although in this case the pairs consist of dissimilar genes (type A and type B), transcription is divergent, and the distance between the 5′ ends of the two members of the pair is only ~300 nucleotides[8]. In chicken, both divergent and convergent pairs of histone genes have been identified[9]. Two dissimilar genes, H2A and H4, are convergent while there are two identical copies of H3 which are divergent, with 5′ ends separated by less than 1 kb. Also, in *Drosophila*, two different cuticle genes, II and III, form a closely linked divergent pair[10].

The other four cloned β-HCG genes are arranged in two tandem pairs; β-HCG 3 and 4 and β-HCG 7 and 8. In both cases these genes are separated by ~5.5 kb. It is also possible to consider β-HCG 2 and 3 as a divergent pair of genes with 5′ ends separated by ~8 kb. Examination of the distribution of restriction enzyme sites in Figs 1–3 reveals extensive regions of repeats: for example, the positions of the *Kpn*I, *Xba*I and *Xho*I sites preceding β-HCG 3 and β-HCG 8 are identical (Fig. 1*a* and *c*). The *Kpn*I site is almost 5 kb upstream from the proposed transcriptional start site.

The significance of the complex organization of the β-HCG genes is not obvious. The inverted and tandem pairs presumably arose from a complicated series of gene duplications and inversions encompassing an area considerably larger than the coding regions themselves. During this process the locations and sizes of the two introns remained the same. As β-HCG is the most recently evolved of the four glycoprotein hormone β-subunits, and is considered to have a common ancestor with β-LH, to which it is most closely related[1], it will be interesting to investigate the organization of the β-LH genes and to compare them with β-HCG. We consider it unlikely that the β-LH genomic organization will show the same complex patterns because the duplications and inversions of the β-HCG sequences presumably arose after the separation of β-HCG from β-LH.

In the hybridization conditions used here, it is possible that the β-HCG hybridization probes could also cross-react with β-LH as there is 82% homology in amino acid sequence between the two β-subunits[1]. Whether this cross-reactivity can be observed depends on the choice of nucleotides in the third positions of the β-LH codons. The homology of β-HCG with β-FSH or β-TSH is too low to expect any cross-hybridizaton to take place[1]. From DNA sequence and restriction enzyme analysis, we have found no evidence of β-LH gene sequences among the cloned fragments. This does not exclude the possibility, however, that β-LH is so closely related to β-HCG that one of the genes (β-HCG 1, 4, 7 and 8) for which we have no DNA sequence, could encode β-LH. It is also possible that a more faintly hybridizing band of total DNA, such as the 2.2-kb *Hin*dIII–*Kpn*I fragment (Fig. 4), which has not yet been cloned, contained β-LH sequences.

The finding that the β-subunit of HCG is coded for by several genes while the α-subunit, which is common to all four glycoprotein hormones, seems to be encoded by a single gene[4,5], is surprising. In the placenta there is an excess of free α-subunit polypeptide over β-subunit polypeptide[11], thus it might be predicted that there would be multiple α- rather than β-genes. It will be interesting to establish whether all the β-subunit genes are functional and, if so, whether there are any significant differences betwen them and between their products.

This work was supported by a grant from the NIH. We thank T. Maniatis and E. Fritsch for the phage libraries, D. Hanahan for the DHI transformation protocol and E. Stavnezer for pSM804; P. Barkley, M. Goodwin and M. Ockler for help with the manuscript and art work; T. Grodzicker, D. Hanahan, S. Hughes, J. Sambrook, J. Sorge and K. Talmadge for valuable advice and discussions; and M. DeLuca for technical help in analysing one of the phage λ isolates.

Note added in proof: We have now established that the gene identified as β-HCG 4 is in fact β-LH (K. Talmadge and J.C.F.). This precludes the possibility that groups *a* and *b* overlap.

Diameters and albedos of satellites of Uranus

R. Hamilton Brown

Dale P. Cruikshank & David Morrison

Institute for Astronomy, University of Hawaii, Honolulu, Hawaii 96822, USA

The five known satellites of Uranus are too small and distant to permit direct measurement of their diameters. Consequently, products of the masses of the satellites, and estimates of their bulk densities and surface albedos have been used in discussions of their probable dimensions in the absence of measurements. The presence of water ice on the surfaces of Ariel, Umbriel, Titania and Oberon has been established spectrophotometrically[1–4] and the brightnesses of the satellites have been measured photoelectrically[5]. Determination of the masses of the uranian satellites depends on observations of perturbations of the satellite orbits and results chiefly in upper limits to the products of the masses of various pairs of satellites[6,7]. The new diameter measurements reported here were made using the photometric/radiometric technique of diameter determination. This widely used technique has enabled the measurement of the diameters and albedos of approximately 250 asteroids and many planetary satellites. A recent recalibration of the technique using independent measurements of the diameters of three Solar System objects results in absolute accuracies of better than 5%. Our new albedo measurements show that Umbriel, Titania and Oberon are similar in albedo to J4 Callisto while Ariel is very similar in albedo to S7 Hyperion; the diameters of all four satellites are similar to those of the large, icy saturnian satellites S5 Rhea and S8 Iapetus.

The observations reported here were made with the 3.0-m Infrared Telescope Facility (IRTF) on Mauna Kea, Hawaii. The data were obtained on three nights in May 1982, as noted in Table 1. During this period, similar observations were made of Pluto and Neptune's satellite Triton without detections of their thermal radiation; results on these objects are given in the accompanying paper[8].

A standard broadband Q filter which transmits from 16 to 26 μm was used for all observations. The star α Boo, for which the Q magnitude was taken to be −3.32, was the primary standard[9]. Extinction on all nights averaged about 0.30 mag per airmass, which is normal for Mauna Kea; the volcanic haze covering part of the Earth's Northern Hemisphere produced no noticeable change in the extinction at 20 μm. Observations of Saturn's satellite S5 Rhea, whose radiated thermal energy distribution is similar to that of the uranian satellites, and whose diameter (1,530 ± 10 km) and photometric properties are well known from Voyager flybys[10,11], provided a consistency check on the calculated diameters of the uranian satellites. To ensure complete cancellation of the scattered thermal radiation from Uranus, the oscillating secondary mirror of the 3-m telescope was adjusted in amplitude and position angle of the oscillation so as to be perpendicular to the line joining a particular satellite and the planet. A 25-min integration on the sky diametrically opposite to the position of Ariel with respect to Uranus, where no satellite was located, resulted in a zero signal, confirming the cancellation of the flux contribution from the scattered thermal radiation of Uranus.

The calculation of diameters and albedos requires that monochromatic IR fluxes be determined from broadband observations. Because the colour temperature of the thermal radiation from airless bodies at the distance of the uranian satellites is quite low (≈80 K) and very different from that of a typical 20-μm stellar standard (≈4,000 K), close attention must be paid to the proper correction of the observed 16–26 μm flux ratios to monochromatic flux ratios at 20 μm. These corrections were made using determinations of the water vapour content of the atmosphere above the observatory derived from near IR spectra obtained on the same or adjacent nights (calibrated against a laboratory cell[12]), as well as measurements of the local atmospheric relative humidity throughout the nights made by the Kitt Peak National Observatory sky survey team. Transmission spectra of Mauna Kea model atmospheres, computed by V. Kunde for various values of precipitable water, were convolved with our filter transmission properties to derive the site-and-instrument-specific correction factors; calculated for each night because of the variability of atmospheric water vapour evidenced in the contemporaneous near-IR spectra. A detailed discussion of the monochromatic correction technique is given by Morrison[13]. The specific correction factors are listed in Table 1.

In addition to the IR observations, we have used new values of the brightnesses of the satellites in the V passband (central wavelength 0.55 μm) obtained 3 or 4 days after the IR measurements and at essentially the same solar phase angle. This angle, 0.03°, is very close to the minimum observable phase angle with the consequence that the visual magnitudes derived are some 0.4 mag smaller than published photometry[5]; in 1981 a strong, near-IR-brightness surge at opposition was discovered[3]. Since the uranian system is now almost pole-on as seen from Earth, the satellites, which are in circular orbits in Uranus' equatorial plane, are not expected to show brightness variations due to orbital motion. A detailed analysis of the opposition brightness surge will be published elsewhere[14].

For calculation of the diameters and albedos of the uranian satellites we use the standard radiometric model[13] and follow exactly the formulation used by Brown *et al.*[15]. The method is based on the determination of both reflected and absorbed

Table 1 Observations

Object	1982 dates	Integration time (min)	Q	Δ (AU)	R (AU)	Φ (deg)	H_2O (mm/airmass)	Y
Ariel	22.50 May	40	4.35 ± 0.20	17.87	18.88	0	≈1.0	0.88
Umbriel	20.33 May	40	4.67 ± 0.15	17.87	18.88	0	2–3	1.10
Titania	20.50 May	30	3.96 ± 0.10	17.87	18.88	0	2–3	1.10
Oberon	19.40 May	50	3.93 ± 0.14	17.87	18.88	0	3–4	1.20
Rhea	17.25 May	25	1.27 ± 0.04	8.88	9.68	4	2–3	1.03
Rhea	22.40 May	25	1.19 ± 0.04	8.93	9.68	4	≈1.0	0.93

Q is the broadband 20-μm magnitude. Δ is the object–Earth distance. Φ is the solar phase angle. H_2O is the precipitable water vapour. Y is the monochromatic correction factor (to be multiplied by the observed flux to yield the monochromatic flux). All errors quoted are ±1 s.d. of the mean.

Table 2 Calculated diameters and albedos

Object	m_{20}	$V(0°)$	$V(1.0)$	q	Diameter (km)	p_v
Ariel	-1.78 ± 0.22	1.03 ± 0.05	1.3 ± 0.2	0.8 ± 0.1	$1,330\pm130$	0.30 ± 0.06
Umbriel	-1.70 ± 0.18	1.89 ± 0.05	2.2 ± 0.2	0.7 ± 0.1	$1,110\pm100$	0.19 ± 0.04
Titania	-2.41 ± 0.14	0.91 ± 0.05	1.2 ± 0.2	0.7 ± 0.1	$1,600\pm120$	0.23 ± 0.04
Oberon	-2.53 ± 0.17	1.10 ± 0.05	1.4 ± 0.2	0.7 ± 0.1	$1,630\pm140$	0.18 ± 0.04
Rhea	-3.54 ± 0.06	—	0.24	1.02	$1,530\pm45$	0.60 ± 0.04
Rhea	-3.53 ± 0.06	—	0.24	1.02	$1,530\pm45$	0.60 ± 0.04

m_{20} is the 20-μm monochromatic magnitude corrected to an Earth–object distance of 1 AU and 0° solar phase angle (assuming a brightening of 0.01 mag deg^{-1}). $V(0°)$ is the visual magnitude at 0° solar phase angle corrected to 1 AU from the Earth and Sun (see Text). $V(1, 0)$ is the $V(0°)$ with the opposition surge removed (see text), q is the assumed phase integral (except the value for Rhea taken from ref. 11). p_v is the visual geometric albedo. All errors are ±1 s.d. of the mean, except those quoted for the assumed phase integrals and the $V(1, 0)$, which represent our estimates of a reasonable range of values.

solar radiation. For an airless, slowly rotating body, we assume that the surface is in approximate thermal equilibrium with the absorbed component of the incident energy. The absorbed power is reradiated and can be determined from a measurement of thermal IR emission, such as the 20-μm observations reported here, while the reflected power can be determined by conventional photometry.

With observations of reflected and reradiated solar energy, it is possible to obtain a solution for albedo and diameter that is only weakly dependent on assumed parameters, such as the detailed photometric or thermophysical properties of the observed objects. In the case of the uranian satellites, possible departures from thermal equilibrium due to rotation will be unimportant, as the satellites are nearly pole-on with respect to the Earth and Sun. As previously mentioned, a consistency check is provided by the observations of Rhea, an object of known diameter and photometric properties, with a surface temperature distribution similar to that of the uranian satellites. (For more complete descriptions of the method see refs 13, 16, 17, and 15 for details of the mathematical formulation and error analysis.)

The phase integrals of the uranian satellites cannot be measured from Earth and a plausible value must be assumed for each satellite to derive its diameter and albedo. Jupiter's satellite Callisto ($p_v = 0.19$) has a measured phase integral of 0.7 (ref. 18), which we consider appropriate for use in the reduction of the Umbriel, Oberon, and Titania data in view of their roughly equivalent albedos. As the albedo of Ariel is higher, a phase integral of 0.8 (a value measured for Jupiter's Ganymede[18]) was adopted. However, for relatively dark objects, the method of reduction to diameters and albedos is only weakly dependent on the choice of a phase integral. For the case of Ariel, a change of ±0.1 in the assumed phase integral of 0.8, results in about a ±3% change in the derived diameter; for Umbriel, Titania, and Oberon, a change of ±0.1 in their assumed phase integral of 0.7 results in a ±2% change in the derived diameters. The estimated uncertainties in the phase integral have been incorporated into the quoted uncertainties for the diameters and albedos of the four satellites.

As previously mentioned, the visual magnitudes $V(0°)$ listed in Table 2 were obtained at a solar phase angle of 0.03° and the therefore contain a substantial opposition surge. The calibration of the radiometric diameter scale by Brown *et al.*[15] uses visual magnitudes of the calibration objects which do not include the average opposition surge of ≈0.3 mag (ref. 19). To ensure that the diameters of the uranian satellites are calculated with photometric parameters more closely analogous to those of the Brown *et al.* calibration objects, visual magnitudes 0.3 mag fainter than the $V(0°)$ in Table 2 were used in the reduction to diameters. Since the resulting albedos of the uranian satellites are relatively low, the derived diameters will depend only weakly on the visual magnitude[13]. In contrast, the derived albedos are very sensitive to the visual magnitude and the large opposition surges of the uranian satellites imply that their albedos are a strong function of the viewing geometry. For the purpose of calculating the albedos seen at an arbitrary solar phase angle, the satellite diameters should henceforth be considered independent of visual magnitude. The visual magnitudes used in the reduction to diameters are listed in Table 2 in the column $V(1, 0)$. The error bars estimated for the diameters include the tabulated uncertainty in $V(1, 0)$.

The diameters and albedos shown in Table 2 are the first measurements of these important quantities for any of the uranian satellites. Previous estimates of the diameters of the satellites of Uranus are based on, and very sensitive to, assumptions regarding the satellites' albedos, and, except those of a recent spectrophotometric study[4], tended to underestimate the satellites' sizes (It is interesting that the newly measured albedos agree with those inferred from a proposed relation between albedo and *VJHK* colour indices among outer Solar System bodies[20]). Ariel, Umbriel, Titania and Oberon all have diameters roughly similar to the large, icy, Saturn satellites, particularly S5 Rhea, but significantly lower albedos (Rhea's albedo is about 0.6) than all known saturnian satellites except Hyperion, Phoebe, and the dark side of Iapetus. Hyperion has an albedo of 0.3, roughly equal to the albedo of Ariel, and reflectance spectra of Ariel and Hyperion in the 1.5–2.5 μm region are strikingly similar[3,21]. The relatively low albedo of Hyperion and its reddish appearance in Voyager images suggests the presence of a dark contaminant on/in its surface; Hyperion's spectral similarity to Ariel may indicate that the surface contaminants are similar in both bodies. This argument can be extended by analogy to Umbriel, Titania, and Oberon[3].

A comparison with bodies in the jovian system shows that the albedos of the uranian satellites are intermediate to the albedos of Ganymede and Callisto, whose surfaces are known to be largely composed of water ice contaminated with darker particles[22]. The relatively low albedos of the uranian satellites suggest that a dark contaminant is present on/in their surfaces, though there may be significant differences in the degree of contamination, the chemistry of the contaminant, the details of intermixing and the microstate of the surfaces when compared with the jovian and saturnian satellites. The question of the nature of the contaminant(s) in the surfaces of the uranian satellites is being addressed by one of us (R.H.B.), and will be published elsewhere.

Table 3 Satellite masses

Object	Mass (10^{-5} Uranus) $\bar{\rho} = 1.0$ g cm^{-3}	$\bar{\rho} = 1.3$	$\bar{\rho} = 2.3$
Ariel	1.42	1.85	3.27
Umbriel	0.83	1.08	1.91
Titania	2.48	3.22	5.70
Oberon	2.62	3.41	6.03

The satellite mass is shown for different values of an assumed mean density. The mass units are 10^{-5} Uranus mass where the mass of Uranus is 8.66×10^{25} kg. A density of 1 g cm^{-3} is approximately that of pure water, a density of 1.3 g cm^{-3} corresponds to ~60% water ice and 40% silicates by weight and 2.3 g cm^{-3} is typical of carbonaceous chondritic material.

Table 3 lists the masses of the uranian satellites assuming several values for the mean density of each satellite and using the radii from this study. From observations of orbital perturbations, Greenberg[6,7] has derived an upper limit to the product of the masses of Ariel and Umbriel of $\leq 10^{-9} M^2$ (M = the mass of Uranus). If we assume that the mean densities ($\bar{\rho}$) of Ariel and Umbriel are approximately equal, and use the radii from this study, we find that the Greenberg upper limit is satisfied for $\bar{\rho} \leq 2.91$ g cm^{-3}. Veillet and Rattier[23] have reported that new observations and analyses of Miranda's motion yield a value for the product of the masses of Ariel and Umbriel of $1.10 \pm 0.25 \times 10^{-10} M^2$ which, with our radii, is consistent only with mean densities of ≤ 1 g cm^{-3} for both satellites. The same study yields $1.5 \times 10^{-4} M$ for the mass of Titania. This value with our radius yields a mean density of 6.0 g cm^{-3}, which we believe is unreasonably high for a satellite of mainly ice composition. Densities of ≈ 1.3 g cm^{-3}, typical of Saturn's icy satellites[24], and the densities derived from Greenberg's Ariel–Umbriel mass constraints are consistent with the observed icy character of the surfaces of the uranian satellites. Determination of the mean densities of the satellites is crucial to the understanding of the origin and subsequent evolution of the uranian system. With reliable measurements of the uranian satellite radii now in hand, observations from which the satellite masses can be derived become paramount.

The infrared Telescope Facility is operated by the University of Hawaii under contract to NASA. We thank NASA for support of this project through grants NSG 7323, NSG 7312, and NGL 12-001-057, Eric Becklin, R. W. Capps, David Greip, John Hamilton and all the staff at the IRTF for assistance and Jay Goguen for making the photometric results available in advance of publication.

Diameters of Triton and Pluto

David Morrison & Dale P. Cruikshank

Institute for Astronomy, University of Hawaii, Honolulu,

Triton, the major satellite of Neptune, and Pluto, the outermost planet, are too small and distant to permit direct measurement of their size, and indirect arguments must be used to estimate diameter and albedo. These two objects invite a comparative study because they have essentially the same brightness (absolute visual magnitude $V(1,0) \simeq -1$) and current distance from the Sun (30 AU). In addition, the presence of methane frost on the surface, and of a possible methane atmosphere, have been detected for both objects from IR spectroscopy[1–4]. On the basis of these similarities, Triton and Pluto were selected as targets for possible detection of thermal IR emission. We report here new upper limits to the thermal IR emission from these objects that permit us to set significant upper limits on their diameters and to demonstrate that both are high albedo objects. These results clearly exclude the possibility that Triton is the largest planetary satellite, and they are consistent with the small size of Pluto deduced from other data.

Our observations were made using a Ge bolometer at the 3.0-m Infrared Telescope Facility (IRTF) on Mauna Kea. This instrument, located at an elevation of 4.2 km, is among the most sensitive in the world for observations in the 20–40 μm spectral region where thermal radiation from these objects should be most easily detected. Observations were made on three nights (19, 20, and 22 May 1982) under photometrically clear skies. Atmospheric water vapour, as monitored from 1 to 3 μm spectrometry, declined over this observing period from about 3 mm precipitable H_2O to <1 mm. We were concerned about the effect on the observations of the worldwide high-altitude volcanic haze, which was dramatically apparent near sunrise and sunset and produced anomalously high visible extinction, but the performance of the IRTF at 20 μm appeared to be unimpaired by this dust cloud.

All observations were made through a standard broad-band Q filter, covering wavelengths from ~16 to 26 μm. Stellar standards, and their adopted Q magnitudes, were α Lyr ($Q = -0.10$) and α Boo ($Q = -3.32$) (refs 5, 6). Measured stellar extinction coefficients were in the range 0.2–0.4 mag per air mass. As an additional standard with a spectral energy distribution more like that of Triton and Pluto, we selected Saturn's satellite S5 Rhea. Other programme objects observed on these nights were the uranian satellites Oberon, Titania, Umbriel, and Ariel; the results for these satellites together with additional details of the observing procedures are reported by Brown *et al.*[7] in an accompanying paper.

Pluto was observed in excellent conditions on 20 May for a total of 4,200 s. Triton, which is at a more southerly declination and is therefore viewed through larger air masses, was observed for a total of 13,800 s, approximately equally distributed over three nights. Neither object was detected.

The observations are summarized in Table 1. The signal and noise levels are given in units of the signal through the Q filter from a star of magnitude $Q = 0$, as determined from the observations of α Boo and α Lyr. Each 'observation' consists of a 300-s integration period, made up of 15 pairs of 10-s integrations, with the programme object centred alternately in each beam. Each 300-s data block generates a value for the signal and for a standard deviation in the mean computed from the 15 individual integrations. These observations are then corrected for extinction and averaged to yield a single value for each night. The uncertainty is calculated both from the standard deviation of the 14–16 individual observations and from the average of the individual observations divided by $\sqrt{N}$, where N is the number of observations (14 or 16). These two estimates of uncertainty agreed well in all cases, demonstrating freedom from nonstatistical sources of error.

The final Q-band values for Triton and Pluto are given in Table 1. For Pluto we obtain $(3 \pm 20) \times 10^{-4}$ where the indicated uncertainty is the mean of the two values calculated. For Triton the final value is $(15 \pm 18) \times 10^{-4}$. In these units, a flux of

Table 1 IR observations 17–22 May 1982

† Signal relative to that of a star with $Q = 0$.

‡ Monochromatic 20-μm magnitude (corresponding to 1σ values for Pluto and Triton).

20×10^{-4} is equivalent to magnitude $Q = +6.8$. For both objects, the 3σ upper limit is $Q = +5.3$.

For a planetary object in approximate thermal equilibrium with the incident sunlight, the diameter and albedo can be calculated from two quantities: the absolute visual magnitude $V(1, 0)$ and the monochromatic 20-μm magnitude m_{20} (refs 8, 9). We present results of these calculations for both the 1σ and 3σ values of Q given above.

The values of $V(1, 0)$ for Pluto and Triton are obtained from previous photometry and will be used here without correction for possible dependence on solar or orbital phase angles. For Pluto, we adopt the value of $B_0 = 15.98$ obtained in 1980 by Tedesco and Tholen[10]. For a colour $B - V = 0.79$ and a mean distance 39.4 AU, this value of B_0 implies $V(1, 0) = -0.7$. This absolute magnitude is fainter than that generally used in the past, reflecting the gradual decline in brightness of Pluto observed in recent years[1]. For Triton, we use the value $V(1, 0) = -1.0$ obtained in 1972 and 1977 by Degewij *et al.*[11].

The Q magnitudes obtained in our observations are converted to monochromatic magnitudes (m_{20}) using the methods described by Morrison and others[8,12]. We have calculated the sensitivity of our photometer as a function of wavelength over the Q filter band for a variety of atmospheric transmission functions, depending on the humidity. The corrections were made separately for each night, using the depth of the 1.4-μm telluric water band and the value of the Q-magnitude extinction coefficient as indicators of the absorption by telluric H_2O in the Q band. The calculated values of m_{20} are given in the final column of Table 1. The 1σ and 3σ values of m_{20} adopted for our calculations are 7.1 and 5.6, corresponding to 20-μm fluxes of 0.014 and 0.054 Jy, respectively.

The diameters and albedos were calculated from these magnitudes using the recent small revisions in the radiometric diameter scale by Brown *et al.*[12]. We adopted for these calculations a phase integral $q = 1.0$, appropriate for objects with moderately high albedo. As a check, we used the same methodology to calculate the diameter of Rhea from observations made at the same time. For Rhea we obtain $R = 765 \pm 25$ km, in good agreement with the Voyager value of $R = 765 \pm 5$ km, for this satellite[13].

For Triton, the 1σ limit yields $R = 1{,}800$ km and albedo 0.43, while the 3σ values are $R = 2{,}100$ km and 0.25. For Pluto, the 1σ limit yields $R = 1{,}500$ km and albedo 0.37, the 3σ values are $R = 1{,}950$ km and 0.22.

The diameter of Triton has long been a subject of speculation but of few firm data. Because its absolute brightness [$V(1, 0)$] is comparable to that of Titan and Callisto, it has frequently been noted that Triton could, in fact, be the largest of the satellites, if its albedo were low (<0.1). In 1954 Kuiper attempted to measure its size directly with the 5-m Hale telescope, estimating $R = 1{,}900$ km (ref. 14), but the uncertainty in this value was both large and poorly defined[15]. In reviews published in 1974 and 1977[16,17] only upper and lower limits to the radius of 6,500 and 1,100 km, respectively, were listed based on plausible albedos.

In 1978 Cruikshank *et al.*[15] presented spectroscopic evidence that the surface of Triton was 'rocky', leading them to estimate that the albedo was confined to the range $0.02 \leq p_V \leq 0.5$, corresponding to radii between 7,400 and 1,500 km. These authors also used the radiometric technique to set a 3σ limit of $m_{20} > 4.3$, constraining the radius to be smaller than ~2,600 km, which is very near to the radius of the largest satellites: Ganymede, Callisto, and Titan. Thus their final estimate for the radius of Triton was $2{,}600 \geq R \geq 1{,}500$ km.

The 3σ upper limit for the radius of Triton set in this study is 2,100 km, 80% of the limiting value obtained by Cruikshank *et al.*[15]. To estimate a lower limit, we reason by analogy with other outer Solar System satellites. With but one exception, the icy satellites of Jupiter and Saturn have albedos ≤ 0.7. (Enceladus, with $p_V \simeq 1.0$, is an exceptional object, apparantly subject to a long history of surface activity)[18]. An additional constraint is suggested by the downturn in Triton's spectral reflectivity in the UV, which resembles that of Europa ($p_V \simeq 0.6$). We adopt here a limiting albedo $p_V < 0.7$, corresponding to $R > 1{,}300$ km.

The range of sizes for Triton quoted above ($2{,}100 > R > 1{,}300$ km) represents limits, not standard errors in the usual statistical sense. Our conclusions about the size and albedo of Triton, presented in the more conventional form of a probable value and standard deviation, would be $R = 1{,}600 \pm 200$ km, $p_V = 0.4 \pm 0.1$. This is the same size range as Io and Europa, and it is clearly smaller then the giant satellites Ganymede, Callisto, and Titan. The albedo is that of an icy surface with no more than moderate contamination, roughly similar to Ganymede in the jovian system or to the major icy satellites of Saturn, but distinctly brighter than the uranian satellites.

The size of Pluto is unknown, although its mass is fairly well constrained by the known parameters of the orbit of Charon, Pluto's satellite. The first indication that Pluto might be a lunar-sized object ($R \sim 2{,}000$ km) was derived from the detection of methane ice on its surface, suggesting that it probably had a moderately high albedo[1]. From its mass of 0.0022 Earth masses [19] and the physical constraint that its density be unity or greater, a radius of $R < 1{,}460$ km is implied. However, recent speckle interferometric results[20,21] give radii in the range 1,500–2,000 km. A radius in the middle or upper end of this range would lead to a density that appears implausibly low, but all the data are consistent with a radius ~1,500 km.

The 3σ upper limit to the size of Pluto derived from our observations is $R < 1{,}950$ km, while a more probable upper limit is ~1,700 km, consistent with the other estimates quoted above. The albedo of Pluto for $R = 1{,}500$ km and $V(1, 0) = -0.7$ is 0.4, similar to that judged most likely for Triton and rather typical of icy satellites in the jovian and saturnian systems, but not of the uranian satellites.

The radiometric upper limits derived in this paper for the diameters of Triton and Pluto are consistent with icy objects of sub-lunar size, and with the hypothesis that the two objects are physically similar to each other. If, as we suspect, they both have albedos ~0.4, then about a factor of two improvement in IR systems will be required to measure their thermal emission.

Flow and instability of a viscous current down a slope

Herbert E. Huppert

Department of Applied Mathematics and Theoretical Physics,
Silver Street, Cambridge CB3 9EW, UK

If viscous fluid is released on a horizontal surface it rapidly takes up a circular plan form as it spreads. This form is observed[1,2] to be stable to any small disturbances which are initiated on the front due, for example, to irregularities in the horizontal surface or to chance perturbations. Alternatively, if some fluid is released onto a sloping surface—for example, some liquid detergent on a slanted plate—a quite different plan form occurs. One, two or more extended regions of fluid develop downslope, as shown in Fig. 1*a*, *b*. A situation intermediate between these two is now discussed. Consider a broad band of viscous fluid, uniform in depth across a slope, released so as to flow down a constant slope. By following the motion, which is initially independent of the cross-slope coordinate, the speed of advance and the depth of the flow before it breaks up into a series of waves of ever increasing amplitude can be determined. I present an expression for the wavelength of the front, which is determined by surface tension and is independent of the coefficient of viscosity.

With the coordinate system depicted in Fig. 2 and use of the approximations of lubrication theory[3], the y-independent, down-slope momentum equation can be written as

$$0 = g\sin\alpha + \nu u_{zz} \tag{1}$$

In deriving equation (1) we have neglected both surface tension, the effects of which will be analysed below, and contact line effects[4], which are negligible[1] under the assumption that the Bond number $B = \rho g l^2/T \gg 1$, where ρ is the fluid density, l a representative length scale of the current and T the surface tension. Use of the equation of continuity then leads to

$$h_t + (g\sin\alpha/\nu)h^2 h_x = 0 \tag{2}$$

as the nonlinear partial differential equation for the unknown free surface $h(x, t)$. To equation (2) must be added the global continuity equation

$$\int_0^{x_N(t)} h(x,t)\mathrm{d}x = A \tag{3}$$

where $x_N(t)$ is the value of x at the front of the current and A is the initial cross-sectional area. The particular solution of equations (2) and (3) is sought in the range $0 \leqslant x \leqslant x_N(t)$.

Equation (2) shows that h is constant along characteristics given by

$$\frac{\mathrm{d}x}{\mathrm{d}t} = (g\sin\alpha/\nu)h^2 \tag{4}$$

Thus if initially $h = f(x)$, say, the equation of the characteristics is given by

$$x = x_0 + (g\sin\alpha/\nu)f^2(x_0)t \tag{5}$$

where x_0 is the initial value of the characteristic. The solution of equation (2) is thus

$$h = [\nu(x-x_0)/g\sin\alpha]^{1/2}t^{-1/2} \tag{6a}$$

$$\to (\nu/g\sin\alpha)^{1/2}x^{1/2}t^{-1/2} \qquad (x \gg x_0) \tag{6b}$$

independent of the initial conditions. When combined with equaton (3), in order to evaluate the length of the current, equation (6*b*) proves that some time after the initiation of the current, no matter what the initial shape, the solution takes the form

$$\begin{gathered} h = (\nu/g\sin\alpha)^{1/2}x^{1/2}t^{-1/2} \\ 0 \leqslant x \leqslant x_N = (9A^2 g\sin\alpha/4\nu)^{1/3}t^{1/3} \end{gathered} \tag{7}$$

Expressed alternatively, equation (7) represents the unique similarity solution of equations (2) and (3). The profile of the predicted current ends abruptly at $x = x_N$ with $h = h_N(t) = 1.5A/x_N$ there. The profile can be smoothed off at x_N by including the effects of surface tension. This will be done below after a discussion of an experimental investigation of the validity of the truncated profile expressed by equation (7).

Some 30 experiments were conducted using a pentagonal sheet of Perspex. The longest side was 101.7 cm and from it two sides of length 82 cm emanated at right angles. The remaining two sides were 60 cm. The sheet was surrounded by a Perspex wall 5 cm high to make a tray which was firmly attached to a rigid, flat board. Before each experiment the board was tilted by raising the 101.7-cm long side by the required amount. A removable Perspex gate was fitted 5.0 cm from the back edge of the tray and fluid poured into the space behind the gate. Three different fluids, whose physical properties are listed in Table 1, were used. After the fluid behind the gate had been left a sufficiently long time that it had become quite stationary, the gate was raised and the fluid proceeded to pour down the slope.

At first the motion was virtually independent of the cross-slope coordinate except near the walls where viscous drag retarded the flow. This form of motion is clearly evident in Fig. 1*c*. Observations of the length of the current as a function of time were taken and some typical results plotted in Fig. 3. It can be seen that the agreement between the experimental observations and the theoretical prediction (7) is good. The agreement justifies the neglect of both surface tension and contact line effects in predicting the temporal development of the two-dimensional current.

After the two-dimensional motion had continued for some time, the flow front seemed spontaneously to develop a series of small amplitude waves of fairly constant wavelength across the slope, as seen in Fig. 1*d*. The amplitude of the waves increased in time as the maxima (points furthest down the slope) travelled faster than the minima, as seen in Fig. 1*e*. The wavelength remained unaltered. The long-time shape of the flow front was different for the two fluids used. Both silicone oils developed the form shown in Fig. 1*f*. This consisted of a periodic, triangular front with tightly rounded maxima. The maxima were connected by very straight portions at an angle to the slope to extremely pointed minima. The glycerine developed the form shown in Fig. 1*g*. This was also periodic, though with much less tightly rounded maxima. These were again connected by extremely straight portions, but in this case they were almost directly down slope and connected to very broad minima.

Table 1 The fluids used, their viscosity and surface tension

Fluid	Viscosity at 17 °C ($\mathrm{cm^2 s^{-1}}$)	Surface tension at 17 °C ($\mathrm{dyn\ cm^{-1}}$)
Silicone oil MS200/100	1.15	20.6
Silicone oil MS200/1000	12.8	22.0

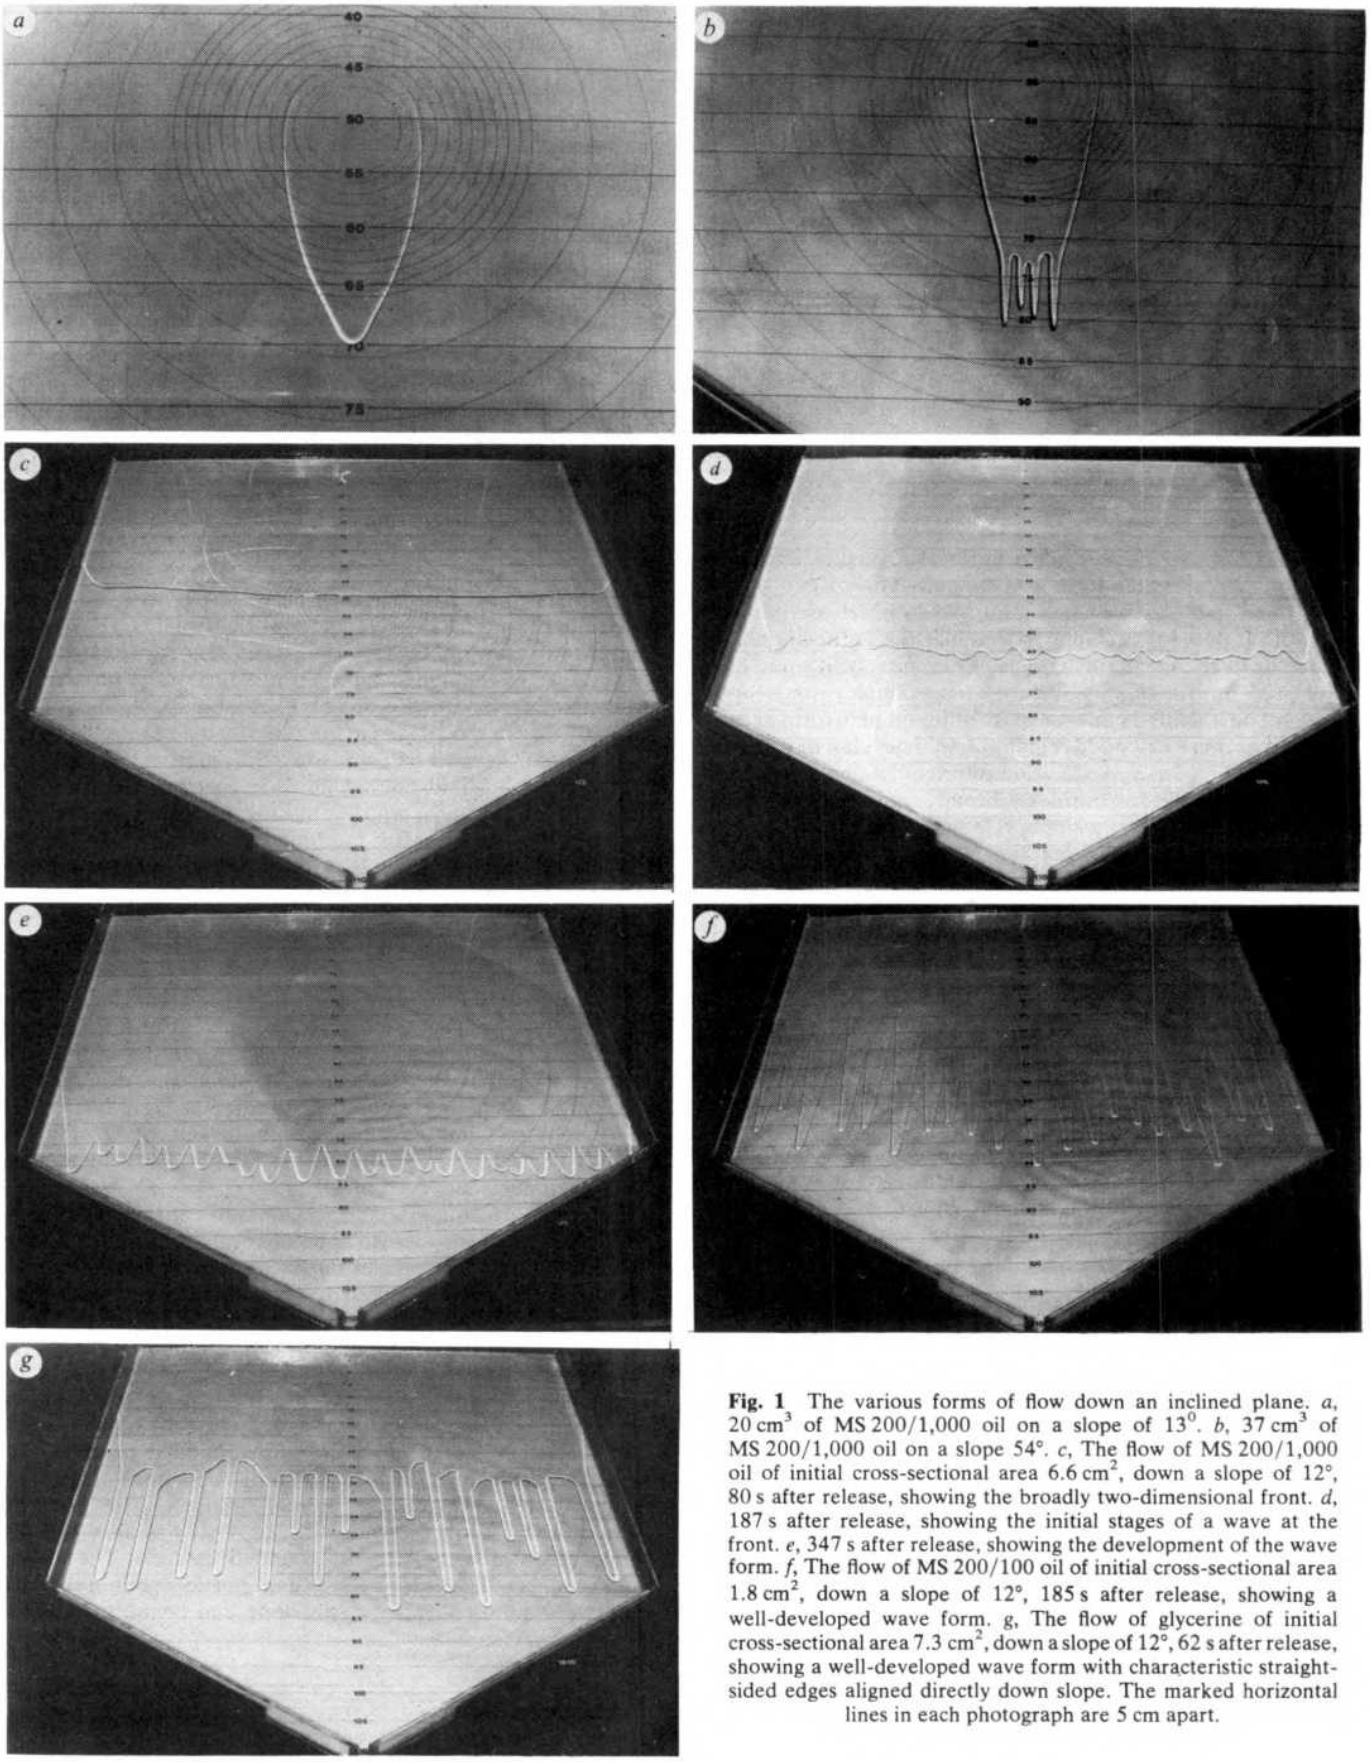

Fig. 1 The various forms of flow down an inclined plane. *a*, 20 cm^3 of MS 200/1,000 oil on a slope of 13°. *b*, 37 cm^3 of MS 200/1,000 oil on a slope 54°. *c*, The flow of MS 200/1,000 oil of initial cross-sectional area 6.6 cm^2, down a slope of 12°, 80 s after release, showing the broadly two-dimensional front. *d*, 187 s after release, showing the initial stages of a wave at the front. *e*, 347 s after release, showing the development of the wave form. *f*, The flow of MS 200/100 oil of initial cross-sectional area 1.8 cm^2, down a slope of 12°, 185 s after release, showing a well-developed wave form. g, The flow of glycerine of initial cross-sectional area 7.3 cm^2, down a slope of 12°, 62 s after release, showing a well-developed wave form with characteristic straight-sided edges aligned directly down slope. The marked horizontal lines in each photograph are 5 cm apart.

The instability cannot be explained by viscous effects alone, since any cross-slope variation in depth of the current tends to be diminished, that is stabilized, by the cross-slope pressure gradient the variation induces. Surface tension must be taken into account.

Experiments with silicone oils whose coefficients of viscosity differ by an order of magnitude, although their surface tensions are almost equal, indicated that the wavelength of the instability is independent of the coefficient of viscosity. Experiments with the two fluids of comparable viscosity yet different surface

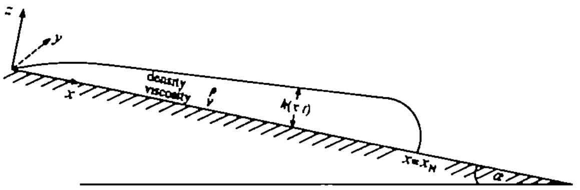

Fig. 2 A sketch of the flow and coordinate system.

tensions indicated that the wavelength is a function of the surface tension. Finally, observations taken during experiments using the same fluid but with amounts differing by up to a factor of 10 indicated that the wavelength is weakly dependent on the initial cross-sectional area A.

The form of the quasi-steady, two-dimensional tip, which is determined by including surface tension and by matching the tip onto the main flow given by equation (7), can be easily determined. The addition to equation (2) of the terms due to surface tension T leads to

$$h_t + (g\sin\alpha/\nu)h^2h_x - 1/3(T/\rho\nu)h^3h_{xxxx} = 0 \tag{8}$$

In the tip the dominant balance is between the second and third terms of equation (8), the solution to which can be written as

$$h = h_N(t)H(\xi) \qquad \xi = (\rho g\sin\alpha/Th_N)^{1/3}(x_N - x) \tag{9}$$

where $H(\xi)$ satisfies

$$H^3H''' + H^3 = 1 \tag{10}$$

$$H \to \left(\frac{16}{15}\right)^{1/4}\xi^{3/4} \qquad (\xi\to 0) \tag{11}$$

$$\to 1 \qquad (\xi\to\infty) \tag{12}$$

The length scale of the tip is thus given by $(Th_N/\rho g\sin\alpha)^{1/3}$.

The experiments indicated that the instability occurs after the two-dimensional flow has propagated to a critical length X_N^C proportional to $A^{1/2}$. Evaluating the length-scale of the tip at this point and conjecturing that the wavelength, λ, is given, in scale, by this length, suggests that $\lambda \sim (A^{1/2}T/\rho g\sin\alpha)^{1/3}$. The results of the various observations, normalized in this way, are presented in Fig. 4. The data are seen to collapse together systematically with this normalization and are well represented by

$$\lambda = 7.5(A^{1/2}T/\rho g\sin\alpha)^{1/3} \tag{13}$$

The wavelength remained constant as the amplitude of the instability increased. For the silicone oils, the distance from the origin of the furthest points down the slope increased with time like $t^{0.35}$ while the distance of the minima increased like $t^{0.28}$. For glycerine, the distance of the front of the instability, once well established, increased like $t^{0.6}$ while the minima were virtually stationary.

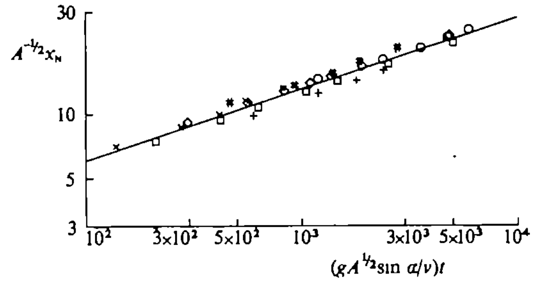

Fig. 3 The length of the two-dimensional flow, normalized with respect to $A^{1/2}$, as a functon of a suitably non-dimensional time. The straight line is the theoretical prediction obtained from equation (7). The experimental points are for values of ν, $\sin\alpha$, A in cgs units of: □, 12.9, 0.093, 8.9; ◇, 12.9, 0.20, 3.1; ○12.9, 0.65, 5.9; +, 9.8, 0.20, 9.0; ×, 9.8, 0.15, 3.6; #, 1.2, 0.11, 1.0.

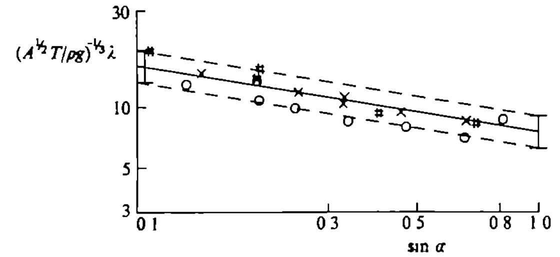

Fig. 4 The wavelength of the instability at the front, normalized with respect to $(A^{1/2}T/\rho g)^{1/3}$, as a function of the slope angle, α. Experiments with fluids of viscosities 12.9, 9.8 and 1.2 cm^{2}s^{-1} are plotted as ○, × and # respectively. The solid line is given by equation (14) and is the best-fit to the data. The two error bars at the end of the line represent ±15%, a typical standard deviation of the wavelength across the slope. Where two or more data points fell on top of each other all but one were omitted for the sake of clarity.

I thank E. J. Hinch for stimulating and helpful conversations, many other of my colleagues in DAMTP for useful discussions, J. M. Wheeler for experimental help and for preparation of the figures, and D. C. Cheesley, D. Lipman, G. Parker and E. J. Sharp for technical assistance.

Forces between two adsorbed polyethylene oxide layers immersed in a good aqueous solvent

Jacob Klein*† & Paul Luckham*

* Cavendish Laboratory, Madingley Road, Cambridge CB3 0HE, UK
† Polymer Department, Weizmann Institute, Rehovot, Israel

Recent measurements of the forces acting between two polystyrene layers adsorbed onto mica surfaces, immersed in a poor solvent for the polymer, show strong initial attraction as the surfaces approach, followed by ultimate repulsion[1]. This has been attributed to attractive osmotic interactions between the adsorbed layers, and possibly to the effect of bridging[2,3]. We have extended these measurements to the case of polyethylene oxide (PEO) layers adsorbed on mica, immersed in an aqueous 0.1 M KNO_3 medium at pH 6 (a good solvent for PEO). Using monodispersed polymer of two molecular weights, we find that an equilibrium force–distance profile is indicated. As the surfaces bearing the adsorbed PEO approach, repulsive forces commence at a surface separation $D \simeq 6\pm1R_g$ (unperturbed radius of gyration of the respective polymers) and increase monotonically on approach; on subsequent separation the forces decrease monotonically to zero. We find no evidence for attraction or adhesion between the adsorbed layers in this system.

The experimental technique and procedure closely resemble those previously described[1,4]. The method permits the measurement of the force $F(D)$ acting between the mica surfaces a distance D apart, as well as the mean refractive index $n(D)$ of the medium separating them.

The forces were first determined between the bare mica surfaces in pure electrolyte. Polyethylene oxide solution was

0028–0836/82/480429—03$01.00

then added to the required concentration (either 10^{-5} or 1.5×10^{-4} g ml^{-1}), and the surfaces left to incubate for 16±2 h. Forces were then measured both in compression and decompression at different intervals (1 min to 1 h) and at various approach and separation rates (15–60 min per cycle), following which the PEO solution was replaced by pure solvent, and measurements repeated. The overall duration of experiments was generally between 48 and 72 h.

The PEO samples used were obtained from Toyo Soda (Japan). They were anionically prepared and their molecular characteristics (manufacturers data, determined by GPC) are shown below.

	M_w	M_w/M_n	R_g
PEO1	4.00×10^4	1.03	6.5 nm
PEO2	1.60×10^5	1.04	13 nm

The results are shown in Fig. 1. In the pure electrolyte (Fig. 1*a*) the forces between the mica surfaces are typical of electrostatic double-layer (DLVO) interactions[4], with a secondary minimum as indicated in the inset and the characteristic strong short range repulsion (Fig. 1*a*). The surface potential of the mica deduced from the Debye length is ~100 mV. The force–distance profiles as well as the surface potential correspond closely to those observed previously for mica surfaces in various aqueous electrolytes[4].

Following adsorption of the polymer, the force profiles change as shown in Fig. 1*a*: no forces are observed as the surfaces approach from $D\simeq500$ nm down to $D\simeq6\pm1\,R_g$ (corresponding to 35–40 nm for PEO1, 65–75 nm for PEO2), and thereafter monotonically increasing repulsion sets in. The surfaces were generally brought in to about 6±1 nm separation. The shape of $F(D)$ on decompression and recompression of the surfaces depends to some extent on the rate at which these are carried out: if decompression is rapid (up to about 5 min for separation to $F(D)=0$) the dashed curve (Fig. 1*a*) is followed. However, if separation is sufficiently slow (30–60 min for separation to $F(D)=0$), the decompression curve merges (within error) into the original compression profile (solid curve). A similar effect is observed on recompression: if the surfaces are compressed, then rapidly separated, (<5 min) and then brought together again within 5 min, then the resulting $F(D)$ profile on subsequent compression follows the broken curve. If a longer time (30–60 min) elapses between separation and approach, the compression profile reverts to the original solid curve. Thus the variation of $F(D)$ with compression–decompression rates in these experiments is within the shaded regions indicated. We find no evidence for the build-up of thick adsorbed layers with time beyond the values corresponding to the solid curves in Fig. 1. The results described were obtained (within experimental error) for the two incubation concentrations used, both in solution and following the replacement of polymer solution by pure electrolyte. They suggest that there is a quasi-equilibrium force–distance profile for this system, represented by the solid curves, while the broken curves indicate the effect on $F(D)$ as a result of incomplete relaxation of the adsorbed polymeric layers at short times ($\leqslant5$ min).

Figure 1*b* shows the variation of refractive index $n(D)$ with surface separation D for PEO1. These values of $n(D)$ were measured both in compression and decompression, and were the same (within error) both in solution and following the replacement of solution by pure electrolyte, at the two incubation concentrations. They indicate (as for polystyrene adsorbed onto mica from cyclohexane) that there is little desorption or extrusion of polymers over the times and in the conditions of our experiments. The adsorbance Γ of polymer onto the mica may be estimated from $n(D)$ (ref. 1), and corresponds to $\Gamma\simeq5$ mg m^{-2} of mica surface. To our knowledge there are no independent measurements of PEO adsorbance onto plane surfaces to compare this value of Γ with, though we note that it is comparable to adsorbance values for other polymers on plane surfaces[5]. It is, however, higher than PEO adsorbance onto colloidal silica particles[6] (for which $\Gamma\sim1$ mg m^{-2}).

The onset of interactions between the adsorbed layers in the present study suggests an effective extension of polymer from each mica surface of some $3R_g$. This compares with values of $\sim2R_g$ measured for various polymers (but not PEO) adsorbed on plane surface from θ-solvents[7], and with an effective extension of some $1.5\,R_g$ for polystyrene adsorbed onto mica in worse-than θ conditions[1]. Our value of 2.5–$3R_g$ is comparable with a hydrodynamic thickness of about $2R_g$ for PEO layers adsorbed onto polystyrene latex particles in a good aqueous solvent, as measured by light scattering[8], and also with theoretically predicted values of some $3R_g$ for adsorbed poly-

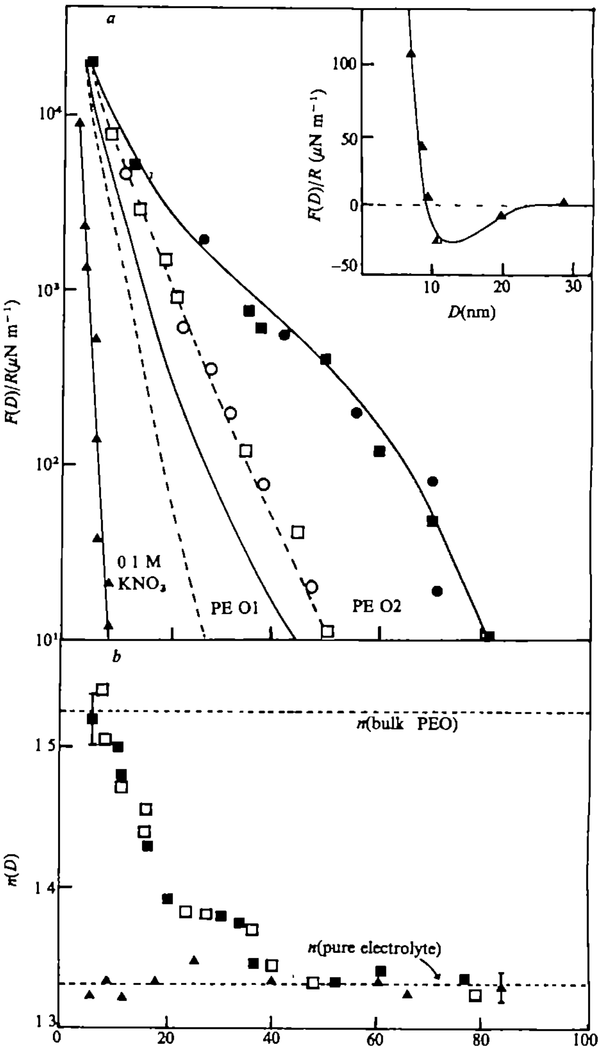

Fig. 1 *a*, Forces $F(D)$ between curved mica surface (mean radius of curvature $R\simeq0.5\times10^{-2}$ m) in 0.1 M KNO$_3$ (BDH Analar grade, in de-ionized double-distilled water) at 20±2 °C. ▲, Force profile in pure electrolyte. mers in an athermal solvent[2]. The monotonically repulsive nature of the interactions suggests that for this system there is little effect of bridging or desorption (which could lead to attraction)[2,9], the forces being due to an increasingly repulsive osmotic interaction as the opposing polymer layers come into overlap in the good solvent[2,3,9].

Our results contrast with the earlier study by Israelachvili and co-workers, who used a similar method to measure $F(D)$ between mica surfaces in an aqueous solution of highly polydisperse PEO[10] (Carbowax resin WSR N80, Union Carbide). Their investigation indicated the continuous buildup with time of progressively thicker layers of surface adsorbed material (up to 1,000 nm over 24 h), as well as complex short- and long-time hysteretic behaviour suggestive of gel-like material on the surfaces. This may be due to the polydisperse nature of the polymer, as well as the possible presence of microgels or trace chemical impurities in the as-received Carbowax Resin (ref. 11 and J. N. Israelachvili, personal communication).

The present findings indicate that the interactions between adsorbed layers of monodispersed PEO across a good aqueous solvent are monotonically repulsive, and may be represented by a quasi-equilibrium force–distance profile at times longer than ~1 h. The extension of the adsorbed layers from each surface is somewhat larger than corresponding, independently measured values for polymers on plane surfaces in θ-solvents; the refractive index data indicates (in accordance with previous studies) a quasi-irreversible adsorption of polymer onto the mica surface.

We thank Professor D. Tabor for interest and helpful discussions, and Dr J. N. Israelachvili for useful suggestions.

Magnetostratigraphical dating of loess deposits in China

Friedrich Heller

Institut für Geophysik, ETH-Hönggerberg, CH-8093 Zürich, Switzerland

Liu Tung-sheng

Institute of Geology, Academia Sinica, PO Box 634, Beijing, China

The age of Chinese loess deposits has long been disputed. Biostratigraphical and earlier magnetostratigraphical investigations placed the entire loess formation within the Pleistocene. The new palaeomagnetic measurements reported here on a bore hole section near Lochuan (Shaanxi province) suggest a clearly defined magnetic polarity zonation which extends below the Olduvai subchron. A late Pliocene age of ~2.4 Myr is assigned to the oldest loess sediments measured. The intensity variations of natural remanent magnetization (NRM) and low field magnetic susceptibility are indicative of climatic changes during loess deposition.

In northern China nearly half a million square kilometres are covered by loess sediments. Along the middle Huangho valley these wind-transported, yellow to red-brown sediments occupy a coherent area of more than 300,000 km^2, known as the loess plateau[1]. Here the loess deposits generally approach a thickness of 80–120 m. Typically they consist of an alternation of (1) silty loess layers which developed in cold and arid climatic conditions and (2) clayey loess or palaeosoil beds which are indicative of warm and humid climate (see Fig. 1: succession of loess- and soil(S)-horizons). Some of the soil horizons are developed in such a way that they can be recognized and correlated over large distances. They serve as stratigraphical marker horizons[2]. The environmental variations during loess formation are documented by faunal changes, especially of snail assemblages[3], by the degree of crystallization of clay minerals[4], and by carbonate content and other geochemical indicators[5].

On the basis of lithology, unconformable contacts and erosion surfaces the loess deposit has been subdivided into three main stratigraphical units[6–9] which all have been assigned a Pleistocene age: The Malan Loess of late Pleistocene age, The middle Pleistocene Lishih Loess and the early Pleistocene Wucheng Loess (Fig. 1). The biostratigraphical age estimates have been supported by several palaeomagnetic investigations[10–12]. According to remanent magnetization directions obtained after alternating field (a.f.) demagnetization, the Brunhes–Matuyama boundary has been found to coincide roughly with the Wucheng–Lishih transition. The Jaramillo subchron was identified in the middle of the Wucheng division, thus the oldest strata were estimated to have an age of <1.2 Myr.

We have sampled a long core from a bore hole near Lochuan (Shaanxi province) ~800 km south-west of Beijing (lat. 35.4 °N; long. 109.5 °E) for palaeomagnetic analysis. The core penetrates a 136-m thick loess sequence which has been deposited on top of an Upper Pliocene (Hipparion bearing) lateritic substratum. More than 230 samples were obtained from the core with an average sampling interval of 60 cm. The samples were oriented relative to the vertical but not azimuthally. Before demagnetization the NRM intensity is relatively strong with a mean value of 5.08×10^{-2} Am^{-1} for 150 soil samples, and 2.26×10^{-2} Am^{-1} for 181 loess samples. The low field susceptibility of the soil horizons (mean: 2.49×10^{-3} SI units) also is about twice that of the loess layers (mean: 1.16×10^{-3} SI units). High field experiments show that the main magnetic minerals are magnetite and haematite. The NRM is strongly affected by secondary, viscous remanent magnetization (VRM) so that the NRM vector always gives inclinations consistent with the present field of the Earth. Advantage was taken of this property to detect several misoriented (inverted) samples. Because major portions of viscous magnetization (up to 80% of total NRM) are removed by low a.f.s of the order of 10–15 mT, the VRM apparently resides mainly in magnetite. However, viscosity tests in the laboratory show that progressive a.f. demagnetization increases the instability of NRM. A.f. cleaning of NRM often results in rather erratic or badly defined demagnetization curves. Thermal demagnetization also removes a large secondary VRM component up to 200 °C, but above 300 °C a well defined and stable component is observed which has either positive or negative inclination depending on the stratigraphical position. On orthogonal vector plots this characteristic component decreases undirectionally towards the origin of projection on further heating. Maximum unblocking temperatures are usually above 575 °C. Thus the characteristic remanent magnetization of the loess is probably carried by haematite. Details of the loess rock magnetic properties will be described elsewhere.

After thermal demagnetization at 350 °C the core is subdivided into several clearly defined polarity zones, separated by sharp transitions (Fig. 1). In contrast to the results of earlier investigations which were based on a.f. cleaned NRM directions[10–12], the positive and negative inclinations average vectorially to the absolute value of the present local geomagnetic field inclination ($I = 52.5°$). From top to bottom of the core the polarity changes are correlated with: (1) the Brunhes–Matuyama boundary at core depth 53.05 m; (2) the Jaramillo subchron between 67.30 and 72.50 m; (3) the Olduvai subchron between 107.40 and 113.10 m.

No definite evidence of shorter term geomagnetic excursions is indicated in our data. Three samples (out of a total of 231)

0028–0836/82/480431—03$01 00

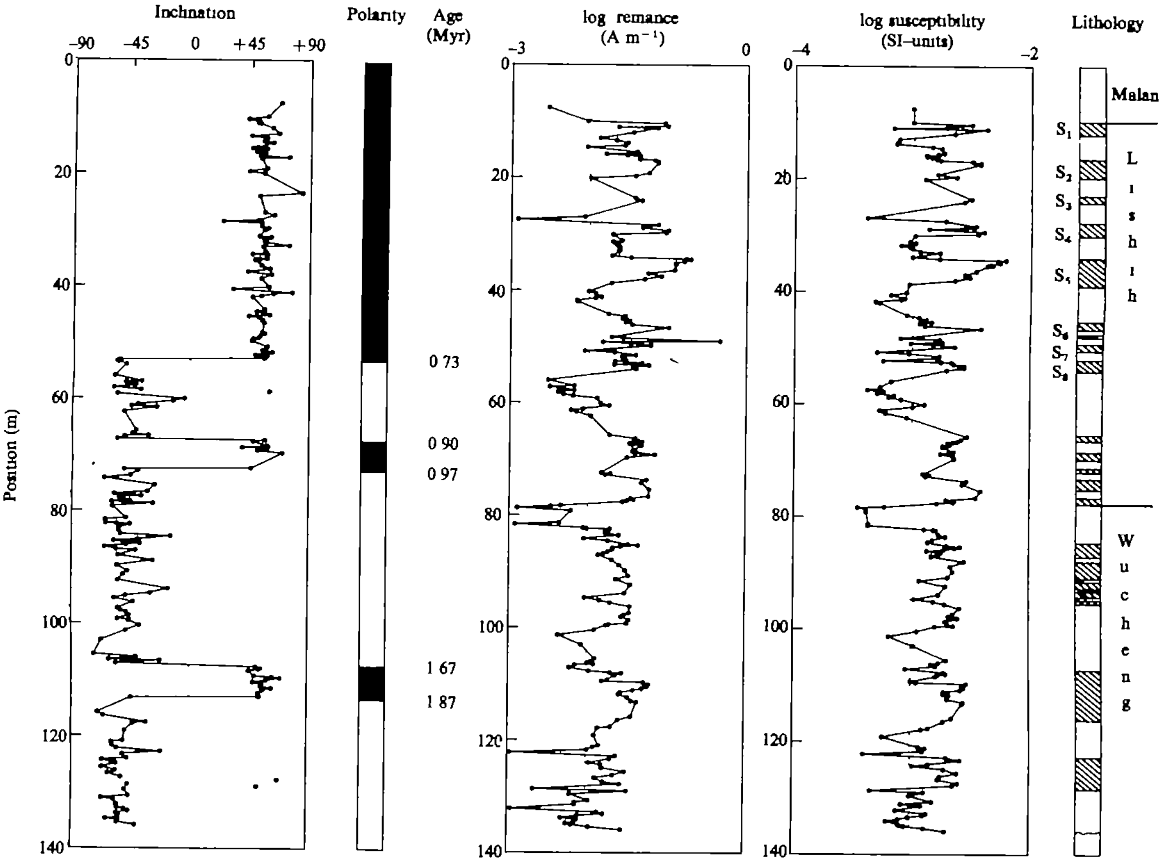

Fig. 1 Magnetic properties of the Lochuan bore hole versus core depth. Inclination data were mostly cleaned at 350 °C. The ages of polarity chron boundaries are according to Mankinen and Dalrymple[13]. Remanence intensities and susceptibilities are plotted before thermal cleaning. Lithological sequence of loess (white) and numbered soil layers (hatched) is according to Liu *et al.*[2].

do not fit to the observed polarity sequence. Possibly these samples may be completely remagnetized by a normal (present day) field or may suffer from unrecognized misorientation. Alternatively, they may indeed record field excursions or short polarity chrons (the two samples near 130 m depth would fit closely the Reunion events). Viscous remagnetization still affects the data to some extent, since the reversely magnetized portions of the core show higher directional scatter. No correlation is found between polarity and remanence intensity (Fig. 1) or low field susceptibility.

Our observations require a revision of some earlier ideas about the dating of Chinese loess. The Brunhes–Matuyama boundary is found to occur much higher in the loess profiles than thought previously[10–12]. The Olduvai event has been identified for the first time, implying much greater ages for the entire loess formation. Converting depth into age by using the time scale of Mankinen and Dalrymple[13] we notice an increase in apparent accumulation rate from 4.6 cm kyr^{-1} below the Jaramillo event to 7.3 cm kyr^{-1} in the upper 73 m. By linear extrapolation beyond the Olduvai event and due to the fact that the Matuyama–Gauss boundary is not observed in the loess sediments, we assign a minimum age of ~2.4 Myr to the beginning of loess sedimentation. This date coincides with age estimates for a general deterioration of climate in the Northern Hemisphere[14]. The age of the Plio–Pleistocene boundary is still controversial; however, if it were correlated with the top of the Olduvai event[15,16], then Chinese loess deposition, the older portions of which cover nearly the complete Matuyama epoch, started before the Pleistocene and dates back into the late Pliocene like the Central European loess deposits[17]. Also, the stratigraphical boundary between Lishih and Wucheng Loess no longer coincides with the Brunhes–Matuyama boundary, but has to be placed at ~1.1 Myr BP as it lies below the Jaramillo. Note that the negative polarity recorded in the bottom part of the loess profile (Fig. 1) continues down into the top of the Upper Pliocene red clay. After a few metres the polarity in the clay reverses again to normal (not illustrated in Fig. 1). As the lithology changes from clay to loess soil rather gradually, it is tempting to assume continuous sedimentation between clay and loess so that this reversal would actually document the Matuyama–Gauss boundary.

The intensities of NRM (before cleaning) and low field susceptibility (Fig. 1) vary by 2–3 orders of magnitude throughout the section, being closely correlated to each other. High intensities characterize the soil horizons, whereas low values are typical of loess deposits[11]. These features are ascribed to the pedogenetic processes of rock formation which favour haematite enrichment in the soils due to alteration in a relatively warm and humid climate. The carbonate content of the soil horizons is reduced[2] causing an overall volume decrease of up to 20%. Pre-existing magnetite becomes oxidized, the iron available from other minerals is mobilized and re-precipitates later in the form of oxides and hydroxides[18,19]. Especially the latter process of formation of ferromagnetic minerals is thought to cause the intensity fluctuations of remanence and susceptibility which therefore are due to climatic changes and not to geomagnetic field variations as suggested by Wollin *et al.*[20] for Pleistocene deep sea sediments.

Thus the stable part of NRM may have a completely chemical origin. Using the magnetic intensity record we can estimate that about 17 glaciations have occurred in China since the Olduvai event. This number of glaciations is similar to that encountered in European loess deposits[17,21]. It is also consistent with the number of oxygen isotope stages in post-Olduvai deep sea sediment from the Atlantic[22]. The Brunhes–Matuyama boundary is found in the soil layer S_8 (Fig. 1) which follows a loess unit deposited during a major glaciation period. Similar observations have been made in the oxygen isotope record of the deep sea sediments where this field polarity change is placed within the interglacial stage 19 (refs 22–24). The rock magnetic intensity variations become especially pronounced after 1.2 Myr ago (above core depth 82 m) and are interpreted to record rather drastic climatic changes coinciding with major episodes of loess deposition at about 1.15, 0.85, 0.55, 0.44 and 0.18 Myr ago (age estimates by linear interpolation). The first of these episodes, presumably marking major glaciations, is accompanied by an increase of sedimentation rate by about a factor of two.

Our investigation demonstrates that, after thermal demagnetization, the NRM of the loess deposits in China renders a reliable record of geomagnetic field polarity. The rock magnetic properties apparently are largely controlled by chemical alteration processes during rock formation and therefore reflect climatic fluctuations during late Pliocene to Pleistocene times.

We thank Professors D. V. Kent, G. J. Kukla and W. Lowrie for critical reading of the manuscript. Ge T. M. and W. Gruber carried out many of the palaeomagnetic measurements. Contribution no. 387, Institut für Geophysik, ETH Zürich.

Origin of desert loess from some experimental observations

W. B. Whalley*, J. R. Marshall† & B. J. Smith*

A longstanding problem of Quaternary geology has been the origin of the silty deposit known as loess. Of the many explanations for its formation and distribution[1,2], the most commonly accepted is that the silt is produced by subglacial grinding processes[1,3,4], followed by redistribution and deposition by the wind. The large expanses of loess in central Europe are therefore considered to be the consequence of Quaternary glaciation[5]. There is, however, a view[6,7] that loessic silt may also originate as the product of processes in hot deserts. Some proponents of the desert loess hypothesis consider that silt-size material is the product of weathering processes[7] which may include salt weathering[8] or weathering down incipient cracks[9]. An alternative mechanism is aeolian attrition of sand grains, although, probably as a result of the experimental work of Kuenen[10], Smalley and Krinsley[11] consider that only fine silt (2–6 μm) is produced in large quantities by the abrasion of quartz grains. We have simulated aeolian attrition of angular quartz grains previously produced by weathering in deserts. The products of abrasion show that both coarse and fine silt sizes are produced. These findings suggest that desert aeolian processes can produce loess. We also suggest that much of this material from many deserts has been deposited in the sea but that the Chinese loess could have been produced in the Gobi desert. The finest particles produced by such attrition may be a source of silica for silcrete formation.

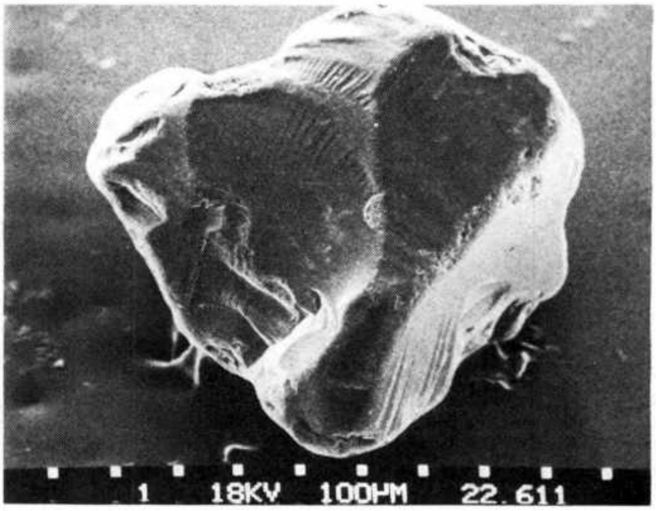

Fig. 1 An originally angular grain after 600 h of gentle erosion in the attrition device. At this stage the abrasion is confined to edges and corners but has already produced a considerable quantity of fragments. On this, and subsequent micrographs, the scale is given by the interval between the successive white squares at the bottom; the value (in μm) the second group of figures from the right.

We have concentrated on the aeolian attrition of quartz sand size grains released from the parent rock by weathering. In particular, whether there is a mechanism to produce particles in the 20–50 μm range from coarser material. Previous experiments on sand abrasion[10,12] have tended to examine the larger products of attrition without either collecting or examining the smaller fragments chipped off the sand size grains. These fragments may, however, provide the very silt size material that the experiments were designed to detect. We have designed an experimental apparatus which, we believe, samples all the products of any attrition taking place. A triple-head 500-ml flask was used as an abrasion chamber in which ~10 g of crushed vein quartz (710–840 μm sieve size) was placed and agitated gently in a regulated airstream. The centre orifice was used to introduce a glass tube which vented air just above the base of the flask. The grains followed a regular saltating path with both interparticle collision and dune face avalanching. The 'air velocity' means little in these conditions but as field conditions are themselves very variable we do not consider this a limitation. Sampling of attrition debris was carried out in the outflow air at the top of two 300 mm high 'stilling wells' positioned on the flask side necks. This arrangement prevented the main, original particles from escaping. A scanning electron microscope (SEM) stub was placed in this airstream with double-stick tape on its surface. This was changed at intervals to allow periodic examination of small particles. The exhaust from the stilling wells was allowed to escape down polyethylene tubing. Fine particles are trapped by their own electrostatic charge in the first 10–20 mm and this region was removed at each sampling interval. The tube was cut and a portion examined by use of the SEM, together with fragments caught on the stub and 10 of the original grains in the flask. Collection efficiency is believed to be better than 95% of the fines produced. We have been able therefore to examine not only the abrading, original, grains and their progressive attrition but also the nature of the fine particles produced. Vein quartz, without apparent weaknesses introduced by the crushing, was used because the experiment was designed to look at the products of attrition as far as possible. Kuenen's experiment also used this type of material.

Figure 1 shows a grain after 600 h of gentle abrasion. Although it is rather poorly rounded compared with Fig. 2 the latter is from a desert dune environment[13] and has been abraded for a very much longer period and probably at much higher tractive velocities. Indeed, it is surprising that such abrasion

0028–0836/82/480433—03$01.00

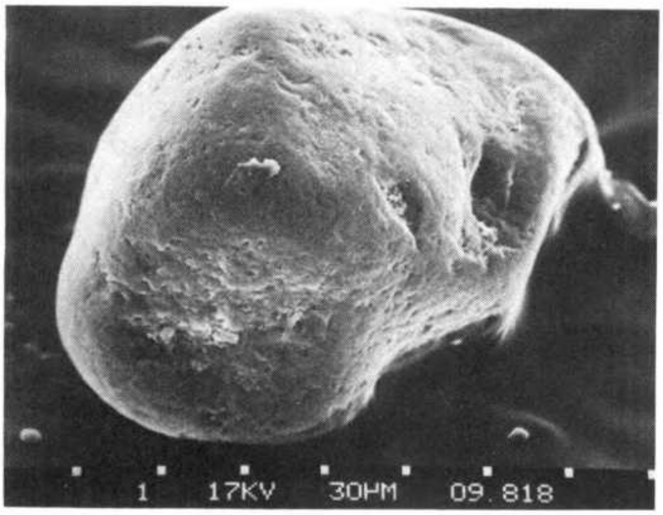

Fig. 2 This grain was taken from a fossil desert dune environment in Nigeria. There is considerably more rounding than seen in Fig. 1, abrasion now covers faces rather than just on corners. It is not known how long this grain might have been subjected to abrasive action but is likely to be very much longer than 600 h. The deposits are probably at least 25,000-yr old but the length of active dune formation is not known.

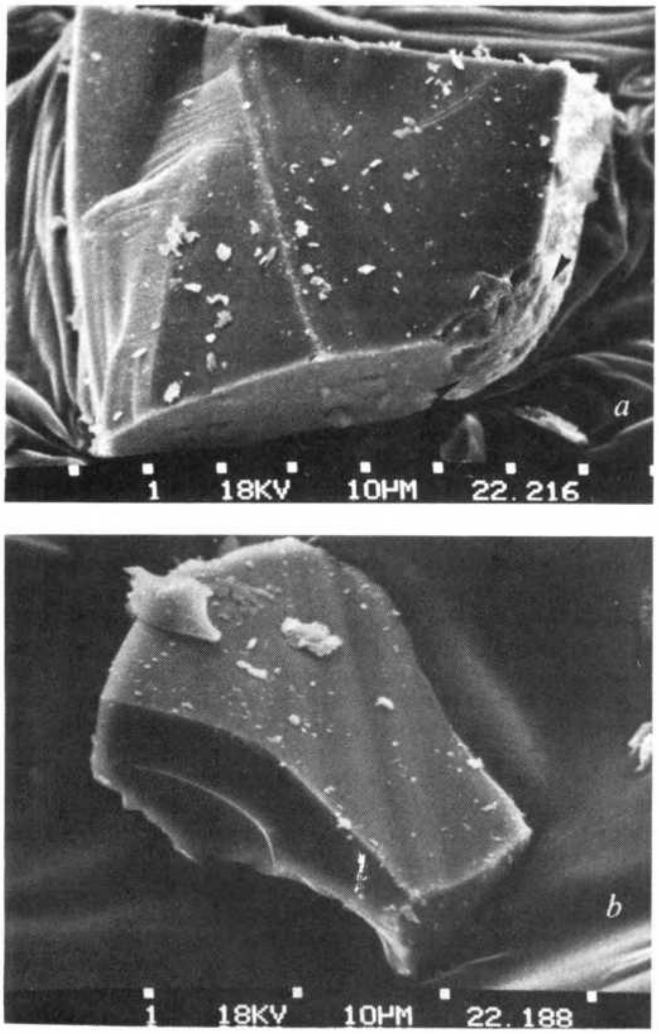

Fig. 3 Two coarse silt fragments (at roughly the extremes of this size range) produced by the attrition in the experiments reported. *a*, A grain with a section which has been rounded (between the arrows). The surface texture of this area is similar to that seen in Figs 1 and 2. *b*, A finer fragment with no such surface texture apparent. *a* was extracted after 200 h of attrition and *b* after 60 h.

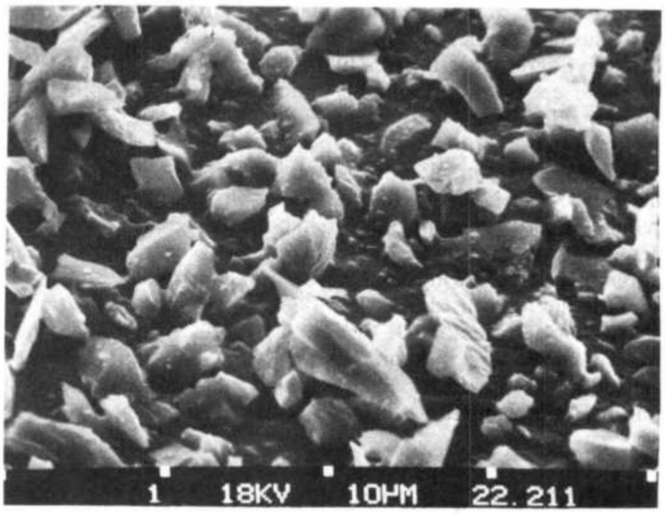

Fig. 4 Finer material than that seen in Fig. 3 is produced in the experiment. This micrograph shows fine silt and clay-size material caught in the polyethylene final trap.

seen in Fig. 1 has occurred. Not all desert grains are as rounded as that in Fig. 2 (ref. 14), this is possibly because they have not been abraded either for very long or sufficiently energetically. The abrasion process is one of progressive removal of small fragments, generally <30 µm but with rather fewer larger chips (<100 µm). Figure 3 shows two of these larger fragments which, in this case, are products of edge rounding. Such rounding, however, is not often visible. Chips of this size may be produced in the manner suggested by Moss[15] and Smalley and Vita-Finzi[4] but are rather less common than these investigators imply. Kuenen's[10] finding that "no quartz particles are produced in the size range dominating in loess" (although he did obtain some dust <5 µm) may have been a major factor in the reluctance to accept aeolian abrasion as a means of producing loessic silt. Our experiments have shown that silt-size as well as some clay-size material is formed in low energy aeolian environments (Fig. 4). Exact determinations of the quantities of attrition products is not possible but (after 60 h) a mass reduction of about 1–5% was found; of this about 20% was <5 µm. It is not yet known what are the relationships between particle velocity and size and quantity of fine material produced by aeolian action. In our experiment, fine material was still being produced after 600 h action. It is not known why Kuenen only detected the fine dust in his experiment. The surface textures seen in Figs 1 and 3*a* are very similar to that of the known aeolian origin of Fig. 2 and it seems reasonable to assume that the experimental production of fine material was matched naturally to give the rounded grain of Fig. 2.

There are several points of note. (1) Abrasion takes place primarily by point impacts of (originally) angular edges (Fig. 1) probably by grain spinning[16]. (2) Chips knocked off are of predominantly silt-size and are rather blocky in nature. This compares with published size ranges and SEM micrographs of loess[17–19]. (3) Abrasion may be achieved at very low particle velocities. (4) There is some resemblance of rounded edges to so-called 'chemical precipitation' surface textures seen on SEM micrographs of quartz grains from desert dunes[20]. (5) The very fine material produced in nature may be entrained by wind and removed completely from any desert system. The very finest abrasion products may even be dissolved and could be an important contributor to silicification of sediments[21].

Finally, it seems that an aeolian abrasional origin for some loessic material is quite possible. It is unlikely that much European loess is produced in this way even though long distance travel from the Sahara is possible[22]. Most Saharan produced silt lies not on the southeastern Mediterranean land surface[6,7] out in the Atlantic Ocean[23,24] or even South America in the case of fine dust[25].

It would, for example, seem that a mechanism may exist whereby weathered grains in the Gobi desert could produce a substantial amount of China's loess. It is also possible that silts in the south-west of the United States and northern Mexico were produced by an aeolian abrasion mechanism, perhaps coupled with silt production by weathering mechanisms[9].

We acknowledge the facilities provided by Professor D. H. Krinsley for the work described here and also to Queen's University Electron Microscope Unit.

We have demonstrated recently that electron spin resonance (ESR) spectroscopy can detect a narrow signal from electron gain (E′) centres in flint (Upper Cretaceous lepispheric chert)[1]. This signal, caused by the effect of natural radiation, is lost on heating and may be useful for dating[2]. ESR signals from various organic radicals are now reported in a wide variety of cherts. The thermal dependence of the signals may provide valuable information about the duration and temperature of ancient chert heatings.

The organic radical signals have been observed in Upper Cretaceous lepispheric cherts from Europe and the Middle East, and in Tertiary chalcedonic cherts from south-west France. The chalcedonic cherts comprise a coarse, fibrous α-quartz (chalcedony) and the lepispheric cherts predominantly comprise α-quartz lepisheres cemented by an interstitial microchalcedony.

The most important, and most unexpected result is the detection at ambient temperature of a well-defined quartet of lines (1:3:3:1) with a hyperfine coupling of 22.7G and a g-value of 2.0025 which is characteristic of methyl radicals[3] (See Fig. 1 and Table 1). In addition a triplet due to two equivalent protons has been detected which we assign to $X–\dot{C}H_2$ radicals. Other unassigned features due to organic radicals have also been detected.

Most of the cherts studied have given a very weak methyl signal. After heating the chert, the signal is more intense, the methyl concentration reaching a maximum at around 350 °C before rapidly decreasing (Fig. 2). The temperature giving maximum methyl radical concentration varies with the duration of heating. Surprisingly, γ irradiation of chert did not alter the methyl radical concentration. γ irradiation followed by heating gave less growth of the methyl signal than did an identical heating of an unirradiated sample. It is thus necessary to postulate a radiation sensitive precursor ($Y–CH_3$) which is thermally labile:

Table 1 ESR data for methyl radicals in various environments, together with data for $X–\dot{C}H_2$ species

Radical	System temperature	g-value (average)	Hyperfine coupling (G)	Ref.
$\cdot CH_3$	CH_3I/vycor glass (RT)	—	22.7	4
$\cdot CH_3$	CH_4 (4K)	2.0025	22.9	5
$\cdot CH_3$	Chert (RT)	2.0025	22.7	This work
$\geqslant SiO\dot{C}H_2$	CH_3OH/vycor glass (−140 °C)	2.0031	20.5	6
$X–\dot{C}H_2$	Chert (RT)	2.0031	21.0	This work

$1G = 10^{-4}$ T; RT = room temperature

$$Y–CH_3 \rightarrow Y\cdot + \cdot CH_3$$

Several aspects of the environment of these $\cdot CH_3$ radicals can be delineated. The fact that the lines are narrow shows that the radicals are freely rotating, but not in the 'gas-phase'[3]. Also, the absence of 'spin-flip' satellite features at high power indicates that they are trapped in an environment free of paramagnetic nuclei[3]. Obviously, they cannot be close to any species with which they can react, and they are well separated from the radicals Y· (if they are radicals) because there is no spin–spin reaction broadening the lines. Almost certainly they are trapped in molecular-sized holes in a purely silica environment.

Similar comments apply to the $X–\dot{C}H_2$ radical. Furthermore, the group X- must contain only non-magnetic nuclei close to carbon as no further hyperfine coupling can be detected. γ irradiation increases the concentration of $X–\dot{C}H_2$ radicals. Their thermal behaviour is complex. The precursor of the methyl radicals, $Y–CH_3$, is unknown. Species such as

$$\begin{matrix}—O\\—O\\—O\end{matrix}\!\!>\!Si—CH_3 \quad \text{or} \quad \begin{matrix}—O\\—O\\—O\end{matrix}\!\!>\!Si—O—CH_3,$$

though attractive, are unlikely as there is no reason to believe that the Si—C or O—C bonds are exceptionally weak. These bonds might be weakened by the proximity of a radical centre, but since the thermal yield of methyl is decreased by irradiation this is improbable. We favour the presence of some labile molecules trapped in the silica system, but cannot guess their identity at this stage. It is possible that the same species is the source of $X–\dot{C}H_2$ radicals on radiolysis (that is, $X \equiv Y$), as this

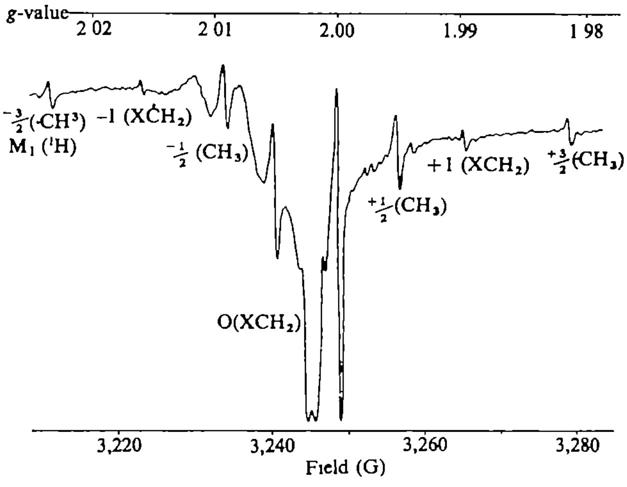

Fig. 1 Electron spin resonance spectrum of a chert sample from Ksar-Akil, Iraq, recorded at room temperature showing signals assigned to $\cdot CH_3$ and $X–\dot{C}H_2$ radicals. The sample volume was $\sim 0.2\ cm^3$. Spectra were recorded on a Varian E109 spectrometer capable of detecting $\sim 10^{11}$ spins.

0028–0836/82/480435—02$01 00

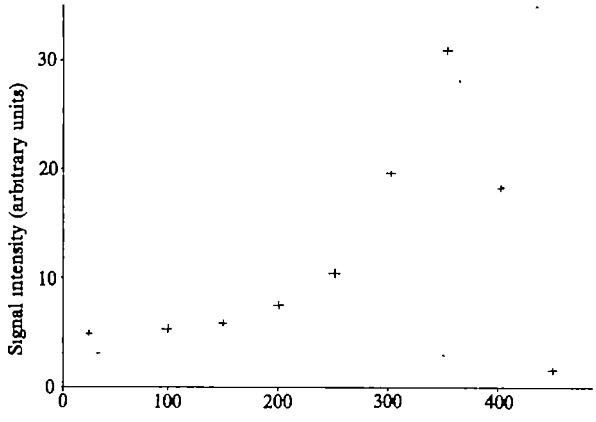

Fig. 2 Isochronal annealing curve showing the intensity of the methyl signal (measured at room temperature) after successive heating episodes of 15 min duration at each of the marked temperatures. The chert sample was from Al-Beidah, Jordan.

would account for the lower yield of methyl radicals on heating after irradiation. It seems to be important that many varieties of chert should contain a compound that is a thermal source of methyl radicals, since such compounds are most unusual.

The thermal behaviour of the organic radicals in chert is being further studied and is likely to prove useful in determining the temperature and duration of ancient heating episodes. Such information is of considerable interest in the study of ancient stone-working techniques. It is also useful in determining whether, or not a sample has been sufficiently heated to be suitable for dating by thermoluminescence of ESR techniques.

We thank the SERC for financial assistance.

Effects of aerosols on photosynthesis

Siegfried A. W. Gerstl & Andrew Zardecki

Theoretical Division, University of California,
Los Alamos National Laboratory, T-DOT, MS-B279, Los Alamos,
New Mexico 87545, USA

Air pollution can cause various problems to agriculture through its direct or indirect effects on plants[1,2]. The net effects of air pollution on agricultural crop yields are very difficult to estimate quantitatively, and are generally considered secondary to the effects of fertilizers or chemical disease control measures. However, continually increasing air pollution may represent a persistent and largely irreversible threat to agriculture in the future. Here we have examined only one indirect aerosol effect on agricultural plant life—the reduction in photosynthetically active radiation (PAR) reaching the ground in the presence of significant air pollution. This effect can be quantified confidently from results of detailed model calculations of the transfer of solar radiation through the atmosphere with varying levels of air pollution. For the biologically effective wavelength region between 0.35 and 0.72 μm, the reductions in PAR due to increasing tropospheric aerosol loads have been determined for rural and urban pollution scenarios. For example, for the north-eastern United States during the summer months, a reduction in PAR of about 20% and 33% was obtained when the visual range due to rural and urban aerosols, respectively, was decreased from clear air conditions to 10 km.

The effects of aerosols on the natural radiation balance in the atmosphere have been studied by using extensive measurement programmes[3] and theoretical modelling[4]. Only recently, however, have detailed data on realistic air pollution scenarios become available to allow an accurate description of the optical parameters of aerosol-loaded atmospheres. For our model calculations we used the very detailed and recent data base for the optical properties of atmospheric aerosols compiled by the Air Force Geophysics Laboratory (AFGL)[5,6]. Four altitude regimes with different aerosol models in each region are considered. Within the boundary layer (up to 2 km height), rural and urban-type aerosols are specified with varying meteorological ranges (surface visibilities). These models are intended to distinguish between aerosol types of natural and man-made origin over a land area. The 'rural model' represents aerosol conditions over continental areas having natural environments that are not directly influenced by anthropogenic pollution. These aerosols are assumed to consist of a mixture of 70% water-soluble substances (ammonium and calcium sulphate and also organic components) and 30% dust-like aerosols. The refractive index for the individual components is based on the measurements of Volz[7]. The size distribution is parameterized as the sum of two log-normal size distributions. In contrast, the 'urban aerosols' are considered typical to stagnant polluted air originating from combustion products and industrial sources. This model, therefore, is taken to be a mixture of 80% rural aerosols with 20% carbonaceous aerosols. These soot-like aerosols are assumed to have the same size distribution as both components of the rural model.

To describe aerosol attenuation in finite wavebands, integral turbidity coefficients are often used[8]. For simplicity, we characterize an existing pollution level by its associated surface visibility. Using Koschmieder's law, the visual (meteorological) range V(km) is inversely proportional to the total extinction coefficient at 0.55 μm: $V=3.91/\sigma$, where $\sigma=\sigma_m+\sigma_a$ (km^{-1}) ('m' and 'a' refer to molecules and aerosols, respectively). In our data base, clear air (that is, $\sigma_a=0$), corresponds to $V=$ 300 km. For increasing pollution levels, the visual range decreases from 300 to 2 km as the aerosol concentration increases from zero to 70,000 particles cm^{-3} for urban aerosols (86,000 particles cm^{-3} for rural aerosols) in the boundary layer up to 2 km height. The particle number densities depend strongly on the relative humidity and the particle size distribution[5]. The values given are for a relative humidity of 90%. In the rest of the atmosphere (up to 70 km height) a constant (light) background pollution level is assumed: the 'tropospheric' aerosol model[5] up to the tropopause and the 'background stratosphere' model[5] above the tropopause. This background aerosol is considered to consist largely of sulphate particles formed by photochemical reactions. Aerosol angular scattering is represented by a height-dependent Henyey–Greenstein phase function:

$$P(\theta, z)=\omega_0(z)[1-g^2(z)][1-g^2(z)-2g(z)\cos\theta]^{-3/2} \quad (1)$$

where ω_0 is the aerosol single scattering albedo, and g is the asymmetry parameter. The total phase function is the appropriately weighted average of Rayleigh (molecular) scattering and aerosol scattering as a function of height, z.

Our new calculations use a highly efficient and versatile radiative transfer code[9] in which we incorporate the detailed atmospheric data base described above[10]. The computational method is based on the finite-element discrete-ordinates solution of the radiative transfer equation and has been verified[11] against other calculations and actual telephotometer measurements. The computations include the anisotropic scattering characteristics of aerosols, according to equation (1), as well as the detailed vertical distribution profiles for aerosols, molecular scatterers (mainly Rayleigh scattering) and absorbers, as described in the AFGL data. All orders of scattering are taken into account.

We compute the total solar irradiance at ground level for 42 wavelength bins in the photosynthetically active regime from

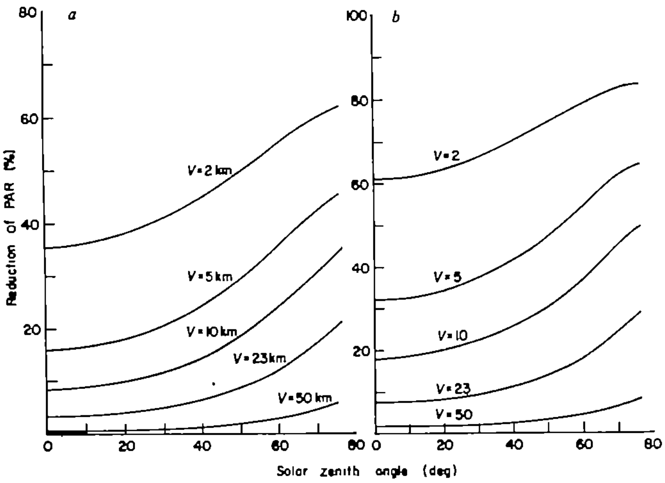

Fig. 1 Per cent reduction of photosynthetically active radiation (PAR) for corn plotted against solar zenith angle. Degree of air pollution is indicated by the surface visual range, *V*. *a*, Mid-latitude summer atmosphere with rural aerosols in boundary layer. *b*, Mid-latitude summer atmosphere with urban aerosols in boundary layer.

0.35 to 0.72 μm assuming varying aerosol concentrations in the 2 km surface boundary layer. A measure of the biologically effective irradiance is the PAR, defined by

$$\mathrm{PAR} = \int_{\lambda_1}^{\lambda_2} P(\lambda) I(\lambda, Z_0)\,\mathrm{d}\lambda \qquad (2)$$

where $I(\lambda, Z_0)$ is the spectral irradiance at ground level for the solar zenith angle Z_0, and $P(\lambda)$ denotes the photosynthesis action spectrum for a particular plant. Equation (2) broadens the conventional definition of PAR by introducing the weighting function $P(\lambda)$, a convenient way of characterizing the special response of a specific plant species; λ_1 and λ_2 are the wavelengths for which $P(\lambda)$ tends to zero. Photosynthesis action spectra measured for 22 crop plants[12,13] were found to be fairly similar. Therefore, we report here only our results for corn, which is typical of most agricultural crop plants.

Figure 1 shows the percentage reduction of PAR compared with clear air for five different surface visual ranges that arise when the amount of rural or urban aerosols in the 2 km boundary layer is increased. The increasing values for all curves with increasing solar zenith angle are clearly due to the increased path length for the solar radiation as it passes through the atmosphere at larger angles of incidence. Any fixed solar zenith angle may be thought of as an effective zenith angle, determined as a daily average over the continuously varying direction of the Sun at a given date and latitude[11]. For example, for the northeastern United States during the summer months, an effective solar zenith angle of 55° is appropriate. In this case we conclude from Fig. 1*a* that if the visual range due to rural aerosols decreases to 10 km, the PAR for corn will be reduced by about 20% compared with clear air conditions. For urban aerosols (Fig. 1*b*) the respective PAR reduction is 33% for the same visibility degradation. In the case of more severe pollution, the calculated PAR reduction increases nonlinearly to very high values, for example, for $V = 2$ km, urban aerosols and $Z_0 = 55°$, we obtain a 75% PAR reduction. As a typical example, a visibility of 20 km (10 km) and more has been observed[14] over the Chicago Metropolitan area for only 40% (70%) of the time between 1970 and 1972.

We note that in the solar radiation measurements of McCartney[15], only small turbidity changes ranging from 0.1 to 0.5 were found. However, when the visual range decreases from 50 to 5 km, the turbidity coefficient (average optical depth, τ) increases from 0.1 to 1.0. The intensity of direct sunlight, which is proportional to $\exp(-\tau)$, therefore decreases by about 60% while the diffuse radiation field due to multiple scattering increases.

The large calculated PAR reductions demonstrated here may appear alarming. Note, however, that any reduction in photosynthetically active radiation cannot be translated directly into an equivalent crop yield reduction because many additional effects in plant physiology and local climatology must be considered also.[16,17]. For example, the so-called C_3 plants reach saturation of their daily photosynthesis at radiation intensities of about one-third full sunlight. Other species, for example the C_4 plants like sugar cane and maize, increase their net photosynthesis continually up to very high irradiance. Also, if constant high air pollution levels are considered, shifts in the main growing season may occur that also affect plant growth and crop yield. Therefore, to estimate quantitatively the influences of our calculated PAR reductions on crop yield, an additional dynamics system study is required for which our model results could be used as input.

We thank Dr Dan Golomb (Center for Energy Policy, MIT) and Dr John Bachmann of the US Environmental Protection Agency for their guidance and technical assistance during the project.

No significant deviation from random mating of worldwide populations of *Drosophila melanogaster*

N. R. Henderson & D. M. Lambert

Department of Zoology, University of Auckland, Private Bag, Auckland, New Zealand

Multiple choice experiments using 29 populations of *Drosophila melanogaster* from around the world were performed to measure any divergence in the mating system of this species. Courting flies were observed in a total of 691 mating experiments and 9,280 copulations. Only two of the 38 interpopulation crosses exhibited a significant divergence from random mating. However, neither of these represent a trend towards positive assortative mating. This suggests that there is considerable stability in the mate recognition system of *D. melanogaster* in spite of the substantial genetical and morphological differentiation which exists throughout the cosmopolitan distribution of this species.

Components of mating success in *Drosophila*. are under genetic control[1] and in laboratory populations the component of darwinian fitness which includes the 'selection' of mates is important in determining reproductive success[2–4]. Genetically based variation in 'premating isolating mechanisms' occurs among geographically separated populations of a species[5–7], either as a result of selection, genetic drift, or both[5,8,9]. Although much is known about the genetics of reproductive behaviour of *D.melanogaster* in the laboratory, studies have mainly used

Table 1 Results of multiple choice experiments among populations of *Drosophila melanogaster*

The experiments were performed at 25 °C by direct observation, a technique originally devised by Elans and Wattiaux[10]. For each experiment 11 virgin males and females of one strain, plus 11 virgin males and females of a second strain, a total of 22 pairs, were used for every set of two strains. Fours types of mating could thus be observed:

♂♂1×♀♀1, ♂♂2×♀♀1, ♂♂1×♀♀2, ♂♂2×♀♀2.

Flies were kept separately for 5–7 days and then introduced into a mating chamber and observed at 6-min intervals for 1 hour. This duration allows for about 60% of the females to mate. Records were made of the number of within and between strain matings. In order to distinguish the flies of the different strains through the transparent cover of the observation chamber, a small dot was painted on the dorsal surface of the thorax with non-toxic ink (Rotring). This marker was rotated from strain to strain, so that no one strain in any combination of two strains tested together, always had the thorax painted. Painting was perfomed on lightly etherized flies at the same time as they were 'sexed' after emergence. Marking was found to have no effect on the strains studied here. All experiments were conduted between 0900 and 1200 hours. All experiments for any one cross were run on the same day. For analysis of the data, comparison with panmixia the χ^2 test was used. In addition isolation was measured by Levenes joint index[11,12]. The number of males and females of the two strains being equal, let the observed number of matings of the four possible types be given by:

	Strain 1 (♀♀)	Strain 2 (♀♀)
Strain 1 (♂♂)	X11	X12
Strain 2 (♂♂)	X21	X22

Levene defines the Joint isolation index as:

$$ZI=\sqrt{\frac{X11\cdot X22}{X12\cdot X21}}$$

ZI = 1 Means random mating. ZI > 1 Means a tendency to homogamic mating. ZI < 1 Means a tendency to heterogamic mating.

The exact distribution of these statistics is unknown but practical tests of significance can be based on the following estimates of variance:

$$\sigma^2(ZI)=\frac{(ZI)}{(4)}H \text{ where } H=\frac{1}{X11}+\frac{1}{X12}+\frac{1}{X21}+\frac{1}{X22}$$

* $P<0.05$, 3d.f.

mutant strains or well established wild-type cultures. We know surprisingly little about the genetic dynamics of the mating systems of natural populations. In order to test for any geographic differences in the male-female communication system, multiple choice experiments[10] were conducted among 29 populations derived from diverse localities around the world (Fig. 1). Wherever possible each population was derived from a large number of recently collected individuals, and populations were kept for only a short time before use. Thirty-eight crosses between localities were undertaken and results were tested for deviations from random mating using a chi-squared test (Table 1). This does not, however, indicate the degree and nature of the mating preference should a significant result appear and for this purpose the degree and nature of any mating divergence was measured using Levenes joint isolation index[11].

The data show no significant deviation from random mating. Only two crosses resulted in a significant deviation and neither of these are the result of a tendency to mate within populations. The cross between the two Russian populations 26 and 24, for example, is significant because males of population 24 have a higher propensity to mate. The remaining cross which yielded a significant result, cross 4 × 14, was the result of a higher mating propensity on the part of females of population 14.

Previous studies of natural populations of *D. melanogaster* involved crosses between French, Japanese and Afrotropical strains[12,13], also showed a lack of divergence. Our techniques were very similar so we propose that this is a general characteristic of populations of *D. melanogaster*. There is a similar lack of divergence in mating behaviour of populations of *D. pseudoobscura*, from western United States and Mexico[14]. The latter authors point out, however, that the opposite result is common in interpopulation crosses involving *Drosophila*

species. They list 21 previous studies, 19 of which cite data showing significant variation in mate recognition. However, they have a number of reservations regrading this result and it remains whether this is a general characteristic of natural populations or a result of experimental technique.

Our results can be interpreted in two possible ways. First, recent dispersion of *D. melanogaster* may have allowed little time for the development of genetic differences between populations. Alternatively, populations of *D. melanogaster* have indeed differentiated genetically in elements of their biology, but stabilising selection acting on the reproductive communication system has prevented it from diverging.

If there is an overall lack of divergence then our results are not surprising. However, recent research on the biology of natural populations of *D. melanogaster* has revealed considerable genetic differences, including biometry[16–20], electromorphs[21,22], chromosomal inversion frequencies[23,24], morphological mutant phenotypes[25], ecology[26,27], physiology[19]. These differences may be the result of selection in different local conditions. Recent investigations of hybrid dysgenesis[28–30] in *D. melanogaster* indicate that potential for 'postmating reproductive isolation' exists among geographically diverse populations. Why then have the genes controlling mating behaviour apparently resisted such change? Deviation in mating behaviour of laboratory populations of *D. melanogaster* has been recorded by Kilias *et al.*[31]. However, this may be due to non-genetic changes in mating rhythms which if corrected for, may result in no significant deviation for example ref. 32.

The second interpretation of our data is that stabilizing selection exerted through the interactions of the organisms themselves, acts on the reproductive communication system to maintain its stability. The function[33] of this male–female communication system is to facilitate the achievement of efficient syngamy in the conditions prevailing in the habitat of the organisms[34]. It has been argued (see ref. 33 for a recent view), that individuals with a deviant mate recognition system, would obtain less matings than those members of the population performing the correct sequences[34–36] that are necessary for successful reproduction. These deviant individuals would thus be less fit. It might be expected then that the mate recognition system should show a degree of geographic stability[37] and the data presented here support this prediction.

We are grateful to the following workers who sent us wild caught material: J. D. Agnew, S. M. Akai, S. Alahiotis, H. M. Bicudo, W. W. Cantello, A. W. Ewing, R. Falk, A. Fleuriet, M. D. Golubovsky, A. Birth sex ratios and social rank in rhesus monkey mothers

M. J. A. Simpson & A. E. Simpson

MRC Unit for the Development and Integration of Behaviour,
Madingley, Cambridge CB3 8AA, UK

The ability to control the sex of her offspring could be of survival value to a mother[1,2], and prompts questions about mechanisms of sex determination. Trivers and Willard have suggested that mothers potentially able to invest much in offspring should bear those kinds of infant that repay high levels of maternal investment most effectively[2]. One hypothesis concerning matrilineal primate species states that a dominant mother would leave more descendants through a daughter rather than a son if that daughter inherited her high rank[3–6]. On the other hand, a low ranking mother of such a species would leave more descendants through a son, for he is likely to emigrate at puberty and not necessarily inherit his mother's low rank[6]. Unfortunately, long-term data on primate birth sex ratios are in short supply. Here we present data collected over 20 years on a captive colony of rhesus monkeys which support the above hypothesis. High ranking rhesus monkey mothers in our captive colony[7] were more likely to give birth to daughters than sons, while the remaining mothers were more likely to bear sons than daughters. Finally, we suggest a mechanism for adjusting birth sex ratios in macaques.

The conceptions and pregnancies referred to in this study occurred in six small social groups of rhesus monkeys (*Macaca mulatta*). Each group was housed in its own indoor room with adjoining outdoor run, at the Subdepartment of Animal Behaviour, near Cambridge[7]. There were 7–12 monkeys in each group—one adult male, two to five adult females (at least 4 yr old), and immature offspring born into that group. The groups shared the same building so that every monkey could see and hear every other one. As far as possible, families of mothers and their female offspring were kept in their original groups. We removed young males before their fifth years, and changed incumbent adult males often enough to prevent them from impregnating their daughters. In this paper our data exclude pregnancies resulting from matings arranged with males held apart from the mother's home group. Also excluded are pregnancies spent partly away from the home group.

Rhesus monkey mothers having high social ranks gave birth to twice as many daughters as sons (Table 1 (1960–82), $P = 0.0026$, binomial test[8]), while the remaining mothers bore more sons than daughters ($P = 0.024$, binomial test). (Among the non-high ranking mothers, middle and low ranking ones did not differ in their birth sex ratios.) The effect of maternal dominance on birth sex ratio was consistent from the 11-yr period preceding 1972 to a subsequent 10-yr period. Most mothers contributed more than one infant to Table 1, but when each mother was classified according to whether she bore more daughters than sons or vice versa, the contrast in birth ratios between high ranking and other mothers was still apparent (Table 2, $P = 0.03$, 0.03 and 0.001 for the three time periods, Fisher exact probability test). The effect also shows in first births to the mothers (Table 3, P = not significant, 0.02 and 0.10 for the three time periods, Fisher exact test), suggesting that it could be independent of a mother's previous reproductive history.

Table 1 Number of infants of each sex born to mothers of different ranks

Births between:	1960–71		1972–81		1960–81	
	Daughters	Sons	Daughters	Sons	Daughters	Sons
High rank mothers	18	6	20	9	38	15
Other mothers	7	15	25	39	32	54

A total of 53 mothers and 139 births are included in the sample. All conceptions and pregnancies occurred in the social group. Eight infants dying between their first and fourteenth days, and all available (16) sexed stillbirths are included. Social ranks of mothers living in small captive groups[7] were assessed before we knew of their possible connection with birth sex ratios. In practice, a high ranking mother is easily recognized as dominating the other females in her group. To represent the mother's rank at the likely time of conception, we used her rank when the resulting infant was 52 weeks old, for in only 20 cases did we have information about the mother-to-be's rank at conception. In none of these cases was there a change between the two rank positions. Information about the ranks of mothers with younger infants was not used because their greater dependence could have influenced their mothers' ranks. From 1960 to 1971, assessments of rank were made by earlier observers[22]. Thereafter, attacking, chasing, displacing, avoiding, fear grinning, and presenting (non-sexual, non-grooming context) between a pair of monkeys were regarded as evidence for dominance. In any dyad, one monkey was deemed dominant to the other if their actions occurred three or more times as often in one direction as in the other. A mother's rank reflects the direction but not necessarily the rate of aggressive behaviour between herself and others. A high ranking female would not be aggressive so long as the others avoided her, but the others could be fighting among themselves at a high rate.

Altmann[3] showed the same effect in free-living yellow baboons (*Papio cynocephalus*), her ratios being 18:10 daughters to sons for high ranking mothers, and 8:15 for the remainder. Silk's[4] low ranking (captive) bonnet macaques (*Macaca radiata*) gave birth to 20:44 females to males, although females from the top half of the hierarchy did not have more daughters than sons.

Until we know more about the mechanisms controlling birth sex ratios and the ways in which social factors operate[1], hypotheses about the adaptive significance of birth sex ratios

Table 2 For mothers holding only one rank across all their infants, the number of mothers of each rank who produced more daughters than sons, or sons than daughters

	1960–71		1972–81		1960–81*	
	More daughters	More sons	More daughters	More sons	More daughters	More sons
High rank mothers	7	2	5	0	9	0
Other mothers	3	10	5	10	8	17

Some mothers contributed infants to both time periods, and 13 mothers who changed rank were excluded.

* Six mothers (three high, three other) had equal numbers of daughters and sons.

must remain tentative, for the mechanism acting in our colony may be triggered by as yet unspecified special conditions in it. Meanwhile, we believe that our socially living mothers bias the birth sex ratios of their offspring according to some aspect of their dominance rank. Such a mechanism would have survival value for high ranking rhesus monkey mothers if daughters best repaid their mothers' high levels of maternal investment in them. This is a general form of the Trivers and Willard hypothesis[2] that mothers potentially able to invest much in offspring should bear and rear the kinds of infants repaying the highest levels of maternal investment most effectively. Such infants could be daughters in some socially living macaque and baboon species[3,4], although they were believed to be sons in the cases considered by Trivers and Willard.

In support of our view, rhesus monkey daughters remain with their mothers and inherit their mothers' social ranks[5], so that a high ranking daughter could contribute more to her mother's fitness by aiding in interfamily fights[9] and by breeding more successfully[10] than a son, who is likely to emigrate at puberty[11–13], and not necessarily achieve high social rank in the group he subsequently joins[6].

However, daughters bring costs as well as benefits to their mothers, for example by competing with each other within their families, and 1- and 2-yr-old females in our colony are especially likely to behave with jealousy and aggression to their mothers and subsequently born siblings[14]. Emigrating sons of high ranking mothers could take with them certain advantages gained from their mothers' statuses even if they did not retain their mothers' ranks.

Table 3 Number of infants of each sex born to primiparous mothers of different ranks

	1960–71		1972–81		1960–81	
	Daughters	Sons	Daughters	Sons	Daughters	Sons
High rank mothers	1	2	4	0	5	2
Other mothers	1	1	3	11	4	12

In the second time period, while 11 'other' mothers had sons as their first infant, only 10 went on to have more sons than daughters (see Table 2).

Functional arguments can be applied to low ranking mothers also. A daughter of a low ranking mother may share with her mother the disadvantages of low rank, including poorer breeding performance[15], while an emigrating son, whose rank is not thereafter tied to his mother's, may gain sufficient rank in his new social group to contribute considerably to his mother's fitness. In addition, young daughters may be more costly to rear than sons, being more involved in family strife, and bringing more aggression to their mothers from other adults[4]. Mothers were also slower to breed again after bearing daughters rather than sons[16].

However, these functional arguments depend partly on results from other social groups and species. To assess the balance of costs and benefits for high and low ranking mothers rearing sons and daughters, we need to know both the costs and the benefits to individuals through the reproductive lives of themselves and their offspring[10].

The mechanisms whereby these sex ratios are controlled is unknown[1]. Differential effects of stress on the proportions of XX- and XY-bearing sperm reaching the ovum[3], or on the post-conception survival of male and female fetuses[17] would explain our bias away from daughters in the births to low ranking mothers, if XX-sperm and/or female fetuses were more vulnerable, and low rank were associated with greater stress. Potentially stressful situations, however, did not increase the chance that our mothers would bear sons: 10 mothers scoring above the median on both aggression received from other adults and submissive behaviour given to others (see Table 1) did not give birth to more sons than daughters. Moreover, a stress hypothesis could not explain our bias towards female births in high ranking mothers.

We suggest that rhesus monkey mothers, like white-tailed deer[18], could adjust the sex ratios of their infants if they controlled the timing of mating relative to ovulation. At present we know of no supporting evidence from non-human primates, although in human beings weak biases towards males have occurred when zygotes are formed early or late in the fertile period rather than in the middle[19], and biases towards females occurred when gonadotropin levels were deliberately made high[20]. The question of how the timing of female sexual behaviour close to the time of ovulation depends on the mother's social situation[21] remains open.

Use of the UCHT1 monoclonal antibody to explore mouse mutants and development

K. W. T. Caddy, D. L. Patterson & T. J. Biscoe

Department of Physiology, University College London,
Gower Street, London WC1E 6BT, UK

Garson and Coakham demonstrated a monoclonal antibody (UCHT1) which specifically labels Purkinje cells in the cerebellar cortex[1]. To investigate mouse mutants with cerebellar lesions, we obtained some of the purified antibody from Beverley[2], who derived it as an antibody to a human T-cell lymphocyte surface antigen. We have used the indirect immunoperoxidase method to label with the antibody Purkinje cells in mutant and normal mice, frog, toad, goldfish, dogfish and 3-acetylpyridine-treated rat. We report here that in the mutant mice tested, only the Purkinje cells in *staggerer* did not stain. The Purkinje cells of frog, toad and goldfish were also unstained but those in the dogfish were labelled. The Purkinje cells in rats which had been injected with 3-acetylpyridine to destroy the climbing fibres, were found to stain with the antibody. These results suggest phylogenetic as well as ontogenetic differences in antigenicity of Purkinje cells.

The cerebella in the mutant mice used all have different, well defined lesions: *stumbler* Purkinje cells have stunted dendritic trees[3]; *Lurcher* loses all its Purkinje cells in the first 60 days abter birth[4]; *weaver* loses all of its granule cells and has abnormal Purkinje cell dendritic trees[5]; *reeler* has a disorganized

0028–0836/82/480441—03$01.00

cerebellar cortex with Purkinje cells in abnormal positions[6], and *staggerer* has reduced numbers of Purkinje cells[7].

Mutant and littermate control animals were all aged between 15 and 20 days postnatal when used for these initial experiments because *Lurcher* begins to lose significant numbers of Purkinje cells after 15 days. The *stumbler, Lurcher, weaver* and *reeler* mutants all showed positive staining of Purkinje cells with UCHT1. In all cases the whole of the Purkinje cell was labelled; the cell body (excluding the nucleus), the dendritic tree, and the axon, which could be traced in some cells all the way to the deep cerebellar nuclei. With this labelling, the abnormal Purkinje cell dendritic trees were seen as described previously in Golgi preparations[3,4,8,9].

In the *staggerer* mutant, however, the Purkinje cells were completely unstained. Figure 1*a, b* shows sections of a control and *staggerer* cerebellum stained with UCHT1 using the indirect immunoperoxidase technique. These sections were not counterstained and were photographed using Nomarski optics to allow Purkinje cells unlabelled by antibody to be seen in the *staggerer* section (Fig. 1*b*).

There was a difference in staining between the control and *stumbler* Purkinje cells. In control animals the staining was uniform whereas in *stumbler* the horseradish peroxidase (HRP) gave a clumped appearance with numerous small clear areas (Fig. 1*c, d*). These abundant clear areas are almost certainly due to the large numbers of mitochondria present in the soma of *stumbler* Purkinje cells[3].

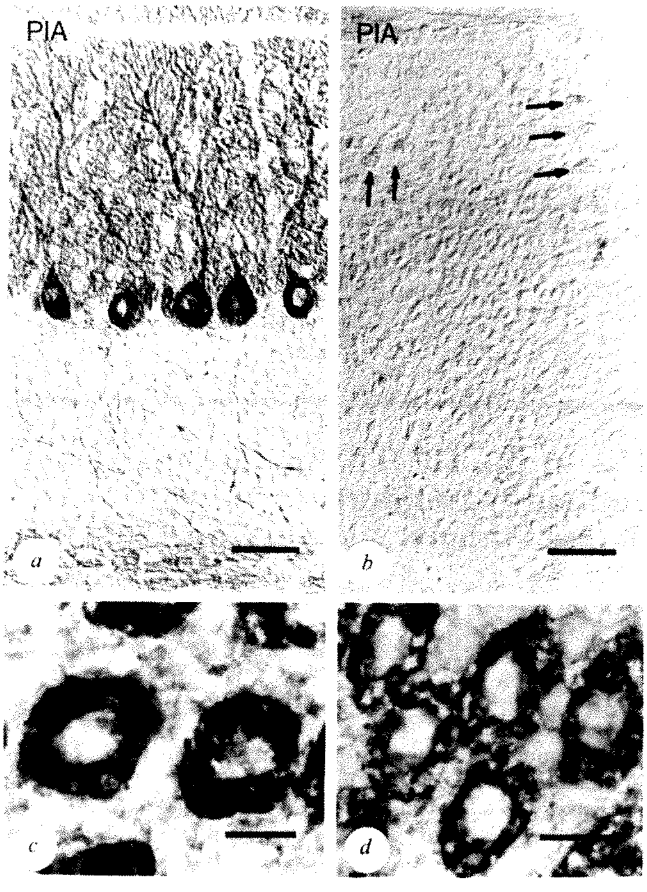

Fig. 1 *a, b,* Sagittal sections of cerebellum of 20-day-old normal and *staggerer* mice, respectively, stained by UCHT1 using the indirect immunoperoxidase technique. Cryostat sections (6 μm) were fixed for 5 min in acetone, incubated for 30 min with a purified IgG fraction of the UCHT1 ascites diluted 1:1,000, washed for 5 min in Tris-buffered saline, and then incubated for 30 min at 20 °C with HRP-conjugated rabbit anti-mouse immunoglobulin (DAKO; 1:100). The peroxidase was visualized using 0.6 mg ml^{-1} diaminobenzidine. Sections were photographed with a Leitz orthoplan microscope and Vario-orthomat camera using Nomarski optics. Arrows in *b* indicate unstained Purkinje cells. Scale, 50 μm. *c, d,* Sagittal sections of Purkinje cells from 19-day-old normal and *stumbler* mice, respectively, stained with UCHT1 and counterstained with haematoxylin. Note that the HRP appears more clumped with numerous small clear areas in the *stumbler* Purkinje cells because of the increased numbers of mitochondrial profiles in these cells. Scale bar, 10 μm.

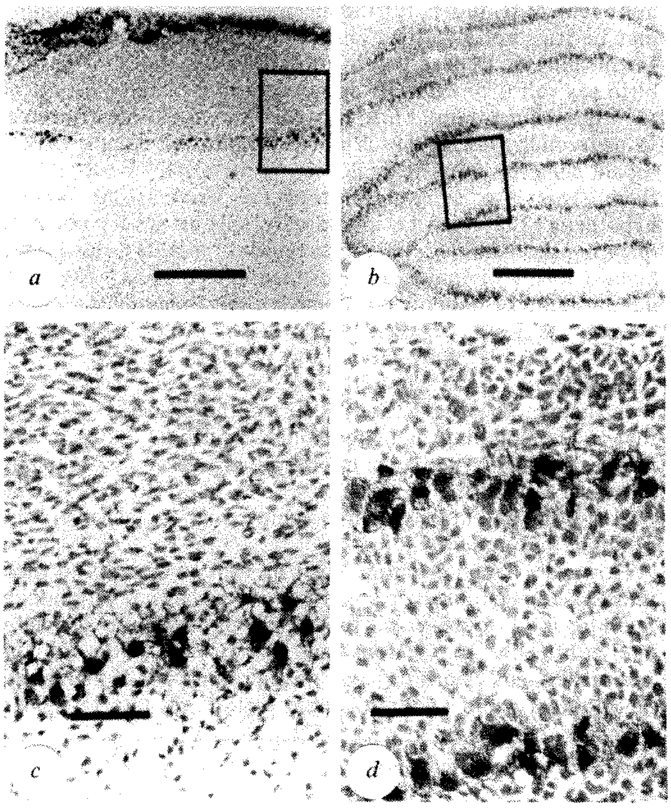

Fig. 2 *a, b,* Horizontal 6-μm sections of 2- and 3-day-old normal mice cerebella stained with UCHT1 and counterstained with haematoxylin. Note the patchy staining of Purkinje cells in *a*. Low power bright field; scale bar, 500 μm. *c, d,* Areas within rectangles in *a* and *b* shown at higher magnification. Scale bar, 50 μm.

We also studied the labelling pattern of normal mice aged 0 (birth), and at days 1, 2, 3, 5 and 8 postnatal. At time 0 and on day 1 the Purkinje cells were found not to stain with UCHT1 but at day 2, patches of stained Purkinje cells were clearly visible (Fig. 2*a, c*). At day 3 (Fig. 2*b, d*) and for all subsequent ages, the Purkinje cells stained as in the day 20 normal control, except that the Purkinje cells at less than 8 days old were noticeably less mature.

We know that between 2 and 3 days postnatal, the age at which the particular antigen appears, the mouse climbing fibres first start to form synapses on the Purkinje cells via somatic spines (K.W.T.C., unpublished observations). Two studies[10,11] indicate that although the synapses of the climbing fibres are present in the *staggerer*, they are not functional except after injection of harmaline; this suggests that the presence of climbing fibres may be correlated with the presence of the antigen. To examine this hypothesis, we treated rats with 3-acetylpyridine, harmaline and nicotinamide[12] to destroy selectively the inferior olivary nuclei, which are believed to be the sole source of climbing fibres[13]. Our experiments showed no change in the Purkinje cell labelling in any part of the cerebellar cortex. We conclude that the continued presence of climbing fibres is not a requirement for the presence of the antigen in Purkinje cells.

The possibility remains that the appearance of the antigen correlates with the appearance of the climbing fibre innervation. This would explain our findings with the young animals but not the results with the *staggerer* mutant. In *staggerer* it has been shown that the development of the Purkinje cells is retarded[14] to the extent that climbing fibre synapses are still present on somatic spines of animals 23 days after birth. It has also been shown that *staggerer* Purkinje cells have no parallel fibre–dendritic spine synapses[15]. This failure to form branchlet spines in *staggerer* is almost certainly due to some inherent defect in the Purkinje cells since these cells have been shown to be the site of action of the mutant gene[16]. Whether or not the absence of the antigen in *staggerer* is causally related to the *staggerer* disorder is an open question.

To determine any further possible correlation between the presence of the antigen and the structure of the cerebellum, we have extended the survey of the animal kingdom begun by Garson *et al.*[1]. The species tested were frog (*Rana temporaria*), toad (*Rana esculenta*), goldfish (*Carassius auratus*), dogfish (*Scyliorhinus canicula*) and pigeon. We used the indirect immunoperoxidase method to label Purkinje cells in at least two of each of these species. Although this study is at best preliminary, it is of interest to note that only in the dogfish and pigeon did the Purkinje cells stain. This finding is interesting because Llinas and Hillman[17] have shown that the cerebellum of the elasmobranchs is more complex than that in frog and other amphibia. By this they mean that there are fewer cell types in the frog (basket cells missing) and the Purkinje cells are less complex. In fact, the Purkinje cells in the frog have far fewer spiny branchlets on their dendrites than elsasmobranchs and probably present a more primitive form of cerebellar cortex[17]. The similarity in the gross morphology between *staggerer* and frog Purkinje cells may be of importance in this context.

It seems that the antigenic determinant for UCHT1 is absent from some species, from at least one mutant mouse and also from mice less than 2 days old. At this stage it is impossible to correlate the antigen with any structure in Purkinje cells but we hope that further electron microscope and biochemical studies may elucidate its location.

We thank Drs Garson and Coakham; Dr P. Beverley of the Imperial Cancer Research Fund, University College Hospital for the gift of the UCHT1; N. Bowery, A. Warner, G. Falk and M. Whitear for supplying the *staggerer*, *reeler* and *weaver* mutant mice, toad, dogfish and goldfish. This research was supported by Action Research.

Meitoic crossing-over between the X and Y chromosomes of male mice carrying the sex-reversing (*Sxr*) factor

E. P. Evans* & M. D. Burtenshaw

In the mouse, as in many other species, the X and Y chromosomes are seen to pair end-to-end at diakinesis[1], which has led to speculation as to whether chiasmata and crossing-over occur earlier in meiosis[1]. Arguments in favour of this have recently been presented[2–4], but because of the absence of appropriate genetic and cytological markers little clear-cut evidence has been obtained. Studies with 'sex-reversed' (*Sxr*) mice[5] carried out earlier this year[6] have suggested that the transfer of chromatin from the Y to the X chromosome takes place during meiosis, but in this instance the interpretation was confused by the claim that X/Y *Sxr* mice possess two Y chromosomes, contrary to earlier reports[7]. We present evidence here that: (1) X/Y *Sxr* mice have a single abnormal Y chromosome possessing an additional dark-staining distal body; (2) during meiosis, this body is transferred by crossing-over from one chromatid of the Y to one chromatid of the X. Furthermore, closer inspection of XY bivalents in mice not carrying *Sxr* suggests that crossing-over is a normal feature of X–Y pairing, and may be a necessary requirement for the production of functional sperm. Details of the mode of inheritance of *Sxr* are given in Table 1.

Thorough examination of the karyotype of X/Y *Sxr* males and their X/Y non-*Sxr* sibs showed no gross departure from the standard XY karyotype, and it was concluded that the claim for the existence of an X, Y, Y1 system[6] resulted from misinterpretations of the precocious separation of the Y chromatids at mitotic metaphase when prolonged colcemid treatments are employed (see also refs 2–4), and of the unusual configurations adopted by the X and Y chromosomes in the sex vesicle during meiotic prophase[8,9].

Detailed analysis of the mouse Y chromosome is difficult as in metaphase of mitosis it frequently shows uniformly dense staining after G-banding[10], and even if bands are revealed they are often distorted by coiling. In the accepted nomenclature[10] the chromosome is described as being composed of five major bands (Fig. 1*a*) but the authors included the proviso that examples from some strains might reveal variant banding patterns. We would add that many, if not all, mouse Y chromosomes have a short arm[11], and in the case of the elongated examples from the control mice studied here, reveal further bands on their long arms (Fig. 1*b*).

Examination of the Y chromosome of X/Y males from the *Sxr* stock (Table 1) revealed that whereas X/Y non-*Sxr* animals possessed a normal appearing Y, the Y of X/Y *Sxr* males possessed an additional constricted dark-staining distal band or body (Fig. 1*c*). In midmetaphase this caused the proximal and distal ends of the Y to be so similarly marked that it became difficult to orientate the chromosome with respect to its centromere. However, the distal body stained in a reverse manner to the centromeric or proximal region of the chromosome, being dark in the early stages and becoming progressively lighter as metaphase proceeds.

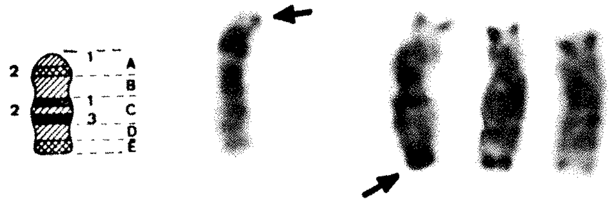

Fig. 1 *a*, The accepted standard idiogram of the mouse Y chromosome[12]. *b*, G-banded, elongated Y from a bone marrow cell of a normal (control) XY male mouse, showing evidence of a short arm (arrowed) and further bands on the long arm. Control mice are derived from the 101/H, Ju/FaCt and Q (Falconer) strains among which no clear Y chromosomal differences were found. *c*, G-banded Y chromosomes from bone marrow cells of an X/Y *Sxr* mouse. Left: in early metaphase, showing the additional, heavily stained, distal body (arrowed). Centre: in midmetaphase, showing the equivalent staining of proximal and distal ends. Right: in late metaphase, showing the fainter staining of the distal body with mitotic progression.

0028-0836/82/480443—03$01.00

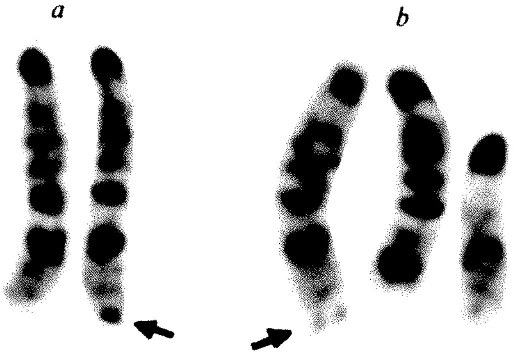

Fig. 2 *a*, G-banded X chromosomes from a bone marrow cell of an X/X *Sxr* male. Left: the normal X; right: the X has an additional, dark-staining, distal body (arrowed). *b*, G-banded X chromosome from a bone marrow cell of an X/X *Sxr* male carrying the T(X: 16)16H X-autosome translocation. Left: the paternally-derived normal X showing the distal body (arrowed).

The X chromosome in mitotic cells of X/Y *Sxr* males was observed to conform to the normal banding pattern of this chromosome[10], as were both X chromosomes from their X/X daughters. However, although one X of their X/X *Sxr* sons also looked normal, the other X possessed a dark-staining body at its distal end (Fig. 2*a*). Furthermore, in X/X *Sxr* males carrying the T(X;16)16H X-autosome translocation it was always the paternally-derived, non-translocated X chromosome that carried this body (Fig. 2*b*).

Meiotic studies at diakinesis in X/Y non-*Sxr* males (the X/Y progeny of X/Y *Sxr* mice shown in Table 1) and X/Y (from unrelated stocks) controls showed that in most spermatocytes the X and Y chromatids paired distally with a clear line of separation between them (Fig. 3*a*). In X/Y *Sxr* males the pairing was also distal but one pair of the X and Y chromatids showed more contact by way of two dark staining bodies (Fig. 3*b*), one on the X and the other on the Y. The bodies were always adjoining and not diagonally opposed, which indicated that a chiasmate exchange had occurred whereby the body had crossed over from one chromatid of the Y to one of the X. Confirmatory evidence of the exchange was provided by metaphase II observations of X and Y chromosomes with single chromatids marked by the dark-staining distal body. Another feature of the first meiotic division of X/Y *Sxr* males is a higher than normal frequency of X–Y univalence which, at diakinesis, may vary from 70 to 90%, as against 5 to 10% in the X/Y non-*Sxr* sibs[7]. In many, if not all, spermatocytes with X–Y univalence dark-staining bodies were observed on both chromatids of the Y with none of the X (Fig. 3*c*), suggesting that pairing failure in meiotic prophase gives no opportunity for transfer.

Our observations with *Sxr* mice indicate that *Sxr* represents a Y rearrangement in which part or all of the male determining region has been transferred from a relatively proximal location on the chromosome to the distal end where, by crossing-over, it can be transferred to the X and thus cause male development in X/X *Sxr* mice (see also refs 2–4). Our mitotic observations with X/Y *Sxr* animals, however, showed no evidence of any chromosomal change in the Y other than the addition of the distal, *Sxr* body. We therefore conclude that the original rearrangement involved either, (1) part of a multiple copy sex-determining region the loss of which from its normal location we cannot distinguish cytologically, or, (2) all or most of this region transferred by excision from one chromatid[5] and attached onto the distal end of the other. Our meiotic observations clearly show that *Sxr* is inherited in a simple manner after the formation of a regular chiasma and a cross-over taking place between the distal regions of the X and Y. Such a configuration produces four different classes of chromatid, X, X with *Sxr*, Y and Y with *Sxr*, which, when transmitted by the gametes, satisfies the segregation ratios observed in the progeny of X/Y *Sxr* males[7]. Pairing failure gives no opportunity for crossing-over and is manifested by X–Y univalence which, from our metaphase II observations appears to act as a cell lethal.

It may seem surprising in view of the many past cytological studies on *Sxr* mice that the *Sxr* body and its Y to X transfer has gone undetected. In part this may have been due to the fact that the apparent autosomal dominant inheritance focused attention primarily upon the autosomes. However, at the mitotic level, failure may also have been due to the staining vagaries of both the Y and the distal, *Sxr* body; at the meiotic level, to the best of our knowledge, no G-band analyses have previously been attempted on the condensed stages and at the synaptonemal complex (SC) level, any possible differences between X and Y pairing in carrier and non-carrier mice might have been obscured by synaptic adjustment[12].

The question of greatest significance which remains is whether crossing-over between the X and Y chromosomes is limited to X/Y *Sxr* males, or is typical of all mouse XY bivalents. Reappraisal of normal XY bivalents in the light of our *Sxr* findings suggests that with some there is evidence of an asymmetry caused by a greater continuity of adjoining pairs of X and Y chromatids (Fig. 3*d*), and this could be taken as evidence of a residual chiasma.

However, this behaviour was only observed in a minority of cells. The apparent inconsistency may be resolved by examining the available evidence for the cytologically visible amount of chromatin expected to be exchanged by crossing-over. Studies at the SC level[13] suggests that there is considerable pairing segment between the X and Y chromosomes and the possibility of a fairly large exchange. However, this can be excluded for the following reasons: (1) a cytological reassessment of the large paracentric inversion of the X chromosome[14], In(X)1H, identifies the distal break-point as being in band F3, or even F4, which is the terminal band, and despite this, the sex-bivalent

Table 1 The inheritance of *Sxr*

Cross	X/X♀	×	X/Y *Sxr* ♂
Progeny	X/X♀		X/Y♂
	X/X *Sxr* ♂		X/Y Sxr ♂

The sex-reversed (*Sxr*) factor causes chromosomal females to develop as phenotypically normal, but sterile males[5]. Transmission is through X/Y carrier males and, hence, all X/Y males, whether carrying *Sxr* or not, normally have the same Y chromosome. The mode of inheritance appears to be that of an autosomal dominant, but all attempts to locate *Sxr* on an autosome have failed[7]. A location in an homologous region of the X and Y chromosomes could give the same pattern of inheritance, however[2]. The observed segregation ratios accord well with expectation, the X/X and X/Y classes of progeny usually being distinguished with the aid of an X chromosomal marker gene. Stock maintenance is by crossing X/Y *Sxr* males × F_1 hybrid (C3H/HeH♀ × 101/H♂) females.

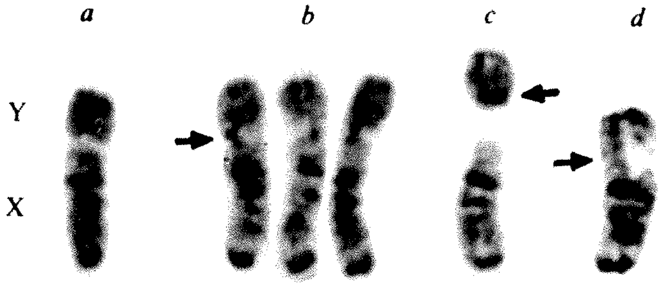

Fig. 3 G-banded X and Y chromosomes at diakinesis. *a*, From a control X/Y male showing the distal pairing of X and Y with a clear line of separation. *b*, Three examples from an X/Y *Sxr* male showing a greater continuity of one pair of adjoining X and Y chromatids by way of two dark staining bodies (arrowed). *c*, Univalent X and Y from an X/Y *Sxr* male showing the retention of the dark staining bodies on both chromatids of the Y (arrowed). *d*, Sex-bivalent from an X/Y non-*Sxr* male showing the greater continuity of an adjoining pair of X and Y chromatids (arrowed) suggesting earlier chiasma formation.

in male carriers shows a near-normal frequency of X–Y pairing at diakinesis, (2) cream (*Crm*), the most distal gene on the mouse X chromosome, lies outside this inversion[16] and yet in male mice with or without the inversion it has never been found to cross-over onto the Y (Lyon, M. F., personal communication). The amount of chromatin visibly available for reciprocal exchange is therefore minimal and the chiasma between the X and Y must be near-terminal, as has previously been suggested from SC studies[16]. It is therefore not surprising that the chiasma is displayed at diakinesis as 'terminalized' and the bivalent as symmetrical in the majority of primary spermatocytes of normal males which do not have the *Sxr* body to serve as a visible cross-over marker. We conclude that in all male mice a small reciprocal exchange between the X and Y is a regular and necessary requirement of meiosis for the production of functional spermatozoa.

In the preceding paper[1], cytological evidence is presented to show that in 'sex-reversed' XX male mice[2] the sex-reversing factor, *Sxr*, is carried on a dark-staining body located on the distal end of the paternal X chromosome. The X-chromosomal location of *Sxr* raises the possibility that it may be subject to the X chromosome inactivation process[3]. However, the regular segregation of *Sxr* and the absence of any indication that intersexes occur with a higher than normal frequency in *Sxr* stocks[4] suggests that either inactivation of *Sxr* does not occur, or, if it does, that the proportion of cells with the *Sxr*-bearing X genetically active is sufficient to ensure normal testicular differentiation. Here we present information on the sexual development of chromosomally XX mice carrying *Sxr* in which the *Sxr*-bearing X chromosome is held in the inactive condition in most if not all somatic cells by use of the T(X; 16)16H (T16H) X-autosome translocated chromosome[5–10] Mice of this genotype were found to develop as normal but sterile males, normal fertile females or intersexes.

That T16H/X *Sxr* animals can develop as males was indicated by two observations. First, the sex ratio among the T16H progeny of the cross of T16H/X females with X/Y *Sxr* males (36:87, Table 1) was not significantly different ($\chi^2_1 = 0.98$) from the 1:3 (females:males) ratio normally found in *Sxr* stocks[4], and also evident among the non-T16H progeny of the cross 36:91, Table 1). Second, examination of the testes of 61 of the 87 males carrying T16H revealed that 17 lacked germ cells and were thus genetically T16H/X *Sxr*[2], and that the remaining 44 possessed germ cells, and were therefore genetically either T16H/Y or T16H/Y *Sxr* (Table 1). Cytological confirmation of the chromosome constitution was obtained in several animals. The T16H/X:T16H/Y plus T16H/Y *Sxr* ratio (17:44) agrees well with the 1:2 expectation ($\chi^2_1 = 0.59$), and provides little reason to suspect that T16H/X *Sxr* animals might develop other than as males. The data at this point therefore suggest that *Sxr* is not inactivated when the X on which it is located is inactivated.

* Based on external sexual phenotype.

Investigation of the T16H females derived from the cross provided reason to modify this conclusion, however. On being test-mated with a normal male, one female produced, among a total of 21 progeny, five X/X *Sxr* sons and two T16H/X *Sxr* sons (Table 2). Clearly, this female must have carried *Sxr*, and this was confirmed by the cytological observation of the *Sxr* body on its normal X chromosome. The occurrence of the T16H/X *Sxr* sons, and also of two non-T16H daughters (Table 2), incidentally provided evidence of meiotic recombination between the T16H breakpoint and *Sxr* in the mother, transferring *Sxr* from the normal X to the T16H X chromosome. Eight other fertile females have now been examined cytologically, and two carried *Sxr*. Thus, among a total of 20 T16H/X *Sxr* animals so far examined, 3 have developed as females and 17 as males. The female development of some T16H/X *Sxr* animals indicates that *Sxr* must be subject to the X-inactivation process in some cells.

Further evidence that *Sxr* can be subject to X-inactivation was obtained from more detailed examination of the T16H/X *Sxr* males. Although all 17 appeared unambiguously male, internally as well as externally, four possessed testes which displayed abnormalities greater than those typically found in X/X *Sxr* (that is, non-T16H) males: their testes tended to be smaller, their tubules appeared more difficult to tease apart than the equivalent sterile tubules of X/X *Sxr* males, and, most strikingly, they were partially covered by blood clots which extended to the epididymis and proximal regions of the vas deferens. One testis from each of these males has been examined histologically and in each one a minor (5–10%) ovarian component was identified. The remaining 13 males possessed histologically normal testes. The occurrence of intersex T16H/X *Sxr* mice is consistent with McLaren and Monk's[11] discovery of three hermaphrodites, with a testis on one side and an ovary on the other, among 10 T16H/X *Sxr* mice.

Two of the three T16H/X *Sxr* females identified have also been examined in detail. In both, the ovaries and reproductive organs were macroscopically normal and the structure of the ovaries was histologically normal. Clearly, therefore, T16H/X *Sxr* mice may show a range of phenotypes from normal male, through intersex, to normal female. An incidental point is that the fertility of the T16H/X *Sxr* females shows that the presence

† Novel XY genotype in which *Sxr* must be carried on the X rather than on the Y.

in the oocytes of the male-determining (*Sxr*) DNA sequences in a form which is presumably genetically active (as both X chromosomes are reactivated at the onset of meiosis[12,13]) does not interfere with their ability to form functional oocytes. This observation is consistent with the finding[14] that XY germ cells could form functional oocytes in a female XX↔XY mouse chimaera.

The gene markers used in the T16H cross (Table 1) clearly showed that the presence of *Sxr* did not modify the non-random X-chromosome activity in the T16H heterozygote. The range of sexual development in animals of a single (T16H/X *Sxr*) genotype therefore suggests that the primary cause is a variable inactivation of *Sxr* in the inactivated *Sxr*-bearing X, generating *Sxr*-active and *Sxr*-inactive populations of cells. As such this may represent a further example of position effect variegation in mammals[15], so far only observed with autosomal loci in certain X-autosome translocations[16,17]. Clearly, secondary factors also must operate in T16H/X *Sxr* mice to influence the final sexual phenotype, and these would include frequency and distribution of the two cell types, the ability of the *Sxr*-active cells to induce *Sxr*-inactive cells to form testicular tissue, perhaps through H–Y antigen coating (as postulated to occur in XX↔XY chimaeras[18]) and also the number of cells in the fetus that form the primordial gonad.

The fact that male development occurs at all in T16H/X *Sxr* mice where the *Sxr*-bearing X is inactive in virtually all somatic cells, indicates that *Sxr* must remain active, although on an inactive X, in a high proportion of cells. Thus, with random X-inactivation, the proportion of cells with *Sxr* inactive must be very low, and it is therefore likely that X/X *Sxr* animals seldom, if ever, develop as females or intersexes due to the presence of *Sxr*. The possibility is, however, being investigated in X/X *Sxr* animals which, because of X chromosome controlling element (*Xce*) allele heterozygosity, have the *Sxr*-bearing X active in only about 30% of their somatic cells[19].

Fertile females produced by inactivation of an X chromosome of *'sex-reversed'* mice

Anne McLaren & Marilyn Monk

MRC Mammalian Development Unit, Wolfson House (University College London), 4 Stephenson Way, London NW1 2HE, UK

Sex-reversed (*Sxr*) is a dominant mutation that confers maleness on X/X *Sxr* mice[1]. Although its mode of inheritance is typically autosomal, all attempts to map *Sxr* to an autosomal chromosome have failed[2]. P. Burgoyne (personal communication) suggested that if *Sxr* were located at the end of the sex chromosomes, distal to a postulated obligatory cross-over in the X–Y pairing segment, it would show such an apparent autosomal pattern of inheritance. To test whether *Sxr* is located on one of the X chromosomes, and is perhaps therefore subject to X-chromosome inactivation, we have examined mice heterozygous for an X-autosome translocation, T(X; 16)H (ref. 3), such that the normal X chromosome postulated to carry *Sxr* is preferentially inactive. Independently, Singh and Jones[4] have now shown by *in situ* hybridization that *Sxr* consists of a duplicated section of Y chromosome material that is indeed translocated to the distal terminus of one X chromatid during male meiosis[5,6]. Our results show that when the X chromosome carrying *Sxr* is preferentially inactivated, fertile T(X; 16)H/X *Sxr* females can be produced, owing to an associated inactivation of the male-determining *Sxr* sequences.

Females carrying T(X; 16)H, hereafter referred to as T16H, and heterozygous for the X-linked enzyme marker *Pgk-1*[7,8], were mated to males carrying *Sxr* and an X-chromosome marker (Table 1). The genotypes of the progeny were deduced as indicated in Table 1. PGK-1 phenotype was determined in order to classify the maternally inherited X chromosome (T16H *Pgk-1*^{b} or X *Pgk-1*^{a}). Male and female *Sxr*-carrying progeny were identified by the presence in their progeny of males with variegated coats after test mating with partners carrying an X-linked coat pattern marker. Sterile males were analysed by a combination of testis weight, testis histology and sex chromosome constitution, to distinguish between T16H/Y males in which spermatogenesis is arrested, and X/X *Sxr* males in which it is absent. The results are shown in Table 2. Progeny inheriting the normal X chromosome from the mother served as controls for those inheriting the T16H chromosome. A deficiency of *Sxr* carriers was observed among the progeny regardless of which X chromosome they inherited from the mother. All the female progeny were fertile. All the X/X *Sxr* progeny (13/13) were sterile males, showing typical X/X *Sxr* testicular histology[1]. However, of the T16H/X *Sxr* progeny, five were sterile males, two developed as fertile females, and three proved to be hermaphrodites, with a testis on one side and an ovotestis on the other. The ovotestes were very small, and contained oocytes, sometimes in well developed follicles, within abnormal testicular tubules.

Identification of the two females carrying *Sxr* was obtained by progeny-testing. Table 3 shows the data for one of the females, which was mated first to a Gs/Y and then to a Ta/Y male. The female produced two phenotypically striped X/X *Sxr* sons, and hence was carrying *Sxr*. The overall sex ratio (23♂:11♀) differs significantly from 1:1 ($P<0.05$), but not from the 3:1 ratio expected from an *Sxr*-carrying female. Moreover, amongst the non-variegated male young five T16H *Sxr*/X males (non-variegated owing to non-random X-chromosome expression) were identified, indicating that *Sxr*, initially present on the *Pgk-1*^{a} X chromosome, may be transferred to the T16H chromosome during oogenesis. The proportion of XX progeny inheriting *Sxr* from the mother (7/18) is consistent with the 50% expected from an *Sxr* heterozygote.

The finding that *Sxr* sometimes fails to be expressed has been confirmed by Cattanach and his colleagues[9], who have found

The female mice in the parental cross were derived from crosses between a stock carrying T16H, obtained originally from MRC Radiobiology Unit, Harwell, and a stock carrying *Pgk-1*^{a}, a variant allele at the X-linked locus coding for the monomeric enzyme PGK-1 (phosphoglycerate kinase 1; EC2.7.2.3), obtained originally from John West, Zoology Department, Oxford. The male mice in the parental cross carried either *Pgk-1*^{a} or one of the X-linked coat-pattern markers *Ta* (Tabby), *Hq* (Harlequin) and *Gs* (Greasy), obtained originally from the Institute of Animal Genetics, Edinburgh. The table outlines the strategy used for classifying genotypically the progeny derived from *Pgk-1*^{a}/Y *Sxr* males; a similar strategy was used for the progeny of *Ta*/Y, *Gs*/Y and *Hq*/Y males. The strategy also allowed the identification of recombinant progeny; these have not been included in the table.

* PGK-1 (A, B or AB) was determined by gel electrophoresis[28] of blood samples taken from the retro-orbital sinus.

† To test fertility, each of the male progeny was mated to two females carrying *Ta*, *Gs* or *Hq*, and each of the female progeny was mated to a male carrying one of the same three markers. Inspection of the coat pattern of the young of fertile animals allowed *Sxr* carriers to be identified (see §) and XX to be distinguished from T16H/X females (the latter have some non-variegated daughters).

‡ Sterile males were killed and their testes weighed. A plot of mean testis weight against body weight allowed X/Y to be distinguished reliably from T16H/Y males. Non X/Y testes weighing at least 25 mg were classified as T16H/Y; below 25 mg there was a region of overlap between the smaller T16H/Y and the larger X/X *Sxr* testes. These testes were therefore analysed histologically (spermatogenesis is absent in X/X *Sxr* and arrested in T16H/Y males); in most cases the mice were also karyotyped from bone marrow preparations. We could not distinguish T16H/Y *Sxr* from T16H/Y sterile males.

§ Fertile males and females carrying *Sxr* were identified by the presence of variegated (striped) males (X/X *Sxr*) among their progeny (for matings, see †). In the case of PGK-1B females (putatively T16H), non-variegated male progeny were also screened by the analysis described above ‡, since the T16H/X *Sxr* sons, although carrying a *Ta*, *Gs* or *Hq* gene on their normal chromosome, would not be variegated.

another fertile T16H/X *Sxr* female, shown to be an *Sxr* carrier by progeny testing, as well as two other T16H/X *Sxr* females identified cytologically. The occurrence of such females among T16H/X *Sxr* but not X/X *Sxr* individuals (Table 2) suggests strongly that the failure of expression is due to inactivation of the *Sxr* male-determining region as a consequence of its attachment to the normal X chromosome, preferentially inactive in the presence of T16H.

The observation that some T16H/X *Sxr* individuals develop as females, some as males, and some as hermaphrodites, is most simply explained by assuming that the *Sxr* male-determining region is inactivated in some cells but not others. Inactivation may spread to a variable extent from the inactive X chromatin into the attached *Sxr* fragment, in an analogous fashion to position effect variegation for autosomal genes translocated onto the inactive X chromosome[10]. We assume that the extent of spreading leading to active or inactive *Sxr* status is a heritable characteristic determined at the time of X inactivation. The sex of each individual will then depend on the proportion of cells expressing *Sxr* in the gonad primordium.

Studies on aggregation chimaeras suggest that a certain critical proportion of XY male-determining cells is required for a mixed gonad to develop as male. Of 31 adult XX↔XY chimaeras reported in 5 different strain combinations[11–15], 21 were male, 7 female and 3 hermaphrodite. Since the relative proportions of the two cell components appear to show a flat distribution from 0 to 100% in aggregation chimaeras[16], this would indicate (ignoring variation from one strain combination to another) that the critical threshold above which development of a normal male gonad occurs is about 32% (10/31) XY cells. In the T16H/X *Sxr* animals that develop as females we propose that this critical proportion of cells with *Sxr* active was not reached. The hermaphrodites would be explained by an *Sxr* mosaicism in the region of threshold proportion, whereas the males of the same genotype would have proportions of cells with *Sxr* active above the critical levels. The relative proportions will vary from individual to individual, and even between the two gonads within a single individual, leading to unilateral hermaphroditism.

If the extent of spreading is linked to the primary X-inactivation event, the distribution of *Sxr* mosaicism among individuals will reflect the small number of cells present when inactivation occurs. The number of progenitor cells present in the embryo at this time has been estimated to be between 13 and 64[17]. Assuming a progenitor cell pool of at least 13 cells, and a requirement of about 30% gonadal cells with *Sxr* active over the period of testis determination for normal male development, a calculation based on binomial expectations suggests that inactivation would need to spread into *Sxr* in more than half the inactive X chromosomes to account for the observed number of hermaphrodites and females among T16H/X *Sxr* individuals.

Our observation of adult T16H/X *Sxr* hermaphrodites is consistent with earlier reports that X/X *Sxr* germ cells occasionally entered meiosis before birth[18], sometimes in association

Table 2 Progeny of T16H *Pgk-1*^{b}/+*Pgk-1*^{a} ♀ × X/Y *Sxr* ♂ matings

	Chromosome from male: X	X *Sxr*	Y	Y *Sxr*	Total
Chromosome from female (X) T16H *Pgk-1*^{b}	18♀	2♀ 5♂ 3⚥	36♂		64
+*Pgk-1*^{a}	23♀	13♂	24♂	11♂	71
Recombinant	2♀	2♂	3♂		7
Total	43	25	74		142

The progeny of the different types of *Sxr* ♂ did not differ significantly from one another and have been combined. The eight non-recombinant classes are expected to be produced in equal proportions.

Table 3 Progeny of T16H *Pgk-1*^{b}/+*Pgk-1*^{a} *Sxr* ♀

		From ♂*	
		X	Y
From ♀	T16H *Pgk-1*^{b} *Sxr*	5♂	10♂

* A *Pgk-1*^{b} *Gs*/Y male was used to sire the first three litters, and a *Pgk-1*^{b} *Ta*/Y male for subsequent litters. Both males were extensively tested with normal females to ensure that they were not carrying *Sxr*.

† Phenotypically variegated coats.

with disturbed seminiferous tubule development[19]. A small proportion of the meiotic germ cells survived birth, to give rise to growing oocytes within the tubules, but no oocytes were seen in 30 adult X/X *Sxr* testes[20]. On their own, these earlier observations of ovotestes in young X/X *Sxr* animals could reflect merely some inadequacy in the masculinizing influence of *Sxr*, and/or the presence of two X chromosomes in the germ cells; but in the light of the present results on T16H/X *Sxr* animals, the earlier findings too can be taken to indicate that *Sxr* may be subject to X inactivation, even in X/X *Sxr* individuals[6]. The proportion of cells with *Sxr* inactivated by spreading will of course be lower in X/X *Sxr* than in T16H/X *Sxr* individuals, since only about half the *Sxr*-carrying X chromosomes will be inactive in the former, but all or almost all in the latter. An X/X *Sxr* individual in which sufficiently few cells expressed the male-determining *Sxr* sequences to allow the development of a fertile female would therefore be very rare indeed.

Two recently formulated sex chromosome models include the prediction that X-chromosome material in an embryo will be protected from inactivation if it has been paired during the preceding male meiosis[5,21]. Burgoyne[5] has accordingly suggested an explanation for the variable inactivation of *Sxr* when it is attached to an inactive X chromosome, namely that the expression of *Sxr* may be associated with a folding back and pairing of the *Sxr* region with the homologous testis-determining region in the same Y chromosome during the preceding male meiosis. If such pairing has occurred during meiosis, the *Sxr* region would be protected from subsequent inactivation in the embryo. To account for the observed hermaphroditism, one could further postulate that multiple male-determining sequences exist and that partial intra-chromosomal Y pairing may be followed by inactivation of a variable number of these sequences.

We did not know whether a T16H/X *Sxr* female, if she existed, would be fertile or sterile. The inactive X chromosome in female germ cells of the mouse is known to be reactivated at or shortly before entry of the germ cells into meiotic prophase[7,22–24]. In oocytes, therefore, both X chromosomes are expressed. The finding that female *Sxr* carriers can be fully fertile implies that the presence in female germ cells of male-determining DNA sequences on an active X chromosome from the time of entry into meiosis onwards does not impede the progress of the germ cells through oogenesis. This conclusion is consistent with a report[13] of a fertile female XX↔XY mouse chimaera that produced a functional XY egg, giving rise after fertilization to an XXY embryo. In another such chimaera, a single XY oocyte in first meiotic metaphase was identified cytologically[25]. A contrary conclusion, namely that the presence of *Sxr* prevents XX germ cells from undergoing oogenesis, was reached by Gordon[26] on the basis of a series of experimental chimaeras thought to have an X/X *Sxr* component. The evidence rests on a single female chimaera that produced germ cells from the non-*Sxr* component only; however, as the author himself points out, this could have been brought about by chance alone. Probably the chimaeras that involved an X/X *Sxr* component developed as phenotypic males.

In a recent study[27], *Drosophila* homozygous for mutant autosomal loci involved in sex determination developed sterile gonads devoid of germ cells. However, when the germ cells were introduced by pole cell transplantation into a normal embryo of the appropriate sex, they gave rise to normal functional gametes, suggesting that the mutant sex-determining loci did not affect development in the germ cells themselves. Our finding that the presence of *Sxr* in female germ cells does not interfere with oogenesis suggests that the same situation prevails in mice.

Synchronized bursting of CA1 hippocampal pyramidal cells in the absence of synaptic transmission

J. G. R. Jefferys* & H. L. Haas

Department of Neurosurgery, University of Zurich,
8091 Switzerland

The synchronization of neuronal firing, seen at its most dramatic in the epilepsies, has generally been attributed to synaptic interactions[1–5]. We have now discovered a rhythmic spontaneous bursting activity produced by non-synaptic mechanisms. It develops in rat hippocampal slices after chemical synaptic transmission has been blocked by incubation in low Ca^{2+}, increased Mg^{2+} solutions, and persists with almost clockwork regularity for several hours. We report here that spontaneous firing of all the neurones recorded in the slice increased, consistent with the known effects of Ca^{2+} on membrane properties and synaptic transmission[6–10], but the synchronous 'field bursts', and presumably their underlying mechanisms, were restricted to the population of pyramidal neurones in the hippocampal CA1 region. Thus, these low Ca^{2+} field bursts are different from the Ca^{2+}-dependent synchronous bursts induced in slices by penicillin which originate in the population of pyramidal cells of the CA3 region[1–3].

While the range of conditions that can elicit these field bursts remains to be established, it is particularly interesting that Ca^{2+} *in vivo* can drop to low levels, and starts to fall before the onset of seizures induced by pentylene tetrazol[11]. The precise roles in the field burst of non-synaptic mechanisms such as ephaptic interactions and K^+ movements have yet to be determined. The interburst interval, but not the burst size or duration, has proved particularly sensitive to manipulation of the Na^+–K^+ pump and also to a variety of drugs and transmitters in nano- to micromolar concentrations.

The methods of cutting and maintaining brain slices in our laboratories have been described previously[12–14] (see Fig. 1 legend). Although incubation of hippocampal slices in low (0.2 mM) Ca^{2+}, high (up to 5 mM) Mg^{2+} solution blocked synaptic responses completely after about 5–10 min, the bursting behaviour described here developed after much more prolonged exposure, typically 1–2 h, and persisted for over 12 h. It was reversed on returning to 2 mM Ca^{2+} solution. At first the bursts consisted of small groups of rather irregular population discharges which grew into mature 'field bursts' (see Fig. 1). These bursts lasted ~4 s and consisted of a large number of population spikes, each of which represented the synchronous discharge of many pyramidal cells, superimposed on a negative potential shift. The field bursts recurred with remarkable regularity, in this case every 21.6 s with a standard deviation (s.d.) of 1.6 s, with little variation in amplitude (mean, excluding spikes, 5.41 mV, s.d. 0.08 mV) or duration (mean 4.32 s, s.d. 0.34 s) during 45 min. Overall interburst intervals ranged from 15 s to several min, the amplitude up to 12 mV, and the burst duration from 0.5 to 20 s. The field bursts occurred synchronously throughout the CA1 in each of 48 investigated slices (12 rats). The two recording sites in Fig. 1*a*, *b* were 1 mm apart in the CA1 pyramidal layer. The bursts were closely synchronized at these and all other recording sites. No single site consistently discharged in advance of the rest of CA1, thus there is no evidence for a group of 'pacemaker' pyramidal cells. Incubation in the low Ca^{2+} solutions also changed the antidromic response evoked in the CA1 pyramidal layer by stimulation of the alveus from a single population spike to a burst of 5–20 population spikes. These brief evoked bursts could often trigger a full field burst. The other pyramidal cells (CA3 and 4) and the granule cells in the slice exhibited no spontaneous or evoked periodic behaviour. Therefore, the present phenomenon differs from the bursting induced by penicillin and bicuculline which is Ca^{2+}-dependent, always involves CA3, and consists of briefer bursts[1–3].

To explore the cellular basis of the low Ca^{2+} field bursts, we impaled neurones while the slices were bathed in normal Ca^{2+} solutions and held them during the change to low Ca^{2+} and the subsequent development of the bursts. The technical difficulty of this procedure has restricted the number of observations to four, but the comparisons are particularly reliable as they avoid problems of interneuronal variation and sampling errors. Results consistent with these prolonged recordings were obtained from a further 19 cells impaled while in low Ca^{2+}. Exposure to low Ca^{2+} increased the input resistance by 25% if the resting potential were held to its initial value by current injection. Otherwise the slowly developing ~20 mV depolarization was associated with an unchanged or reduced resistance. There was no detectable change in the threshold voltage for action potentials.

The intracellular data suggest that both the slow depolarization of the resting potential and the increased spontaneous discharge (from ~1 s^{-1} to 10 s^{-1}) following the change to low Ca^{2+} solution resulted from the block of inhibition by spontaneously active interneurones and from the depression of the afterhyperpolarization [gK(Ca)][7]. It is well known that reducing the concentration of divalent cations bathing a variety of nerve and muscle preparations increases excitability[6–9], probably through their effect on surface charge density. Mg^{2+} is less effective than Ca^{2+} in this role, thus the 0.2 mM Ca^{2+}, 4 mM Mg^{2+} solution used in most of the present experiments would be expected to have a net excitatory effect. The increased excitability may be an essential requirement for field bursts because they were abolished by raising Mg^{2+} to 6 mM, which counterbalances the excitatory effect of the low Ca^{2+} more closely[6]. However, we did not detect any change in the action potential threshold, which would be expected if the hyperexcitability were primarily due to deficiency of divalent cations. The conduction block and irreversible damage of neurones caused by Ca^{2+}-free solutions[6,10] were not seen here and would not be expected with the moderate changes in divalent cations used.

The potential shift recorded during the field bursts consisted of a 10–15 mV depolarization of the pyramidal cell membrane; its field was most negative in the cell body layer, and was positive in the outer two-thirds of the apical dendrites. This is consistent with a depolarization due to K^+, released by the excessive neuronal discharge, accumulating in the laminae around the pyramidal cell bodies. Using ion-sensitive electrodes, we have measured increases in K^+ activity in the pyramidal layer during, but not preceding, the bursts (three experiments). The peak K^+ activity reached 10 mM which approximates the ceiling of the physiological range[15]. If the

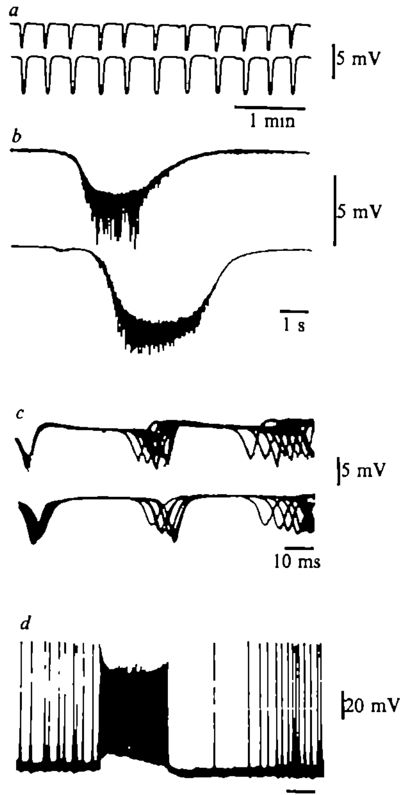

Fig. 1 Spontaneous 'field bursts' recorded from hippocampal slices which were incubated in 0.2 mM Ca^{2+}, 4 mM Mg^{2+}. The methods used have been described previously[12–14]. Briefly, 400 µm slices were prepared from rat hippocampus using a McIlwain tissue chopper or a Vibroslice and were incubated at 32 °C in a perfusion chamber in a thin film of perfusion liquid under warmed and moistened 95% O_2/5% CO_2. The standard media contained the following (in mM): Na^+, 150; K^+, 6.25, Cl^-, 137; Ca^{2+}, 2.0 or 0.2; Mg^{2+}, 2.0 or 4.0; HCO_3^-, 26; HPO_4^-, 1.25; glucose, 10; and were equilibrated with 95% O_2/5% CO_2 gas mixture to maintain the *p*H at 7.4. Micropipettes filled with 3 M NaCl (1–20 MΩ) or K-acetate (50–100 MΩ) were used for extra- and intracellular recording, respectively. *a*, Extracellular recordings from two sites, 1 mm apart, in the CA1 pyramidal layer. The negative field bursts recurred at 3 min^{-1}; *b*, their structure is shown in more detail on oscilloscope traces, population spikes descend from the negative potential shifts. *c*, Several superimposed sweeps during a field burst showing synchronization of population spikes. The recordings were made at sites 0.5 mm apart. *d*, Intracellular events corresponding to a field burst include a rapid, sustained burst of action potentials on a depolarizing shift, followed by a hyperpolarization.

resting potential were entirely due to K^+ this increase would correspond to a depolarization of 11 mV, which is close to the values we observed.

Treatments which depress the activity of ion pumps increased the frequency of the spontaneous bursts with little effect on their size or duration. Ouabain was effective at a concentration of 10^{-6} M; anoxia produced by reducing the gas flow over the slices also greatly speeded up the bursts (for example, from 0.2 min^{-1} to 10 min^{-1} within one minute of stopping the gas flow); cooling the slices from 32 to 25 °C significantly increased the burst frequency. A hyperpolarization was regularly recorded after the bursts, corresponding to a small, ouabain-sensitive, positive field in some extracellular recordings from the pyramidal layer, and may be attributed to the Na^+–K^+ pump. We postulate that sodium pump activity, stimulated by the increased extracellular K^+ (ref. 16), eventually terminates the burst by hyperpolarizing the cells for a period, and that the above treatments depress its ability to hyperpolarize without affecting its sensitivity to K^+.

Several drugs and transmitter candidates, applied in nano- to micromolar concentrations, modified the interburst interval but not the burst size or duration. The frequency of field bursts was increased by the excitatory amino acids glutamate, aspartate and DL-homocysteic acid, and by acetylcholine, noradrenaline, histamine and Li^+. The field bursts became less frequent during the application of the depressant amino acids γ-aminobutyric acid, taurine and imidazole acetic acid, and of serotonin, vasopressin and opiates. The stability of the phenomenon and its sensitivity to this wide range of drugs suggest that it may become a useful pharmacological tool (H.L.H. and J.G.R.J., in preparation).

The population spikes varied in amplitude during each field burst, producing characteristic shapes that varied between slices or even between different sites in CA1 of a single slice. However, our intracellular records showed a rapid and quite regular discharge. Thus for some periods during the field bursts, pyramidal neurones spread over substantial distances discharged in synchrony (Fig. 1*c*). The simplest hypothesis for the synchronization of the spikes is that extracellular currents, generated by pyramidal cells discharging, modulate the excitability of other members of the population, that is, 'field interaction'. Whether enough of the 'extracellular' loop of the action current passes through other cells to produce this effect depends on the detailed local geometry and electrical properties of the dendrites, glia and extracellular space. Experimental support for this possibility may be derived from the sensitivity of the smaller hippocampal granule cell to extrinsic electric fields[13]. The steady depolarization of the pyramidal cells in low Ca^{2+} would tend to increase the effectiveness of field interactions. The synchrony does not arise in the tightly-packed CA1 axons in the alveus as alvear fibre potentials were only seen after, and not preceding, the population spikes.

The synchronization of the bursts across the CA1 region remains to be explained. Paired recordings at sites 0.5–2.0 mm apart show that the leading site may vary between bursts. The latencies observed were up to 1 s, but more often ~50 ms. This is too fast to be explained solely by potassium movements of the kind involved in spreading depression, which propagates at a few mm per min[17]. We observed longer latencies, of the order of several seconds, between sites separated by an alvear lesion, so K^+ may transmit the field burst across these lesions. This also suggests that interactions within, or at least involving, the alveus contribute to the closer synchrony seen in the intact slice; but such interactions are not sufficient for synchronization, as lesions sparing the alveus alone result in two independent burst generators. Perhaps K^+ released by a bursting region can facilitate bursts in distant CA1 pyramidal cells more quickly by affecting their axons in the alveus than is possible through diffusion to cell bodies.

Alternatively, the burst synchronization, and even its generation, could be the result of specialized electrical contacts between the pyramidal neurones in a manner similar to that proposed for recurrent excitatory chemical synapses in CA3 (ref. 1). Electrical synapses are sensitive to the removal of divalent cations[10], although the small net changes involved in the present work might, if anything, be expected to weaken them. The existence of such contacts in CA1 is still controversial[18,19] and even if they were involved here, we would still have to explain why the bursts do not occur in CA3 where similar connections have been described.

Further work is needed to determine whether the mechanisms responsible for the present phenomenon operate *in vivo*. While low Ca^{2+} may not be the only route to their expression, and one might speculate about anoxia or metabolic defects, it is of particular interest that similar conditions can prevail in the intact animal. Measurements with ion-selective electrodes have shown that Ca^{2+} levels fall before the start of seizures induced by pentylene tetrazol[11] and can drop to 0.5 mM. During these seizures K^+ increased to 7–8 mM, which would also have enhanced the mechanisms involved here.

Calvin has commented on the likelihood of there being a wide variety of bursting mechanisms available in the repertoire of neuronal properties[20]. Previous studies of spontaneous synchronous bursting, notably in the hippocampal slice, have emphasized the role of synaptic connections. The phenomenon described here demonstrates how, in the absence of synaptic mechanisms, an increased neuronal discharge can be synchronized into a strongly rhythmic bursting behaviour.

Intracellular recorded synaptic antagonism in the rat dentate gyrus

Vincenzo Crunelli, Susan Forda,
Graham L. Collingridge & John S. Kelly

Department of Pharmacology, St George's Hospital Medical School,
Cranmer Terrace, London SW17 0RE, UK

With the exception of acetylcholine at the motoneurone–Renshaw cell synapse, the excitatory chemical transmitters of the major pathways in the vertebrate brain are unknown[1]. However, on the basis of biochemical and electrophysiological experiments at the extracellular level, the excitatory acidic amino acids glutamate and aspartate have long been suggested as the most likely candidates for this role[2–4]. Unfortunately, difficulties with recording intracellularly from postsynaptic cells at many of these synapses and the lack of selective antagonists have curtailed the criteria by which the identification of glutamate and aspartate as transmitters can be explored. We have now made intracellular recordings from granule cells of the dentate gyrus *in vitro* and report that γ-D-glutamylglycine

0028-0836/82/480450—03$01.00

(γ-DGG) is an effective antagonist of the excitatory postsynaptic potential (e.p.s.p.) evoked by stimulation of the medial perforant path (PP). During this antagonism the reversal level of the e.p.s.p. remains the same and the passive membrane properties of the postsynaptic membrane are unaltered. Quantal analysis shows that the reduction in the e.p.s.p. amplitude can be accounted for almost entirely by a reduction in quantal size while the quantal content remains unchanged, indicating a direct reduction in the postsynaptic sensitivity to the endogenous transmitter. (±)2-Amino-5-phosphonovalerate (APV) proved to be ineffective as a blocker of the PP-evoked e.p.s.p. and *cis*-2,3-piperidinedicarboxylate (PDA) caused excitation. The selectivity of γ-DGG and APV against the depolarization induced by the iontophoretic application of *N*-methyl-D-aspartate (NMDA), quisqualate and kainate closely resembled that in spinal cord. This constitutes the first evidence from a readily identifiable synapse in support of the view that excitatory amino acid receptors of the quisqualate/kainate type are involved in synaptic transmission and offers further support for the suggestion that the endogenous transmitter is aspartate or glutamate.

It has been proposed that three types of pharmacologically distinct excitatory amino acid receptors can be distinguished in the spinal cord, classified according to their most potent agonists as NMDA, kainate and quisqualate[5]. Thus APV is the most specific and potent antagonist of NMDA receptors[5,6]. γ-DGG, as well as blocking NMDA receptors, antagonizes responses to kainate[5,7], whereas PDA antagonizes all three receptor types[5,8]. Using intracellular electrodes we have studied the effect of APV, γ-DGG and PDA on the synaptic excitation evoked by PP stimulation in the granule cells of the dentate gyrus[9] where there is strong evidence favouring glutamate as the endogenous transmitter[10–13].

Impaled neurones, in a standard hippocampal slice preparation (see Fig. 1 legend), were characterized as granule cells by their position in the granular layer of the dentate gyrus, by orthodromic activation from the PP and by antidromic invasion from the mossy fibres region of CA_3[14,15]. Experiments were carried out on only those granule cells whose resting membrane potential (< -60 mV) and membrane input resistance remained stable throughout the experiment. Stimulation of the PP evoked an e.p.s.p. at least 8–20 mV in amplitude yet still below the threshold for initiating action potentials. This may be explained in part by the marked decrease in membrane resistance ($46 \pm 3\%$, $n = 6$) shown to be associated with the peak of the e.p.s.p. by computing voltage–current plots off-line with a PDP 11/23 computer (Cambridge Electronic Design Ltd). The same computer program was used to compute the apparent reversal level of the e.p.s.p. (-14.5 ± 3.4 mV, $n = 4$) by extrapolation from voltage–current plots determined from changes in peak e.p.s.p. amplitude (located mathematically) produced by the intracellular injection of long pulses (200 ms) of depolarizing and hyperpolarizing current. The voltage–current plots showed no significant deviation from linearity indicative of attenuation in e.p.s.p. amplitude caused by significant changes in the time constant of the cell soma or principal dendrites, or by the intracellular injection of current or extracellular application of amino acids.

On 29 granule cells, the iontophoretic application of γ-DGG (25–275 nA) markedly and reversibly reduced the amplitude of the e.p.s.p. evoked by stimulation of the PP (Fig. 1). The mean reduction of the e.p.s.p. was 61% (range 38–80%) of control. The effect of γ-DGG was not associated with a change in the resting membrane potential. Computer-derived voltage–current plots showed the resting membrane input resistance to be unaltered as was the excitability of the cell, tested both by determining the voltage threshold required for antidromic invasion and by the direct injection of depolarizing current.

These results do not exclude the possibility that the antagonism could be due to a presynaptic action of γ-DGG. However, in 12 experiments in which the mass presynaptic fibre volley could be recorded by our intracellular electrode (Fig. 1), its amplitude and duration were unaltered by the application of γ-DGG, even at the highest iontophoretic currents used (275 nA).

Independent evidence in support of the view that the action of γ-DGG on the postsynaptic membrane is competitive, came from a more detailed analysis of the e.p.s.p. For example, in five of six cells, the voltage–current plots showed the apparent reversal potential of the e.p.s.p. to be unaltered by the iontophoretic application of γ-DGG, that is, no systematic alteration occurred in the point of intersection of the extrapolated voltage–current plots derived on and off the peak of the e.p.s.p. in the presence and absence of γ-DGG. In effect, the decline in amplitude of the peak e.p.s.p. was accompanied by an increase in membrane resistance. This continuous linear relationship between the amplitude of the e.p.s.p. and membrane resistance is one prediction of the current theory that the amplitude of the e.p.s.p. is determined by the summation of individual currents generated by the opening of a relatively constant number

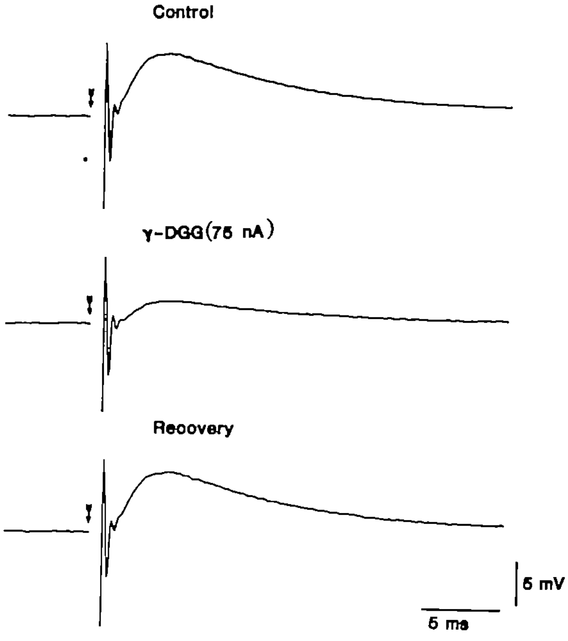

Fig. 1 Reversible reduction by γ-D-glutamylglycine (γ-DGG) of the medial perforant path-evoked e.p.s.p. recorded in a granule cell of the dentate gyrus *in vitro*. After impalement, the position of the iontophoretic electrode was adjusted along the dendritic tree at the level of the middle molecular layer until the response to a short (~1 s) application of glutamate was maximal. Glass micropipettes (tip diameter 3–6 μm) filled with 1 M NaCl were used as stimulating electrodes and positioned in the medial perforant path, 4–6 mm away from the impaled granule cell. Each trace is the computer average of 60 successive e.p.s.p.s recorded before (control), during (γ-DGG) and after (recovery) the iontophoretic application of 75 nA of γ-DGG. The e.p.s.p. was reversibly reduced from 8.5 to 3.2 mV. Our intracellular electrode recorded the presynaptic fibre volley which was unaltered by the application of γ-DGG. Arrows mark the preceeding stimulus artefact. Hippocampal slices (400-μm thick) were prepared from decapitated rats (200 g) using a McIlwain tissue chopper and maintained *in vitro* in a warm (36 °C) continuously oxygenated (95% O_2, 5% CO_2) medium containing (mM): NaCl 134, KCl 5, KH_2PO_4 1.25, $MgSO_4$ 2, $CaCl_2$ 2, $NaHCO_3$ 16 and glucose 10. Intracellular microelectrodes were filled with 1 M potassium acetate and had a resistance of 80–120 MΩ when measured *in situ* with a WPI model 707 electrometer. Drugs were applied by passing negative current through a multibarrelled micropipette containing L-glutamate (1 M, *p*H8), γ-DGG (0.2 M, *p*H8), APV (0.05 M in 100 mM NaCl *p*H8), PDA (0.2 M, *p*H8), NMDA (0.02 M in 150 mM NaCl, *p*H8), quisqualate (0.02 M in 150 mM NaCl, *p*H8), kainate (0.02 M in 150 mM NaCl, *p*H8) and NaCl (1 M, *p*H8). A positive backing current of 1–20 nA was applied when necessary.

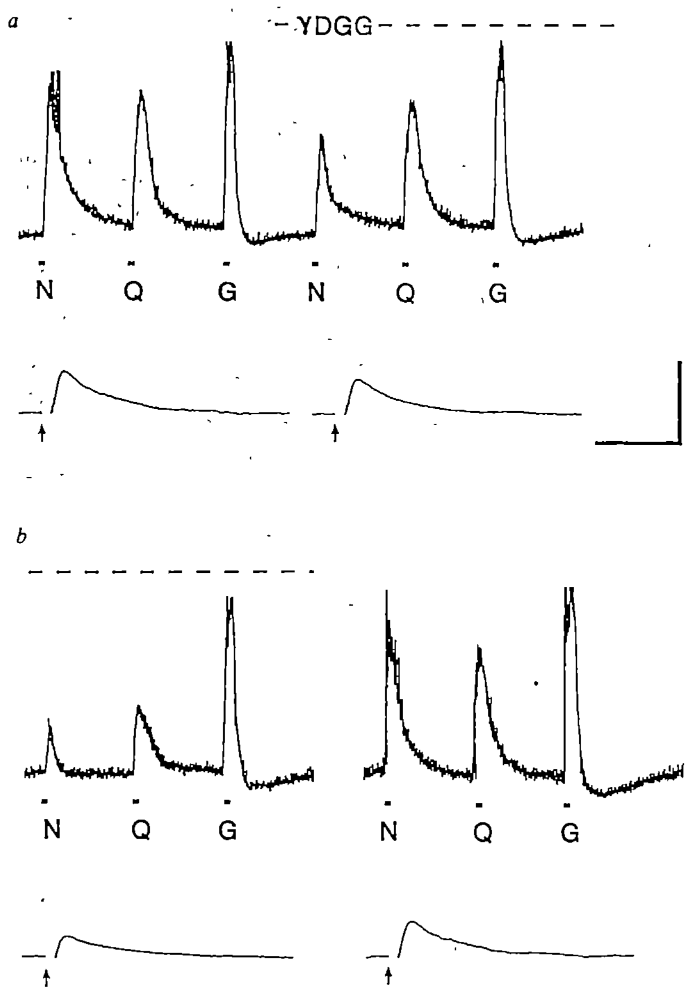

Fig. 2 Intracellular voltage recordings from a granule cell showing the effect of γ-DGG on the medial PP-evoked e.p.s.p. and the depolarization induced by pulsed iontophoretic applications of NMDA (N), quisqualate (Q) and glutamate (G). The upper trace is the intracellular voltage response to drug application, and the lower trace the computer average of 10 e.p.s.p.s. In *a* a 13-s application of γ-DGG was sufficient to reduce the NMDA-induced depolarization to 59% of control, while the e.p.s.p. was unaltered. In *b* the continuing application of γ-DGG reduced the response to quisqualate and the e.p.s.p. amplitude decreased from 11 to 5 mV. *a* and *b* are consecutive records and the gap in *b* is 1.5 min. The action potentials evoked by the drug-induced depolarization have been attenuated by the computer plotting subroutine. The durations of the amino acid applications are indicated by the black bars below the voltage records. Drug ejection currents were (nA): NMDA 100, quisqualate 150, glutamate 200 and γ-DGG 150. Calibration bars represent 20 mV and 30 s for the upper trace, 20 mV and 32 ms for the lower one. Solid arrows mark stimulation of the PP.

of transmitter-specific channels[16], and that antagonists simply combine with specific receptors to reduce the number of channels available. As reported below (Fig. 2) we also tested a further prediction of this theory by exploring the possibility that the potential evoked by the exogenous application of the transmitter involves similar if not identical receptor-activated channels.

In four cells in which all the criteria necessary to carry out a quantal analysis by the variance method[17,18] on trains of e.p.s.ps recorded in the presence and absence of γ-DGG were met, the decrease (46%) in the e.p.s.p. amplitude could be accounted for almost entirely by a reduction in quantal size (control, 294 μV; γ-DGG, 133 μV; $n = 4$) while the quantal content remained unchanged (control, 46; γ-DGG, 50; $n = 4$)[19]. Thus, according to the quantal model of synaptic transmission[20], the effect of γ-DGG on the PP-evoked e.p.s.p. is explained by a decreased sensitivity of the postsynaptic membrane to the endogenous transmitter without any appreciable change in transmitter release.

APV, the most potent and selective NMDA-receptor antagonist in the spinal cord[5,6], was found to be inactive as an antagonist of the PP-evoked e.p.s.p. In eight of nine neurones on which γ-DGG reversibly reduced the e.p.s.p., the iontophoretic application of APV (50–300 nA) was ineffective. In the only granule cell in which it appeared to be active, the decrease in the e.p.s.p. amplitude was not associated with any change in membrane potential or resting input resistance.

PDA, tested with iontophoretic current ranging from 1 to 50 nA, evoked an excitation of granule cells (six of eight neurones) accompanied by a depolarization and an increase in membrane resistance. Even at low iontophoretic currents, PDA produced burst-like activity.

The receptor and channels antagonized by γ-DGG, were characterized by comparing the action of γ-DGG on the PP-evoked e.p.s.p. with the amino acid-induced depolarization of granule cells. As shown in Fig. 2, the reduction in the e.p.s.p. amplitude only occurred when the application of γ-DGG was of sufficient magnitude to reduce the depolarization evoked by quisqualate and/or kainate, even though much smaller applications could block the response produced by NMDA. In the same experiments, we confirmed the even greater selectivity of APV for the NMDA receptor and its inability to effectively block the response induced by quisqualate and kainate.

In another series of experiments, short applications of γ-DGG but not APV were shown to antagonize the PP-evoked e.p.s.p. and glutamate-induced depolarization. However, when the action of γ-DGG on glutamate- as opposed to aspartate-induced depolarization was examined, no clear pattern of selectivity was observed. This was at variance with previous results in the spinal cord[5,7], in fact, in all six granule cells tested, γ-DGG was unselective and reduced the action of both excitants.

The results presented here show that γ-DGG is a potent antagonist of the PP-evoked e.p.s.p. and acts directly on the postsynaptic membrane to decrease its sensitivity to the endogenous transmitter. The amino acid receptors involved at this synapse are of the quisqualate and/or kainate type.

The work was supported by MRC award G8011874. We thank Dr J. C. Watkins (Bristol University) for the supply of antagonists, the Wellcome Trust for financial support to V.C. and G.L.C., and the SRC and ICI for a CASE award to S.F. We also thank Mr J. Wise of the Computer Network Service for his help and enthusiasm and Mrs A. Keable for typing the manuscript.

Cross-neutralization of two different trypanosome populations derived from a single organism

A. F. Barbet, W. C. Davis & T. C. McGuire

Department of Veterinary Microbiology and Pathology,
College of Veterinary Medicine, Washington State University,
Pullman, Washington 99164, USA

Antigenic variation observed during the course of infections with *Trypanosoma brucei* in mammals is caused by amino acid sequence changes in a variable surface glycoprotein (VSG)[1-3]. Antisera to isolated VSGs generally react only with the surface of homologous trypanosomes in neutralization and immunofluorescence tests[1,4], except in the case of certain 'isotypic' populations derived from different field isolates of trypanosomes[5]. An important question in evaluating the possibility of a vaccine is whether a single trypanosome can change into a second population which shares some, but not all, surface exposed epitopes during the limited time span of several sequential infections. If any trypanosomes in a mixture share exposed epitopes, the complexity of the necessary immunogen is reduced. We show here that two trypanosome clones WaTat 1.1 and WaTat 1.12, derived by differentiation from a single organism, have partially homologous VSGs and indeed share some similar exposed epitopes. Hence, a monospecific anti-VSG antiserum neutralizes both trypanosomes. However, several surface-exposed epitopes in WaTat 1.12 VSG exhibit reduced binding affinity for monoclonal antibodies made against WaTat 1.1 VSG and one epitope present on WaTat 1.1 trypanosomes is missing from the surface of WaTat 1.12 organisms.

A large number of trypanosome populations were derived from a single WaTat 1.1 organism as shown in Fig. 1*a*. The objective was to isolate from these populations trypanosomes which had similar exposed, surface epitopes. To do this, trypanosomes from each stabilized population were grown one passage in non-irradiated rats and live organisms analysed by immunofluorescence using rabbit antisera against WaTat 1.1 VSG. Anti-WaTat 1.1-reactive trypanosomes were present in many of the populations examined, but were generally less than 10% of the total population. However, in one population (from stabilate Rb8m7) there were 70% anti-WaTat 1.1-reactive trypanosomes. A clone (WaTat 1.12) was derived from this stabilate in lethally irradiated rats which reacted (>99% of the population) with rabbit anti-1.1 VSG sera. One rabbit antiserum against WaTat 1.1 VSG reacted with WaTat 1.12 trypanosomes to give non-uniform surface fluorescence (dots and lines) even though it reacted with the entire surface of WaTat 1.1 trypanosomes in the same staining conditions. The non-identity of these two trypanosome clones was confirmed by comparison of WaTat 1.1 and 1.12 isolated VSGs by column and analytical gel electrofocusing. On gel electrofocusing, the *p*Is of WaTat 1.1 and 1.12 VSGs were 8.5 and 7.0, respectively, relative to isoelectric point standards (Fig. 1*b*). WaTat 1.1 and 1.12 VSGs both had identical apparent molecular weights of 61,000 on SDS-gel electrophoresis (data not shown), a similar value to those obtained previously for other *T. brucei* VSGs[1,4,5].

Tryptic peptides of WaTat 1.1 and 1.12 VSGs were separated by two-dimensional chromatography–electrophoresis on TLC plates and their positions revealed by fluorescamine staining and examination under UV light (Fig. 2*a*). Complex maps were generated containing about 60 peptides, reflecting the high proportion of lysine residues present in *T. brucei* VSGs[1]. Clearly, many, but not all, of the peptides from the two VSGs were overlapping. This result was confirmed by a second peptide mapping procedure, autoradiographic analysis of tryptic peptides from ^{125}I-labelled VSGs. The effect of this procedure was

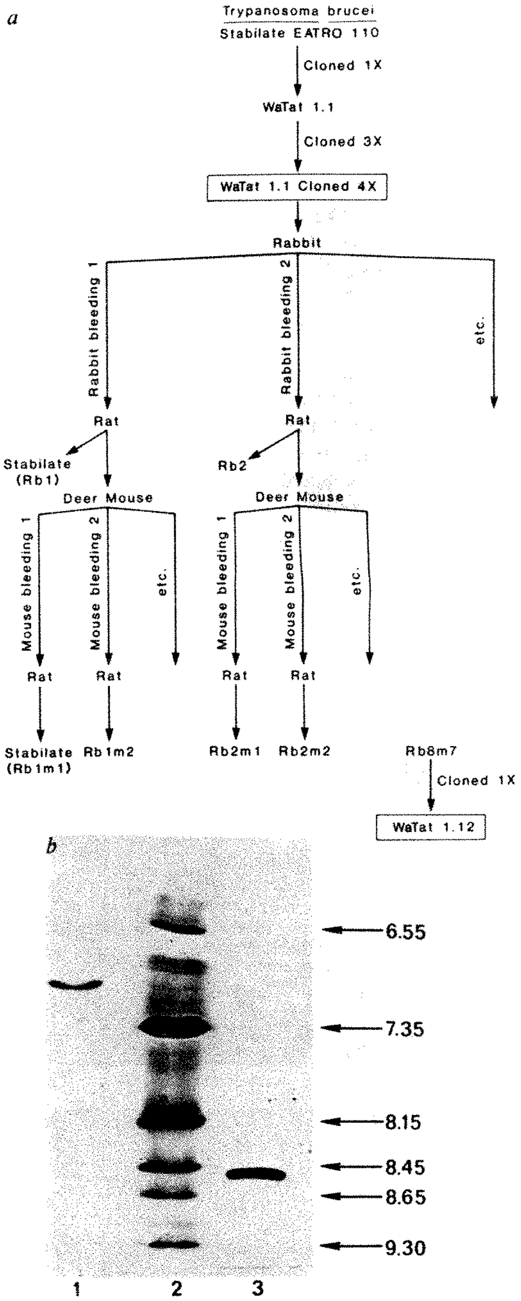

Fig. 1 *a*, Derivation of trypanosomes. Clone WaTat 1.1 was prepared from an EATRO 110 (East African Trypanosomiasis Research Organization, Tororo, Uganda) stabilate by injecting a single organism into the peritoneal cavity of a lethally irradiated (900R) rat. To ensure that all trypanosomes were derived from a single organism, WaTat 1.1 organisms were recloned three further times. VSG from all WaTat 1.1 populations had identical isoelectric points; also, rabbit antisera prepared against each WaTat 1.1 VSG[4] reacted in immunofluorescence with all WaTat 1.1 cloned populations. A rabbit was then infected with WaTat 1.1 trypanosomes (cloned four times) and blood taken from the ear at weekly intervals. Each sample of infected rabbit blood was inoculated into a non-irradiated rat and when the infection became patent stabilates were prepared; 0.2 ml of infected rat blood was also inoculated into a deer mouse (*Peromyscus maniculatus*). Blood was then taken at weekly intervals from the tails of infected deer mice, injected into non-irradiated rats and more stabilates made. A total of 103 stabilates were prepared, all of which consisted of equal volumes of infected rat blood and 15% v/v glycerol in PSG stored in liquid nitrogen. Clone WaTat 1.12 was derived from stabilate Rb8m7. The stabilate Rb8m7 was prepared about 4 months after the rabbit was infected with WaTat 1.1 trypanosomes. *b*, Analytical isoelectrofocusing of purified WaTat 1.1 and WaTat 1.12 VSGs in polyacrylamide gel at 4 °C. Coomassie blue staining of: (1) WaTat 1.12 VSG; (2) Pharmacia isoelectric point standards; (3) WaTat 1.1 VSG.

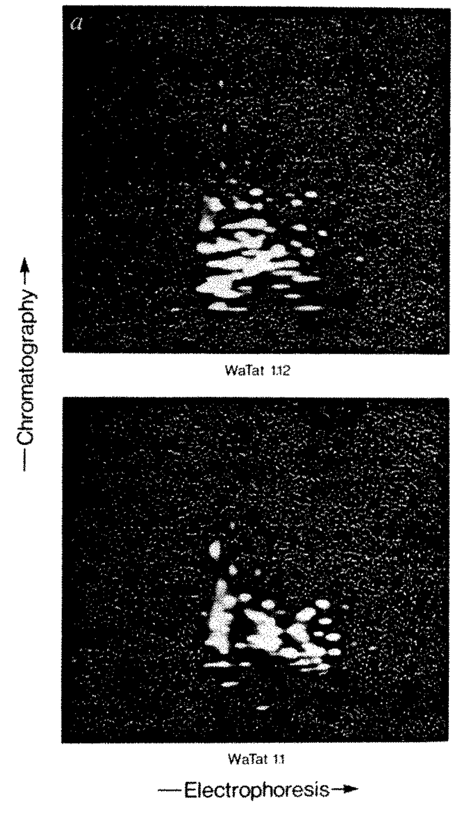
0028-0836/82/480453—04$01.00

to reduce the map complexity but increase the specificity, because of the lower proportion of tyrosine compared with lysine residues in VSGs[1]. The ^{125}I-maps (Fig. 2*b*, *c*) again demonstrated similarity between WaTat 1.1 and 1.12 VSGs, but at least four out of the total 15–19 labelled tryptic peptides were dissimilar. As a control the peptide maps of WaTat 1.1 and 1.12 VSGs were compared to that of WaTat 1.2, a VSG from a third, randomly derived trypanosome clone but no similarities were observed (Fig. 2*b*, *c*). Thus these results agreed with the isoelectrofocusing data showing that WaTat 1.1 and WaTat 1.12 VSGs were not identical. The two VSGs did, however, share amino acid sequences which were not present in a third VSG.

Seven monoclonal antibodies were prepared against WaTat 1.1 VSG either by immunization of mice with isolated VSG or by immunization with irradiated (40,000R) trypanosomes. All seven antibodies bound ^{125}I-labelled WaTat 1.1 VSG but only five reacted in immunofluorescence with live WaTat 1.1 trypanosomes (Table 1). Therefore, not all the epitopes recognized in the isolated VSG were equally accessible in the same VSG on the surface of live trypanosomes. Of the five monoclonal antibodies which were reactive against WaTat 1.1 trypanosomes in immunofluorescence, four also reacted with WaTat 1.12 trypanosomes. One monoclonal antibody (Tryp 22A$_1$) reacted only with WaTat 1.1 trypanosomes, showing that an epitope exposed to antibody on WaTat 1.1 trypanosomes was not present on WaTat 1.12 trypanosomes. No evidence for population heterogeneity was obtained with these monoclonal antibodies, that is, when immunofluorescence reaction occurred, greater than 99% of the trypanosomes in that population reacted. Similarly, monospecific rabbit antisera against WaTat 1.12 VSG reacted with greater than 99% of both WaTat 1.1 and 1.12 trypanosomes.

As some, but not all, exposed epitopes were shared between WaTat 1.1 and 1.12 trypanosomes, we investigated whether cross-neutralization would occur. Results in Table 1 demonstrate that rabbit antiserum to either WaTat 1.1 or WaTat 1.12 VSGs neutralized both WaTat 1.1 and 1.12 trypanosomes and had no effect on WaTat 1.2 organisms. The two control sera (anti-WaTat 1.2 VSG and normal rabbit serum) were without effect on WaTat 1.1 or 1.12 trypanosomes.

We next analysed immunological cross-reactions between isolated WaTat 1.1 and 1.12 VSGs. Previous data have shown that homologous reactions between VSGs and monospecific rabbit anti-VSG sera were not effectively inhibited by heterologous VSGs[4] except in the case of 'isotypic' trypanosomes[5]. In radioimmunoassay, the homologous reactions ^{125}I-WaTat 1.1 VSG versus rabbit anti-WaTat 1.1 VSG serum or ^{125}I-WaTat 1.12 VSG versus rabbit anti-WaTat 1.12 VSG serum were effectively inhibited by both WaTat 1.1 and 1.12



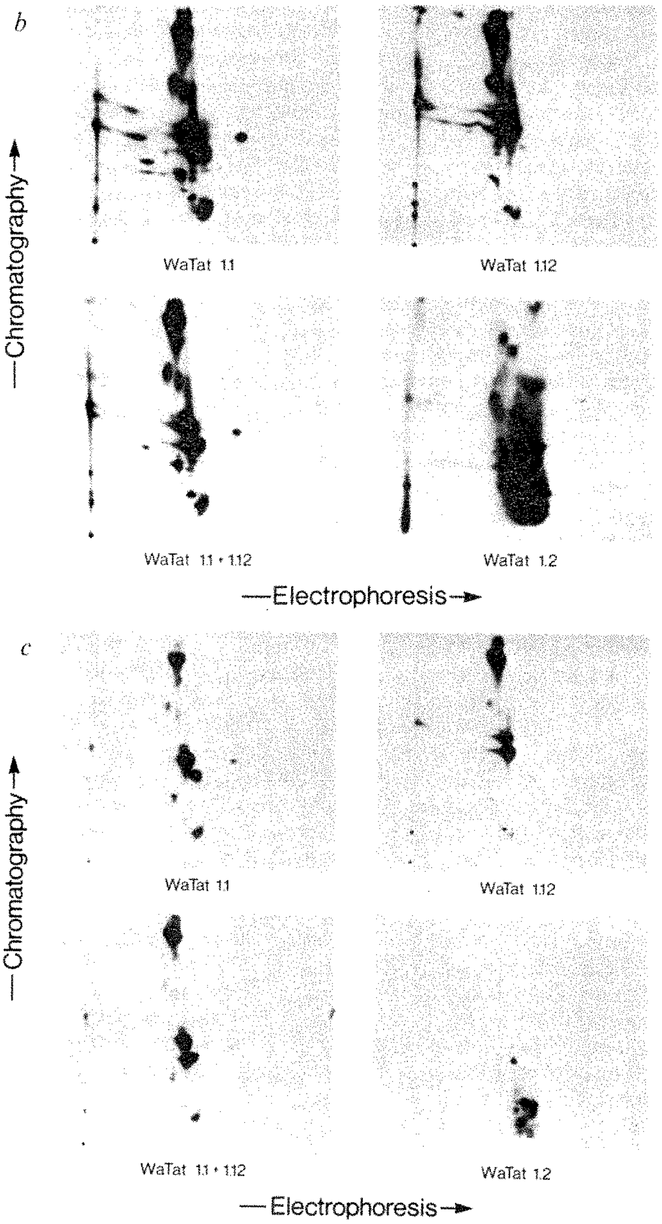


Fig. 2 Tryptic peptide maps of WaTat 1.1, WaTat 1.2 and WaTat 1.12 VSGs. Unlabelled VSGs (*a*) or VSGs labelled with ^{125}I using chloramine-T (*b*, *c*) were reduced with dithiothreitol, alkylated with iodoacetamide, precipitated with trichloroacetic acid and digested with trypsin (Sigma type XI, DPCC-treated) essentially as described in ref. 5 except that tryptic digestions were performed using 4% by weight trypsin: VSG for 17 h at 37 °C. Two-dimensional peptide mapping by thin layer electrophoresis and chromatography[19] was performed on cellulose plates. Electrophoresis was at 900 V for 70 min using as buffer, pyridine : acetic acid : water (1 : 10 : 89) *p*H 3.5. The chromatography solvent was pyridine : acetic acid : water : butanol (25 : 7.5 : 30 : 37.5). The position of peptides was revealed either by spraying with 0.01% w/v fluorescamine in acetone and photography under UV light[19] (*a*) or by autoradiography (*b*, *c*); *c* is an underexposure of *b*.

Table 1 Reactivity of antibody with different trypanosomes and VSGs

Normal rabbit serum	−	−	10/10	−	−	9/10	−	−	10/10

Monospecific rabbit anti-VSG sera were prepared as in ref. 4. Mouse monoclonal antibodies were prepared as described[20,21] using the SP2/0-Ag 14 myeloma cell line. The spleen cells for fusion were from mice immunized either with irradiated (40,000 R) WaTat 1.1 trypanosomes (Tryp series) or purified WaTat 1.1 VSG (WaT series). All hybridomas were double cloned. Radioimmunoassay (RIA) was as in Fig. 3 measuring binding of purified, ^{125}I-labelled VSGs to antibody. Immunofluorescence (FA) procedures were similar to those of ref. 4; the fluorescence of living trypanosomes was recorded immediately after the last wash. Neutralization (N) experiments were performed as follows. Ten trypanosomes in 50 μl of PSG (57mM Na_2HPO_4, 3mM NaH_2PO_4, 45mM NaCl, 55mM glucose, *p*H 8.0) were incubated with 100 μl of rabbit antiserum (inactivated at 56 °C for 30 min) for 30 min on ice and then injected into the peritoneal cavity of a mouse. Parasitaemia was observed by sampling tail blood at 2-day intervals. Numbers represent number of mice dead/total injected; all deaths were the result of trypanosome infection.

unlabelled VSGs. Inhibition of 100%, however, was only achieved by the homologous antigen. The heterologous antigen inhibited by a maximum of 70–90% (data not shown). A reaction of partial identity was also obtained between WaTat 1.1 and 1.12 VSGs in immunodiffusion.

The seven monoclonal antibodies made to WaTat 1.1 VSG were tested for binding to ^{125}I-labelled VSGs (Table 1 and Fig. 3). Six out of the seven bound both WaTat 1.1 and 1.12 VSGs. Monoclonal antibody Tryp 22A$_1$ only reacted with WaTat 1.1 VSG, a similar result to that obtained with the same antibody and live trypanosomes in immunofluorescence. Even though the remaining six monoclonal antibodies bound both WaTat 1.1 and 1.12 labelled VSGs, with four out of the six, more antibody was required to bind a given quantity of WaTat 1.12 VSG than 1.1 VSG. This indicated reduced binding constants of these four monoclonal antibodies for WaTat 1.12 VSG. The binding constant of antibody Tryp 4C$_1$ for WaTat 1.12 VSG was so low that binding was barely observable, even with undiluted antibody. None of the monoclonal antibodies bound ^{125}I-WaTat 1.2 VSG.

The data show that WaTat 1.1 and WaTat 1.12 trypanosomes: (1) are derived from a single trypanosome in a time period comparable with that available for variation in one host animal under field conditions; (2) express VSGs which are not identical in amino acid sequence, but do share regions of amino acid sequence homology not found in other, randomly isolated VSGs; (3) contain both similar and different surface-exposed VSG epitopes. We consider that the most likely mechanisms by which WaTat 1.1 trypanosomes differentiated into WaTat 1.12 are the following: (i) expression of alternative genes (perhaps members of the same VSG gene family[6,7]) present in WaTat 1.1 organisms; (ii) re-expression of the same WaTat 1.1 VSG gene which has undergone rearrangement[8] or mutation[9,10] either before or during re-expression; (iii) a combination of both mechanisms (i) and (ii), that is, expression of alternative genes and rearrangement or mutation. It may be possible to discriminate between these possibilities by analysing for the presence of WaTat 1.1 and 1.12 genes in both trypanosomes.

It might be argued that oligosaccharides could be responsible for the cross-reactions observed between WaTat 1.1 and WaTat 1.12 VSGs. We do not consider this likely because: (1) oxidation of WaTat 1.1 VSG with 100 mol periodate per mol VSG (48 h, 4 °C, as in ref. 11) destroyed binding of the antigen to rabbit anti-WaTat 1.2 VSG sera (due to cross-reacting oligosaccharide[11,12]), but did not affect binding of the oxidized WaTat 1.1 VSG to rabbit anti-WaTat 1.12 VSG sera; (2) various studies using periodic acid–Schiff staining and electron microscopy, immunochemical techniques and sequencing[11–17] suggest that VSG carbohydrate is on the innermost side of the surface coat next to the cytoplasmic membrane, and is not accessible for binding to lectins or antibody when on the trypanosome surface. The monoclonal antibodies shown in Fig. 3 react with surface-accessible epitopes.

These results have theoretical and practical implications. First, a single trypanosome may vary during a short time period into a population expressing a different VSG, from which it might not be distinguished using monospecific or even some monoclonal anti-VSG sera in immunofluorescence. We suggest that amino acid sequence identity between expressed VSGs be the ultimate criterion of whether two trypanosome populations are identified as being similar. The data also provide the first steps to a classification of different trypanosome populations depending on shared, exposed epitopes present on their surface. This classification would be useful in deciding whether cross-immunization between any two trypanosome populations was possible.

Second, reappearance of the same antigenic type of trypanosome at different times during a cattle infection has been suggested previously[18]. This phenomenon could, clearly, now also be attributed to appearance of a trypanosome expressing a similar but not identical VSG.

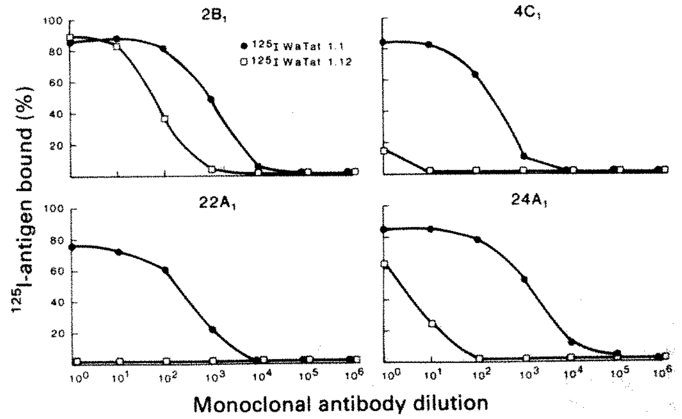

Fig. 3 Binding of monoclonal antibodies to ^{125}I-labelled WaTat 1.1 and WaTat 1.12 VSGs. Reaction mixtures contained 20 μl of ^{125}I-labelled VSGs[4] (5ng in all cases), 20 μl of monoclonal antibody and 20 μl of TEN buffer (0.02 M Tris-HCl, 0.005 M EDTA, 0.1 M NaCl, 0.015 M NaN_3, *p*H 7.6 and 5 mg ml^{-1} bovine serum albumin). The mixture was incubated for 1 h at room temperature then 100 μl of a 10% suspension of formalin-fixed *Staphylococcus aureus* (Pansorbin, Calbiochem) was added. The incubation continued for another hour before the mixture was centrifuged at 1,500*g* for 20 min, washed twice in TEN buffer and radioactivity in the final pellet measured. All dilutions were made in TEN buffer.

Finally, these two trypanosome populations represent the first available for analysing rearrangements and mutations in VSG genes and relating DNA sequence changes to modifications in individual, surface-exposed epitopes.

We thank Eldon Libstaff, Jeff Regnier, Richard Dixon and Sandra Seifert for technical assistance. Research support was provided by the state of Washington Initiative Measure no. 171 and by Rockefeller Foundation grant GA-COH-8013.

A human suppressor T cell clone which recognizes an autologous helper T cell clone

Jonathan R. Lamb* & Marc Feldmann†

London WC1E 6BT, UK

In contrast to the many reports of IL-2 dependent proliferating, helper or killer cell clones[1], there is only a single report of an IL-2 dependent suppressor cell clone[2], in the mouse. However by the same cloning procedures used to generate human helper cells[3], suppressor cell clones to influenza virus could not be generated, and so another strategy was used. Jerne's network hypothesis[4] proposes that immune regulation results from lymphoid cell receptors recognizing determinants on other lymphoid cell receptors. If this is the case it should be possible to generate regulatory T cell clones against other T cells and we report here the generation of an autologous suppressor cell clone which recognizes and inhibits the function of a human helper T cell clone. Such an autologous suppressor cell clone provides a new approach to understanding the pathways and molecular events involved in immune regulation. Mutual stimulation of the suppressor cell clone and the target helper cell clone in the absence of back stimulation, provides direct experimental evidence for the existence of interactions between T cell receptors, and thus suggests that the specificity of the suppressor cell clone is for the antigen receptor of the helper cell.

Human immunology, unlike mouse immunology, is limited by restricted access to genetically uniform cells. In order to circumvent this problem, all the experiments reported here were performed with cryopreserved cells from a single individual. T lymphocyte clone 6 (TLC 6) is a helper cell which recognized influenza A matrix protein in conjunction with HLA-DR1[3-6]. It was used to generate anti-idiotype suppressor cells because it grows well in culture, and its helper activity is easy to measure *in vitro* using the influenza virus specific antibody response and assay system developed by our colleagues, Callard, Beverley and Zanders[7-9], using either the cells themselves, or its antigen specific helper factor.

To stimulate autologous peripheral blood cells (PBL) with irradiated TLC6, a 10-day mixed lymphocyte culture was performed. The resulting blasts were purified on Ficoll–Hypaque and restimulated with irradiated TLC6. The ensuing lymphoblasts purified on a Percoll gradient three days later, and cloned as described in Table 1. Approximately 60 clones were grown up, and tested for their specificity. For simplicity, proliferation was used as the criterion of responsiveness, and cells from individual clones were cultured with irradiated autologous PBL and either the immunogen TLC6, another helper clone from the same donor HA1.9, influenza A virus, or just PBL alone. After 72 hours, cultures were pulsed with tritiated thymidine and cells were collected 16 hours later. Several patterns of reactivity were seen. Clones from these experiments were termed AC1 to 60. The most common response was to influenza virus (for example clone AC10), which could have been still present on the surface of washed TLC6 even after one week's culture. Other clones showed no detectable response to any of the stimuli used (for example AC57). This is paradoxical, as only activated cells respond to TCGF and can be cloned[1]. It seems likely that these clones were responding to TLC6, but the response was not detectable by the assay used. Clone AC34 is presumably recognizing an antigen on PBL (or serum), whereas clone AC5 is recognizing an activated cell antigen. The specificity of clones AC19 and AC22 is not known.

The most relevant clone, chosen for further analysis, was clone AC50. This proliferated in response to TLC6, but not other clones, PBL or influenza virus. Thus it seemed to be specific for TLC6, and was a candidate for an anti TLC6 clone. In the absence of any antibodies which unambiguously define human T-cell receptors, we used a functional assay to analyse the specificity of clone AC50 further.

We argued that if receptors on AC50 recognized anti-TLC6 receptors, then TLC6 might be stimulated to respond to irradiated AC50 *in vitro*, as its receptors would be bound. Thus a variety of influenza specific clones (all from the same donor) were stimulated with irradiated clone AC50, or AC50 plus irradiated E^- cells (T depleted cells) as a source of antigen presenting cells. As a control the response to AC50, PBL and influenza virus was assayed. As shown in Table 2, all the clones responded to influenza virus and TCGF, but only TLC6 responded to AC50, with or without the addition of irradiated E^- cells. This result is compatible with the notion that AC50 is an auto anti-idiotype clone, that is, recognizes antigen-specific receptors on TLC6. The response in the absence of additional antigen presenting cells (APC) is of interest, implying that the reaction between TLC6 and AC50 may not require antigen presenting cells. However, a few APC, which had not adhered to the plastic in the week of culture since irradiated PBL were added could still have been present, and this question needs to be analysed in detail. It is of interest that Infante *et al.*[10] recently found that anti-idiotype antisera stimulate mouse T cell clones to proliferate even in the absence of added antigen presenting cells, in analogy to the results shown here with anti-idiotype T cells.

The results in Table 2 indicate that AC50 and TLC6 interact in a specific manner. But they do not conclusively indicate that the reaction is anti-receptor. An alternative interpretation is that the proliferation of TLC6 is due to back stimulation[3,11] with irradiated AC50 recognizing TLC6, and it is the release of lymphokines from irradiated AC50 which causes TLC6 to incorporate thymidine. This possibility was investigated, using a cultured (not cloned) T lymphocyte line (CTLL) which responds well to TCGF (Table 3). A mixture of irradiated AC50

Peripheral blood lymphocytes (PBL, 5×10^5 per ml) were cultured with irradiated (2,500 rad, ^{137}Cs) TLC6 (5×10^5 per ml) in RPMI 1640 supplemented with 10% pooled A$^+$ serum in a 24 well plate (Costar). Both the responder (PBL) and stimulator (TLC6) cells were derived from the same donor. After 10 days of primary culture the viable cells were isolated on Ficoll–Hypaque and blast cells (10^5 per ml) were restimulated with irradiated TLC6 (10^5 per ml) in the presence of autologous irradiated PBL (5×10^5 per ml) Three days after restimulation the lymphoblasts were enriched on a discontinuous Percoll (Pharmacia) density gradient (35–40%) and plated at 0.3 cells per well in sterile 60 well Microtest II trays (Falcon) in the presence of T cells growth factor (TCGF or Interleukin 2) irradiated stimulator cells (TLC6; 5×10^3 per well) and autologous irradiated PBLs (5×10^3 per cell) as a source of antigen presenting cells (APCs) TCGF was prepared from PBL (1×10^6 per ml cultured with PHA (0.1%) in the presence of 1% autologous serum for 48 hours as described elsewhere[3,11]. The wells that showed positive growth (3.4% of the total number of blast cell seeded) at 7 days were transferred to 96 well flat bottom microtitre trays (Falcon) and cultured with irradiated TLC6 (5×10^4 per well) and autologous irradiated PBL (5×10^4 per well) in the presence of TCGF. Following a further 7 days in culture, the clones were transferred to 24 well trays containing TCGF, irradiated TLC6 (5×10^4 per well) and autologous irradiated PBL (1×10^6 per well). In the preliminary screen clones were examined for antigen specificity in a 72 hour array by using titrated methyl thymidine (^{3}H-TdR; NEN). A 1:200 dilution of individual clones from 24 well trays were cultured with autologous irradiated PBL (25×10^3 per well) and irradiated TLC6 (5×10^3 per well) in a total volume of 200 µl. Clones T cells from the same donor but with a different antigen specificity (HA1.9) together with autologous PBL, PBL alone or influenza A virus (A Texas/1/77; 5 haemagglutinating units (HAU) per ml) in the presence of PBL were added as controls. After 72 hours, cultures were pulsed with 1.0 µCi of ^{3}H-TdR and cells were collected 16 hours later. Incorporation of ^{3}H-TdR was measured by liquid scintillation spectroscopy. Results are expressed as mean c.p.m.±s.e.m. We have checked AC50 for its reactivity with other helper clones from the same individual but with different fine specificities. It did not react with 2 other helper clones (HA1.7, HA1.9) as well as other autologous clones (37, 53, 72).

and TLC6 could not stimulate CTLL to proliferate (31 c.p.m.) in contrast to TCGF (6,503 c.p.m.), as shown in Table 3. There was no effect of AC50 and TLC6 even in the presence of E- cells.

Thus the induction of thymidine incorporation in TLC6 by AC50 was not due to back stimulation, and thus the bidirectional nature of the TLC6–AC50 interaction and its specificity for TLC6, but no other autologous clones would appear to indicate that AC50 recognizes antigen-specific receptors on TLC6. Because the reaction is autologous, and specific for TLC6 it cannot be directed against MHC or differentiation antigens. The criteria we have used to define the anti-idiotype nature of clone AC50 (that is, specificity, stimulatory effects) are the same as used for anti-idiotypic antisera (discussed in refs 10, 12).

The effects of clone AC50 on the helper response of TLC6 were assessed *in vitro* (Table 4). Very small numbers of AC50 diminished the response. Only 10 clone AC50 cells inhibited the helper response of 500 TLC 6 (to 100,000 E$^-$ cells in a 200 µl culture volume) by 95%. Fifty cells of AC50 per culture abolished the response altogether. These results indicate that AC50 is a potent suppressor cell. The mechanism of suppression is unknown, but it is unlikely, due to the ratio of cells used (1 suppressor to 50 helpers) and the capacity of irradiated AC50 to induce TLC6 to incorporate thymidine (Table 2), that AC50

Various numbers of irradiated AC50 cells (5×10^2, 1×10^3 and 5×10^3 per well) were cultured with a panel of influenza A virus-specific TLCs (5×10^3 per well) in the presence or absence of autologous irradiated sheep erythrocyte (SRBC) rosette negative (E$^-$) cells (5×10^3 per well) and Influenza A virus. E$^-$ cells were separated from those cells forming rosettes with AET (aminoethylisoethiouronium bromide hydrobromide)-treated SRBC by centrifugation over Percoll (1,080 g ml^{-1}). Proliferative responses were determined by the incorporation of ^{3}HTdR as described in the legend to Table 1. Results are expressed as mean c.p.m. (±s.e.m.). CTLL, influenza specific T lymphocyte line.

* E$^-$ and AC50 irradiated 2,500 rad.

Table 3 Lack of back stimulation in mixed cultures of AC50 and TLC6

Responder cells	Stimulation (c.p.m. ± s.e.m.) AC50	6	AC50+6	FluA	Medium	TCGF

Irradiated AC50 (5×10^3 cells per well) and TLC6 (5×10^3 cells per well) were cultured alone or together with an influenza specific cultured T lymphocyte line (not the same as in Table 2) CTLL (5×10^3 cells per well) in the presence or absence of autologous irradiated E^- cells. As controls CTLL cells were cultured with and without irradiated E^- cells and influenza A virus. Proliferative responses were measured and results expressed as described in Table 1.

is cytotoxic for TLC6. The mechanism of suppression remains to be elucidated, but because it occurs at the clonal level should be amenable to precise analysis.

These results indicate that as in the mouse, it is possible to generate a human specific suppressor T cell clone dependent on IL-2. In contrast to the mouse suppressor cell clone, specific for antigen, the specificity of the human suppressor clone was for the immunizing cell (and not other autologous helpers). The reciprocal stimulation, in the absence of back stimulation, suggests that the target of AC50 is the receptor for antigen of TLC6. This is a direct experimental test of the 'idiotype network' at the T cell level. The potency of the suppressor effect suggests that this type of suppressor cell may be of major importance in immune regulation.

The generation of suppressor T cells recognizing helper cell receptors resembles work reported by Binz and Wigzell, who injected antigen-specific lymphoblasts into autologous mice[13]. Specific unresponsiveness resulted, which was mediated by either T killer, suppressor or helper cells, or B cells[13]. Conceptually the results are analogous, but the experiments reported here were performed entirely *in vitro*, and at the clonal rather than the population level. There are reports of suppressor cell pathways to the haptens nitrophenyl (NP) or azobenzene arsonate (ABA) for delayed hypersensitivity which involve second order suppressor cells, which recognize idiotype bearing cells[14]. However, the final suppression was not idiotype specific[15]. These experiments were also performed at the population level.

Table 4 Cloned auto (anti-idiotypic) suppressor T lymphocytes

	Stimulus		Suppression	Response
Helper T cells	Autol. E^- (5×10^5 per ml)	A/Texas/1/77 (0.5 HAU per ml)	(AC50 per ml)	Anti-influenza A virus antibody (ng ml^{-1})
E^{+*}	−	−	−	0
E^+	−	+	−	0
−	+	−	−	0
−	+	+	−	4±1
E^+	+	+	−	145±26
TLC6†	−	−	−	0
+	+	−	−	0
+	+	+	−	208±22
+	+	+	50	10±2
+	+	+	250	3±1
+	+	+	500	0

Cloned helper T cells (TLC6; 2.5×10^3 per ml) or E^+ cells (5×10^5 per ml) were cultured with autologous E^- cells in the presence of influenza A virus (A/Texas/1/77; 0.5 HAU ml^{-1}) in RPMI 1640 supplemented with 10% horse serum in 96 well round bottom microtitre trays. TLC AC50 cells were added at 50, 250 and 500 cells per ml at the initiation of the cocultures each of 200 µl. After 6 days incubation at 37 °C, triplicate cultures were washed and recultured in 150 µl of RPMI 1640 supplemented with 5% fetal calf serum (FCS). Supernatants were collected after 24 h and assayed for anti-A/Texas/1/77 antibody using a solid phase enzyme immunoassay. Antibody production was determined by reading absorbance at 405 nm of the transformed substrate of alkaline phosphatase[9]. The actual amount of antibody (ng ml^{-1}) ± standard error of triplicate cultures. Results are expressed as the mean (ng ml^{-1}) and for each triplicate the s.e. was <20%. Background responses of TLC6, E^+ and E^- cultured alone or with influenza A virus were measured. * 5×10^5 ml^{-1}; † 2.5×10^3 ml^{-1}.

By possessing a clone of suppressor cells (AC50), specific for a clone of helper cells (TLC6), we have a powerful system for analysing the mechanism of T cell suppression. There is no reason to believe that the principle demonstrated here will not apply with other clones. Thus, situations with undesirable clones of helper (or killer) cells such as autoimmunity or perhaps even leukaemia may be controllable by suppressor cells of this type, generated *in vitro*.

A protein with kinase and phosphatase activities involved in regulation of tricarboxylic acid cycle

D. C. LaPorte & D. E. Koshland Jr

Department of Biochemistry, University of California, Berkeley, California 94720, USA

Phosphorylation–dephosphorylation reactions as a form of regulatory control are assuming increasing importance in our understanding of cellular processes. The phosphorylation–dephosphorylation reaction was the first example of covalent modification in control and has been found to be present in almost every type of cellular process including synthesis of cell constituents, metabolic pathways and even gene expression[1]. It has assumed increasing importance as a result of the finding that some proteins coded for by carcinogenic viruses apparently are involved in a phosphorylation reaction[2,3]. To better understand the principles underlying these processes, we have studied the role of phosphorylation of isocitrate dehydrogenase (IDH) in the regulation of the branch point between the tricarboxylic acid (TCA) cycle and the glyoxylate bypass. We report here that in the process of purifying the kinase and phosphatase, we made two surprising observations—the kinase and phosphatase activities appear to be associated with the same protein, and the phosphatase activity has an absolute requirement for ATP.

During growth on acetate, *Escherichia coli* achieves net synthesis of cellular intermediates by induction of the glyoxylate bypass[4]. This anapleurotic pathway competes with the TCA cycle, the principal producer of metabolic energy, for a limiting amount of isocitrate. The branch point between these pathways

0028–0836/82/480458—03$01.00

has been shown to be regulated, at least in part, by phosphorylation of IDH[5-7].

Our first goal in the study of this branch point was to purify the relevant enzymes. We purified IDH kinase by using three steps: ammonium sulphate fractionation, chromatography on DEAE–Sephacel and affinity chromatography using IDH immobilized on Sepharose 4B. Absorption of the IDH kinase to the affinity column was found to require the non-hydrolysable ATP analogue, 5′-adenylylimidodiphosphate. After sample application, the column was washed with buffer containing the analogue until the effluent was free of protein. The bound enzyme was then eluted by washing the column with a buffer which did not contain the analogue. Figure 1 presents the results of electrophoretic analyses of the peak activity fractions; they each contain a single protein band, the intensity of which was proportional to the amount of IDH kinase activity. The mobility of the protein band indicates a molecular weight (MW) for the protein of 66,000.

We then proceeded to purify the IDH phosphatase. During preliminary experiments it became apparent that the steps needed for phosphatase purification paralleled those for the kinase and, indeed, that the ratios of the two activities remained almost constant. We therefore focused our attention on attempts to separate the two activities by various techniques. In our first attempt we used ion-exchange chromatography on DEAE–Sephacel (Fig. 2). This column yields good resolution of the applied protein, typically producing 8–12-fold purification of the IDH kinase. Despite this efficiency, the kinase and phosphatase activities eluted superimposably. Our next attempt to separate the two activities used a Sephadex G150 column, and again the activity peaks were indistinguishable. Finally, we re-examined our IDH–Sepharose affinity column and found that both the kinase and the phosphatase absorbed to the column in the presence of the ATP analogue and were superimposably eluted when the analogue was removed. The single protein band which eluted with the enzyme activity, as described above, showed a constant ratio of kinase to phosphatase activity. Thus, IDH kinase and IDH phosphatase are chromatographically indistinguishable when tested by ion-exchange, gel filtration and affinity column techniques. The purified activities exhibit a single protein band. Therefore, these activities appear to be associated with the same protein and possibly the same polypeptide chain. These observations do not, however, completely exclude the possibility that the two activities exist on highly similar proteins, or on non-identical subunits of a heterodimer.

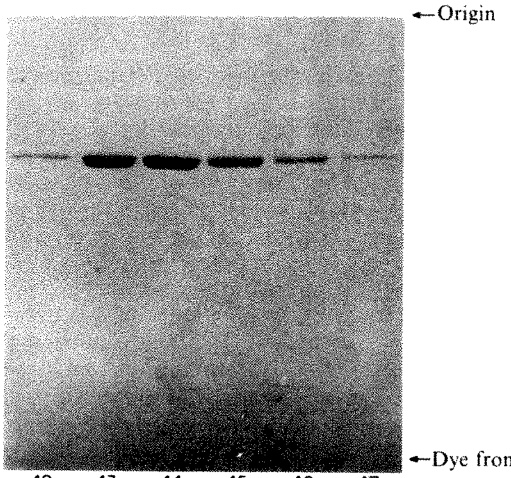

Fig. 1 SDS-polyacrylamide gel electrophoresis of purified IDH kinase following IDH–Sepharose chromatography. Partially purified IDH kinase was prepared by ammonium sulphate precipitation and DEAE–Sephacel chromatography. The sample, in buffer A (25 mM MOPS *p*H 7.0, 50 mM NaCl, 5 mM $MgCl_2$, 2 mM 2-mercaptoethanol, 0.5 mM 5′-adenylylimidodiphosphate), was applied to an affinity column prepared by immobilization of IDH on Sepharose 4B. The column was then washed with buffer A until the effluent was free of protein. The bound IDH kinase was then eluted by washing the column with 25 mM MOPS *p*H 7.0, 50 mM NaCl, 5 mM EDTA, 2 mM 2-mercaptoethanol. After assay for IDH kinase, samples from peak activity fractions were subjected to SDS-gel electrophoresis on 10% polyacrylamide gels. The gels were stained with Coomassie brilliant blue and destained with 10% acetic acid. Molecular weight standards, electrophoresed simultaneously, were phosphorylase *b* (94,000), bovine serum albumin, BSA (67,000), ovalbumin (43,000) and carbonic anhydrase (30,000).

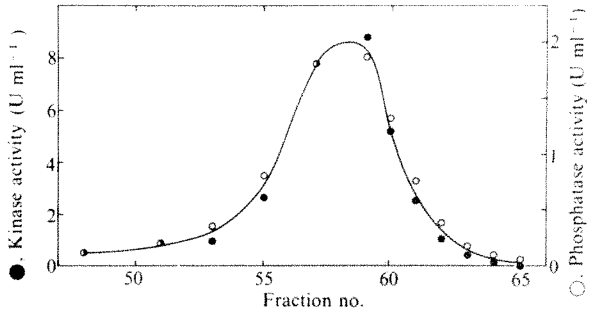

Fig. 2 Chromatography of IDH kinase and IDH phosphatase on DEAE–Sephacel. Following cellular disruption, centrifugation and ammonium sulphate precipitation, the sample was dialysed against buffer B (25 mM MOPS *p*H 7.0, 100 mM NaCl, 1 mM EDTA, 2 mM 2-mercaptoethanol), then applied to a DEAE–Sephacel column (2.5 × 35 cm) equilibrated in buffer B. After application, the column was washed with 100 ml buffer B and eluted with a linear gradient from 100 to 300 mM NaCl (750 ml each). Fraction size was 10 ml, flow rate 150 ml h^{-1}. IDH kinase was assayed by its ability to inhibit IDH in an ATP-dependent manner. The reaction mixture contained buffer C (25 mM MOPS *p*H 7.5, 5 mM $MgCl_2$, 100 mM NaCl, 2 mM dithiothreitol, 1 mM EDTA), 1 mM ATP, 0.5 mg ml^{-1} BSA and 0.6 μM IDH in a final volume of 50 μl. The reaction was started by adding ATP and terminated by addition of 50 μl 20 mM EDTA. Aliquots were then withdrawn and assayed for IDH activity in a reaction mixture containing 25 mM MOPS *p*H 7.5, 250 μM DL-isocitrate, 100 μM NADP, 5 mM NaCl. One unit of IDH kinase will produce 50% inhibition of IDH in 1 min. Calculations consider the IDH kinase reaction to be pseudo-first order with respect to IDH. IDH-phosphatase was assayed by its ability to catalyse the release of ^{32}P from phospho-IDH. The reaction mixture contained buffer C, 1 mM ATP, 2 mg ml^{-1} BSA and 0.1 μM ^{32}P-phospho-IDH (~20,000 c.p.m.) in 100 μl. The reaction was begun by addition of phospho-IDH and stopped by adding 150 μl of 20% trichloroacetic acid. The precipitated protein was removed by centrifugation and aliquots of the supernatant withdrawn for determination of ^{32}P. One unit of IDH phosphatase will catalyse the release of 50% of the ^{32}P in 1 min. Calculations consider the IDH phosphatase reaction to be pseudo-first order with respect to phospho-IDH. Typically, less than 20% of the phospho-IDH was hydrolysed during the reaction.

Initial studies of the IDH phosphatase showed that the activity in crude extracts was too low to account for observed rates of dephosphorylation *in vivo* and was very unstable as regards purification attempts. In resolving these problems, we discovered that the phosphatase activity had an absolute requirement for ATP or ADP. The activator has actually been shown to be Mg-ATP and all studies have been performed in 5 mM Mg^{2+}. This observation, together with the co-purification of kinase and phosphate activities, suggested that the activity identified as IDH phosphatase was, conceivably, the back reaction of the kinase. In such a case, ADP should be a far superior substrate as the ATP-dependent activity would actually result from the presence of ADP, either as a contaminant of the ATP or generated from it during the assay. In fact, ATP was found to be the superior substrate, with Michaelis–Menten constants of 100 and 400 μM for ATP and ADP, respectively.

To add weight to the conclusion that the ATP-dependent release of phosphate from phospho-IDH did not result from the ADP-dependent back reaction of the kinase, we tested the effect of adding an ATP regenerating system (Table 1). As such a system efficiently converts ADP to ATP, it would be highly inhibitory to any ADP-dependent reactions. The ATP regenerating system had no effect on the ATP-dependent phosphatase activity. When the ADP-dependent activity was examined, conversion of ADP to ATP by the regenerating system actually increased the phosphatase activity to a level slightly greater than that observed with an equivalent concentration of ATP; this increase appears to be due to an unidentified minor contaminant in the ADP preparation.

The products of the kinase back reaction are ATP and IDH. Thus, if the kinase back reaction were responsible for the release of ^{32}P from ^{32}P-phospho-IDH, the label should appear in ATP. When the products of the ATP- or ADP-dependent phosphatase reactions were treated with activated charcoal, we found that none of the released ^{32}P was absorbed, although the nucleotide was absorbed quantitatively. This observation, taken together with the results given above, indicates that the ATP-dependent phosphatase reaction is not the back reaction of the kinase.

The location of IDH kinase and phosphatase on the same protein resembles two previously described systems. It has been shown that the enzymes responsible for the adenylation–deadenylation of glutamine synthase in *E. coli* are located on the same polypeptide chain[8,9]. In addition, it has been reported recently that the rat liver 6-phosphofructo-2-kinase and fructose-2,6-bisphosphatase activities, which catalyse synthesis and breakdown of fructose-2,6-bisphosphate, are also physically associated[10,11]. It is interesting to note that, in addition to representing examples of the physical association of opposing activities, all three enzyme systems have major roles in the regulation of intermediary metabolism.

The possible advantages of localizing opposing activities on the same protein presents an intriguing problem. The occurrence of at least three such systems suggests that this is not an evolutionary accident. Such a physical association might have the advantage of allowing both activities to be controlled from a single site on the protein. While such a simultaneous regulation may occur, this is not the only mechanism by which such effects can be achieved. Simultaneous regulation could occur as a result of the interaction of a ligand with two distinct sites, one associated with each activity. Alternatively, in cases where the interconverted molecule is a protein, effectors which bind to that protein could result in simultaneous regulation. Nevertheless, physical association of opposing activities might represent a favourable mechanism for simultaneous regulation.

In addition to the potential for simultaneous regulation, the physical association of kinase–phosphatase for IDH may have been important in the evolution of the protein. The phosphatase site may have arisen from the kinase site by an imperfect gene duplication, possibly including a fusion event. If the imperfect duplication of the kinase site produced a phosphatase activity, the new site would be already designed to act on the common substrate. Although speculative, this suggestion explains the ATP requirement with the nucleotide achieving the same induced conformational change as for the kinase reaction, but with the specificity of the acceptor function altered to allow access by water.

Table 1 Effect of an ATP regenerating system on IDH phosphatase activity

Nucleotide		Phosphatase activity (mU)
ATP (0.1 mM)	No addition	12.4
	+ATP regenerating system	11.9
ADP (0.1 mM)	No addition	4.4
	+ATP regenerating system	14.0

Phosphatase assays were performed as described in Fig. 2 legend. Activity is presented in milliunits (mU). The ATP regenerating system consisted of 2 mM phosphocreatine and 10 U ml^{-1} creatine phosphokinase.

Calcitonin is a 3,500-molecular weight (MW) polypeptide whose main function in man is to protect the skeleton during growth, pregnancy and lactation[1]. It is secreted by C-cells which are localized in the thyroid in mammals, but may be present mainly in the ultimobranchial body and lung of more primitive vertebrates[2]. The hormone is also concentrated in the hypothalamus of several vertebrate species[3,4], including man[5], and in the primitive brain of the chordate *Ciona intestinalis*[6,7]. Based on cloning and subsequent analysis of recombinant DNA, recently we have reported the partial nucleotide sequence of the human calcitonin precursor mRNA[8,9]. This study showed that calcitonin resides towards the C-terminal end of its precursor protein, flanked by cryptic peptides of unknown significance. We now report that the synthetic C-terminal flanking peptide (PDN-21) predicted from the nucleotide sequence is highly active biologically—it approaches the potency of calcitonin in reducing the level of plasma calcium. As immunological evidence suggests that PDN-21 is synthesized *in vivo* and circulates in man, it may represent a novel hormonal cleavage product from the human calcitonin precursor with a physiological role in Ca^{2+} regulation.

Increasing numbers of small peptide hormones have been shown to be synthesized as high molecular weight precursor proteins that are subsequently processed to yield one or more peptides of biological significance[10,11]. Thus it was of interest to determine whether the predicted peptides flanking human calcitonin within the precursor possessed biological activity or were present only to ensure correct processing of the calcitonin precursor protein[9].

To investigate this possibility, the human C-terminal flanking cryptic peptide (H-Asp-Met-Ser-Ser-Asp-Leu-Glu-Arg-Asp-His-Arg-Pro-His-Val-Ser-Met-Pro-Gln-Asn-Ala-Asn-OH) corresponding to the last 21 amino acid residues predicted from the coding sequence of the calcitonin precursor mRNA[9], was

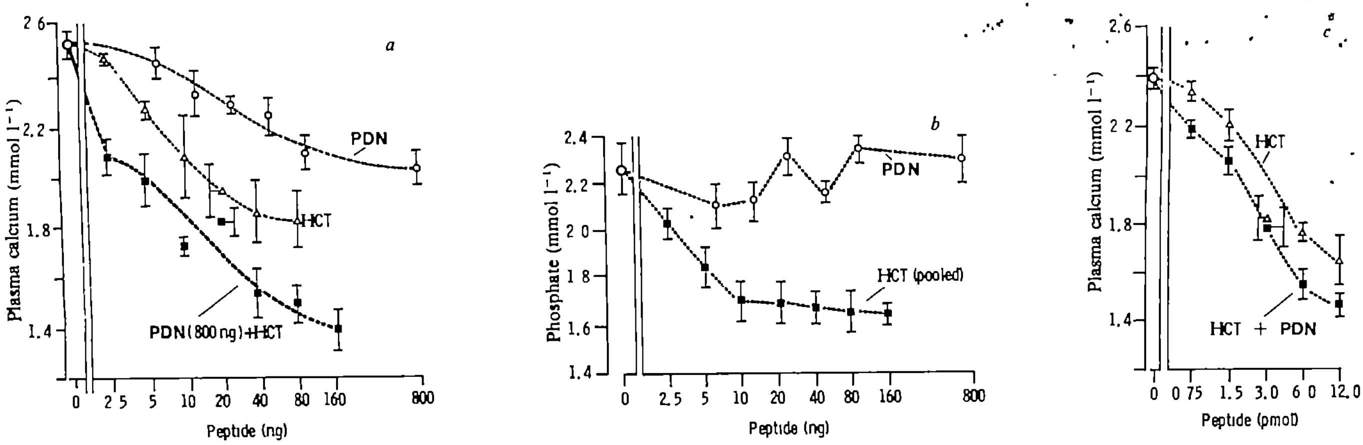

Fig. 1 Effect of PDN-21 on plasma calcium and phosphate. After preliminary experiments had shown that the time courses of the effects of PDN-21 and human calcitonin (HCT) on plasma calcium were similar, peptide was injected in sodium acetate buffer (pH 4.6) into the tail vein of female Wistar rats (mean weight 45 g, range 42–48 g; Oxfordshire Laboratory Animal Colonies) and blood taken from the aorta after 30 min in a randomized bioassay[23]. *a*, Plasma calcium was measured colorimetrically by the method of Gindler and King[24] and the values confirmed by atomic absorption spectrophotometry. Each point is the mean ± s.e.m. from three rats. ○, PDN-21; △, human calcitonin (WHO 1st International reference preparation of calcitonin hormone for bioassay 70/234, supplied by the National Institute for Biological Standards and Control); ■, human calcitonin + PDN-21 (800 ng PDN-21 was injected with each dose of calcitonin). Analysis of variance showed highly significant ($P < 0.001$) dose-related plasma calcium differences among the three treatment groups. The dose giving 50% response (ED_{50}) was 7 and 24 ng for human calcitonin and PDN-21, respectively. Over the linear dose–response range, 1 ng of PDN-21 had the same effect as 0.17 ng human calcitonin; in the human calcitonin + PDN-21 group, 1 ng human calcitonin was as active as 5 ng given alone. Three previous unrandomized experiments gave essentially similar results. *b*, Plasma inorganic phosphate[25,26] was measured in the same rats shown in *a*. PDN-21 produced no significant change at any dose level (○) but both the calcitonin and calcitonin + PDN-21 groups showed highly significant ($P < 0.001$, analysis of variance) dose-related reductions. These latter two groups did not differ and the results were therefore pooled (■). Values shown are mean ± s.e.m. *c*, In a separate batch of female Wistar rats (mean weight 51 g, range 51–53 g) from the same supplier, the effect of calcitonin alone (2.5–40 ng; △) was compared with that of calcitonin injected with equimolar amounts of PDN-21 (1.8–28 ng; ■). Each point is the mean for five rats ± s.e.m. The ED_{50} was 15 and 9 ng for human calcitonin alone and for calcitonin plus PDN-21, respectively. When equimolar PDN-21 was present, 1 ng of calcitonin was as active as 1.6 ng calcitonin alone (95% confidence limits 1.2–2.1 ng).

synthesized (Peninsula Laboratories) by solid-phase methodology, and the identity and homogeneity of the product established by amino acid analysis, high voltage electrophoresis and reverse-phase HPLC. We have called the peptide PDN-21 according to the terminology of Tatemoto and Mutt[12]. This peptide was used to obtain preliminary evidence of biological activity and to raise the antisera required to establish its presence in human tissues and sera.

Initial pharmacological studies yielded striking results. PDN-21 is highly active in reducing plasma Ca^{2+} in the rat (Fig. 1*a*) although the maximum effect is less than that produced by calcitonin. Our findings also indicate that the potency of human calcitonin is increased by the presence of PDN-21; the enhancement was fivefold (Fig. 1*a*) when maximal doses were used but still 60% when equimolar PDN-21 was given with human calcitonin (Fig. 1*c*). As the two peptides are presumably secreted in equimolar amounts, these results imply that PDN-21 may be important in the regulation of plasma Ca^{2+} *in vivo*. Further, because the effect of PDN-21 on calcium is additive to that of calcitonin, it is possible that the peptide acts at a different receptor. This action of PDN-21 (800 ng) is still obvious in nephrectomized animals (Fig. 2) and is therefore unlikely to be due to loss of Ca^{2+} but rather to a redistribution, perhaps involving bone. This is consistent with results from 48-h mouse calvariae explants in culture (Table 1); there is clear evidence of a direct effect of PDN-21 on ^{45}Ca-release from the prelabelled bones ($P = 0.02$ at the higher dose). As yet, we have not determined whether PDN-21 has an important role in Ca^{2+} regulation and bone physiology. It is also intriguing to speculate whether the hypocalcaemia that follows hypercalcaemic thyroid perfusion[13] is due solely to the effect of calcitonin release, or depends also on this new candidate hormone.

It is important to note that this effect on plasma calcium is highly specific. Thus, no effect was observed on plasma sodium, potassium, albumin or plasma phosphate (Fig. 1*b*). This latter finding clearly distinguishes PDN-21 from calcitonin, which lowers both plasma calcium and phosphate[14]. The glucose and magnesium levels did not differ significantly in relation to dose although the latter were slightly higher overall. There were no effects in guinea pigs and rats on smooth muscle contraction (ileum and bronchus), urine flow, milk ejection pressure or blood pressure.

Our experiments thus establish the biological activity of PDN-21 and suggest it has a role as a calcium-lowering hormone in man. However, immunoassay with antiserum specific for

Table 1 Comparison of the effectiveness of human calcitonin and PDN-21 in inhibiting cell-mediated ^{45}Ca-release from prelabelled mouse calvariae *in vitro*

	% Inhibition of cell-mediated ^{45}Ca-release ± s.e.m.
PDN-21	
40 μg ml^{-1}	63.6 ± 14.3 (5)
10 μg ml^{-1}	25.5 ± 9.9 (4)
Human calcitonin	
0.2 μg ml^{-1}	62.8 ± 8.2 (5)
0.02 μg ml^{-1}	48.6 ± 10.5 (7)

The method for studying the response of mouse bones to calcitonin preparations has been described in detail[21]. Cell-mediated release of ^{45}Ca into the culture medium was calculated by substracting the amount of exchangeable ^{45}Ca released into the medium by dead explants of 6-day-old prelabelled mice of the same litter from that released by the living treated explant[22]. The number of treated explants is shown in parentheses; the data were obtained after treatment of explants for 48 h *in vitro*. Although a higher dose of PDN-21 than human calcitonin was required, no attempt has been made to calculate 'potency' ratios because the dose–response curves for human calcitonin and PDN-21 are not parallel, and the relative stability of the peptides in the 48-h culture conditions is unknown. More work is necessary to establish the nature of the action of PDN-21 on explants and whether it is a true inhibition of resorption. Similar experiments with explants prelabelled with ^{3}H-proline, which is incorporated into collagen, should be rewarding. In tests on uptake of ^{45}Ca into explants *in vitro* there did not seem to be any effect of PDN-21 over controls, therefore we conclude that it probably does not alter bone accretion.

PDN-21 shows that the peptide circulates in concentrations approximately equimolar with calcitonin in human medullary carcinoma of the thyroid (Fig. 3). As PDN-21 is also measurable in normal human thyroid tissue, the peptide presumably circulates in a healthy subject, suggesting a normal hormonal role. Although studies of the action of the equivalent rat calcitonin C-terminal peptide (CCP)[15,16] have not been reported, measurements in the rat are in agreement with our results from immunoassay. Thus, antisera against synthetic CCP show that this peptide is present in equimolar amounts with calcitonin in normal rat thyroid tissue, rat medullary carcinoma of the thyroid (MCT), and is secreted by monolayer cultures of rat MCT cells[17,18].

Since the submission of this work, Amara and co-workers[19] have described alternative, apparently tissue-specific RNA processing of rat calcitonin gene transcripts, resulting in the generation of mRNAs encoding two different polypeptide products: calcitonin, and a calcitonin gene-related peptide (CGRP). Calcitonin mRNA was the major species in the normal thyroid but CGRP mRNA predominated in the hypothalamus. The equivalent splicing mechanism giving rise to a human CGRP-like mRNA has yet to be described and it remains to be determined whether or not rat CGRP mRNA is translated into an active product in the brain.

Two main conclusions follow from our work. First, the human calcitonin precursor is a true polyprotein with at least two biologically active cleavage products and falls into the group of precursor proteins typified by pro-opiomelanocortin. Second, in addition to a possible involvement in Ca^{2+} regulation in health, PDN-21 may have therapeutic potential. Its intrinsic activity on calcium, together with its enhancement of the activity of calcitonin, suggests that it may be useful in the treatment of hypercalcaemia or of Paget's disease, where human calcitonin is at present the treatment of choice[20].

We thank Drs Sonia Jupp, John Stevenson and Elizabeth Hughes and Mr G. Abeyasekera for assistance. We also thank Professor Gordon Bisset for pharmacological studies in guinea pigs and rats. Our experiments were supported in part by Celltech Ltd and the MRC.

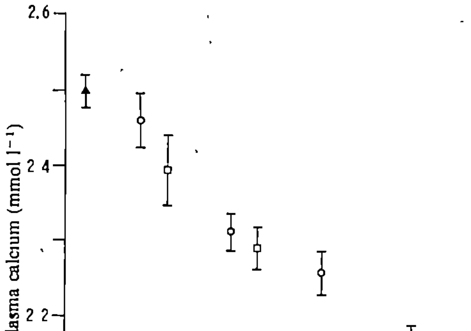

Fig. 2 The effect of nephrectomy on the calcium-lowering action of PDN-21 and calcitonin. Female Wistar rats (mean weight 56 g, range 57–58 g; Charles River, UK) were divided into groups of six, anaesthetized with ether and the kidneys exposed from a posterior incision (sham groups, □) or removed (○). Acetate buffer alone (0.2 ml), PDN-21 (800 ng), human calcitonin (40 ng) and both peptides together, were injected in buffer immediately after operation into both sham and nephrectomized groups. All the peptide preparations produced highly significant calcium reductions ($P<0.005$). The action of PDN-21 was unaltered by nephrectomy although human calcitonin had a slightly smaller effect after removal of the kidneys ($0.01<P<0.05$). The control group (▲) was injected with acetate but not anaesthetized Rats from this supplier are slightly less sensitive to both human calcitonin and PDN-21.

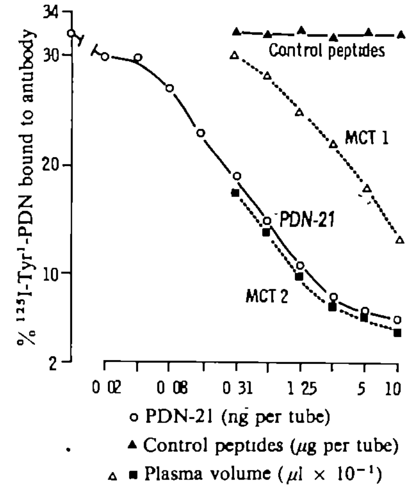

Fig. 3 Immunoassay of PDN-21 in human plasma. Tyr^1-PDN-21 (Peninsula Laboratories) was coupled to ovalbumin[27] and an antiserum raised in rabbits. The serum was used at a dilution of 1:1,200 with ^{125}I-Tyr^1-PDN-21 as tracer. The presence of 10 μg per tube of luteinizing hormone-releasing hormone, salmon calcitonin, human calcitonin, somatostatin, ACTH$_{1-24}$ (Synacthen; Ciba-Geigy), porcine ACTH$_{1-39}$, human parathyroid hormone, oxytocin, insulin, pro-opiomelanocortin, human prolactin, or human growth hormone did not interfere in the assay (▲). The limit of sensitivity was ~40 pg per tube, the intra-assay variability <5% and the inter-assay variation ±10%. We studied plasma from 16 patients with MCT proven at operation; parallel displacement curves were found in 15 of the 16 cases Plasma PDN-21 ranged from 0.6 to 138 ng ml^{-1} and was approximately equimolar with human calcitonin (range 0.8–314 ng ml^{-1}). Results for plasma dilutions from two of the 16 MCT patients are shown together with a displacement curve for synthetic PDN-21 (○). Patient 1 (MCT 1, △): PDN-21 11 ng ml^{-1}, human calcitonin 18 ng ml^{-1}; patient 2 (MCT 2, ■): PDN-21 103 ng ml^{-1}, human calcitonin 314 ng ml^{-1}. As expected due to its equimolar relationship to normal calcitonin levels of 20–100 pg ml^{-1}, PDN-21 was not measurable in 12 normal subjects at this assay sensitivity.

BOOK REVIEWS

Men of science, men of letters

L. Pearce Williams

NATHAN and Ida Reingold, historian of science and mathematician respectively, have conceived the bold idea of presenting the history of science in America from the beginning of the twentieth century until the outbreak of the Second World War in Europe in terms of letters written by American men of science. The various sections devoted to the organization of science in America and the development of the various sciences are prefaced by short essays by the editors intended to introduce the *dramatis personae* and to sketch in the background against which the letters may be intelligently viewed and considered. The work, as a whole, is introduced by a short section whose main purpose is to define science in its American context and to indicate the place that science played in twentieth century America.

There is a notable virtue to this approach, and I should like to stress it at the outset of a review which will be generally critical. The reader is offered a splendid feast of hitherto unpublished and utterly fascinating primary sources. There are letters from almost all the "greats" of modern American science, containing important insights into their personalities, their concern for the public face of science and their own scientific work. Here are candid remarks on the organization and content of American science from William Henry Welch, Ira Remsen, George Ellery Hale, Charles W. Eliot, Irving Langmuir, Norbert Wiener, Jacques Loeb, Alfred H. Sturtevant, Albert Einstein and John von Neumann, to mention only the most famous, with replies from such non-American scientists as Ernest Rutherford, Wilhelm Ostwald and Bertrand Russell. As these names indicate, the sciences of astronomy, medicine, genetics and physics are well represented and readers will be able to discern what the major problems, both social and intellectual, were which concerned these men in the twentieth century. By publishing these letters, the Reingolds have done an invaluable service to historians of American science who might not have recognized the riches that were at their disposal, and by calling attention to the depositories in which these letters were found they have indicated rich veins for further exploration.

In this sense, this is an indispensable volume for all students of the modern American scene and I recommend it highly to them. It should also be on the library shelf of every practising scientist over the age of 40 who will find in it echoes of his own education and scientific upbringing. Such persons will read it with an enjoyment that the non-scientist cannot share. This is, then, an important work but it is also deeply flawed and it is to its flaws that I must now turn.

Science in America: A Documentary History 1900–1939. Edited by Nathan Reingold and Ida H. Reingold. Pp.490. ISBN 0-226-70946-9. (University of Chicago Press: 1982.) $49, £26.25.

In their brief preface, the Reingolds wrestle with a problem that has bedevilled historians of science now for a generation, namely the "internal" versus "external" perspectives on the history of science. The first states that science is an autonomous activity that develops by an internal logic of its own; the second insists that scientists reflect the general culture that surrounds them in their own scientific works. Non-historians of science may well be puzzled that serious scholars find much to argue about here since common sense indicates that both propositions are true. There *is* an internal logic to the sciences and scientists *do* reflect their society. The trick is to discover when each of these applies.

The Reingolds are perfectly aware of the fact that science has both a public and a private face, and they try to deal with this by means of a metaphor. Instead of speaking of a "core" of hard science, dear to the internalist, and an "outside" to which the externalist appeals, they assume that

> there is no core — everything is part of an interface. And if the core with its weighty contents, has the aura of permanence, the interface is like a thin film, almost a soap bubble. Ideas, people, institutions of all sorts — not merely the scientific — exist in the interface. It is too much for such fragility, and tensions are created which produce additional film.

I simply do not understand what this metaphor means. How science exists in a soap bubble, or how tensions at the interface create more film escape me. Nor does the metaphor do much for the Reingolds except to permit them to insist that pure and applied science are both important, and that scientific institutions as well as private biases and prejudices go into the making of science. No one, again, will argue with this conclusion which could have been presented without the metaphor.

The metaphor, however, does get the Reingolds into serious trouble. By defining science as part of an interface, they eliminate any distinction between the private and public face of science. This, then, permits them to publish a book containing documents drawn solely from the private sector and clearly intended by them to be a documentary history of science in America. I have often criticized historians of science whose works have included no references to private papers because they seemed to me to be seriously deficient. This work sins equally heavily on the opposite side. We read a number of letters by George Ellery Hale on various topics, but no reader of this volume would be able to describe Hale's contributions to modern astronomy in any detail. Similarly, the great physiologist, Jacques Loeb, is well represented by letters that, occasionally, refer to his epoch-making scientific work but not a single one of his important published articles is present.

The list of such omissions is as long as the list of letters and any reader who expects to gain an understanding of the course of scientific thought in America in the first third of the twentieth century may be bitterly disappointed by this book. Had it been entitled, *American Scientists: A Documentary History*, there would have been a much closer relationship between title and contents.

Having already praised the variety and interest of the letters printed by the Reingolds, I should also raise some questions about their editorial judgement in presenting them. The editors try to disarm critics by announcing that "the documents are edited with a decent minimum of editing". I should like to disagree. Important information is withheld and this vitiates some of the scholarship involved. One of the fundamental commandments of the editing of historical documents is to locate such documents in both time and place. Throughout the volume, place is systematically excluded. This leads, at best, to confusion as the reader tries to work out where the writer is so that he can understand local allusions. At worst, it makes parts of the letters unintelligible. Works such as this should not force their readers to guess where information is available. This is not a trivial point — anyone wishing to use these letters in other works of scholarship will have to go to their sources to find out this information, thus forcing a duplication of effort that could easily have been avoided.

While I agree that footnotes to letters should be as short and concise as possible, it is important that they also provide the information necessary for the reader to understand what he is reading. In too many letters, there are names which are not identified. When Alfred Sturtevant urges Milislav Demerec "to try and get hold of Pink Jesus (= Bug Forbes)" (p.327), I suspect that few readers will understand the allusion. Professor Forbes was one of Cornell's legendary figures whose beard and ruddy complexion gave him his nickname and who certainly deserves a footnote. In other cases, a person is identified, if giving a first name, last name and dates of birth and death can be counted as identification — surely a brief description of a person's place in science would have been helpful? The Reingolds also do not always provide essential information for their readers about scientific matters. In the same letter from Sturtevant and the one immediately preceding it, Sturtevant mentions *Oenothera lamarckiana.* How many readers will immediately recognize this as the plant used by Hugo de Vries in his studies of mutation? The Reingolds say nothing.

Although these are serious criticisms, I would not like to close on a sour note. This is not an adequate documentary history of science in America, as its title insists; but it is a fascinating slice of scientific Americana that should prove both stimulating and useful to a wide variety of readers. □

L. Pearce Williams is the John Stambaugh Professor of the History of Science at Cornell University. He is the author, among other works, of Michael Faraday, A Biography *(Chapman & Hall, 1965).*

In terms of analytical chemistry

T.S. West

A Dictionary of Chromatography, 2nd Edn. By R.C. Denney. Pp.229. UK ISBN 0-333-31667-3; US ISBN 0-471-87477-9. (Macmillan Press/Wiley: 1982.) £15, $39.95. *A Dictionary of Spectroscopy,* 2nd Edn. By R.C. Denney. Pp.205. UK ISBN 0-333-31670-3; US ISBN 0-471-87478-7. (Macmillan Press/Wiley: 1982.) £15, $39.95.

THESE two second-edition dictionaries of chromatography and spectroscopy are attractive additions to the chemist's bookshelf, where they should serve as useful guides to those not fully expert in either technique. The author has successfully put together a reasonably comprehensive set of terms and definitions and has translated them into SI terminology in keeping with present-day trends. The terminology of the IUPAC "Orange Book" of Analytical Nomenclature has been adhered to fairly closely, and the author has steered a consistently sagacious path through the minefield of inconsistencies that abound in these as in most other areas of nomenclature.

I was, however, disappointed to find no mention of "limit of detection" in either book or "sensitivity" in the spectroscopy volume. Both volumes similarly define the term "signal-to-noise", but in neither is it said exactly what a signal is and the explanation of noise will not be very helpful to the puzzled novitiate, even in the chromatography volume. However, terms such as these are perhaps the most difficult to define and the author may have been wise to avoid or define them minimally. On the other hand, useful reference could certainly have been made to other terms such as "time-resolved spectra" and "background", particularly for the newcomer to these techniques.

In both books the author has made excellent use of explanatory diagrams, 55 each for both chromatography and spectroscopy, and in general the definitions are clear and very much to the point, particularly those in the chromatography volume. Each book includes an extensive list of references for further reading, but a glossary of the terms defined, with the page numbers, would have been useful even though the two books are alphabetical lists from start to finish.

The chromatography volume gives the impression of being more comprehensive and perhaps more sure-footed than that on spectroscopy. However it may well be that the latter serves a more useful purpose in that it deals with some of the newer electron spectroscopies — such as Mössbauer and Auger spectroscopy — that are less well covered in other dictionaries which tend to concentrate exclusively on the more familiar molecular, atomic and electron spectroscopy techniques.

Each book is timely and excellent in conception, and in remarking that I would like to have seen such and such a term defined, I am basically expressing my satisfaction with the other definitions and wishing that there could have been more of the same. Both volumes deserve to sell well; they are especially recommended for student use. □

Integrated enzymes

Athel Cornish-Bowden

Fundamentals of Enzymology. By N.C. Price and L. Stevens. Pp.454. Hbk ISBN 0-19-857175-5; pbk ISBN 0-19-857176-3. (Oxford University Press: 1982.) Hbk £25, $49; pbk £12.50, $24.95.

ENZYMOLOGY has a role in nearly all aspects of research in biochemistry, and is of central importance in the whole subject. Partly because of this, it is commonly taught to undergraduate students as a series of disconnected topics. The people who study protein structure often have little in common with those concerned with the control of metabolic processes in the living organism. A third group of people study enzyme kinetics, and among these there sometimes seems to be an unbridgeable gulf between those who are interested in the steady state and those who are interested in transients. Yet these and other aspects of enzymology are all part of the same subject and it is clearly desirable to integrate them.

The present book is an attempt to describe enzymology as a whole, from the structures and properties of isolated enzymes to their roles as components of complex metabolic systems. It is written at a level where it can easily be understood by undergraduates, but it has enough detail to be of value to any research worker with an interest in enzymes. It is not the first book to attempt such a synthesis, but it is easily the most successful that I have seen, and it deserves to become a standard textbook of general enzymology.

The book is informative and accurate about the aspects of the subject that I know best, and so I feel inclined to believe what it tells me when it ventures into less well known territory, for example (in a final chapter on enzyme technology) about the origin of the holes in Swiss cheese. I found few faults, none of them serious. Although the authors are not themselves confused about the distinction between the Hill coefficient and the number of binding sites on a protein, they may well confuse their readers because they use the same symbol for both quantities on nearly consecutive pages.

Although monstrosities such as SGOT make fleeting appearances (inevitable, perhaps, in a chapter on clinical enzymology), and molecular weights are mentioned throughout, the authors have in general made commendable efforts to refer to enzymes by their recommended names and to use modern units and terminology. Even the clinical chapter is largely written in English, perhaps the first time this has ever been achieved. □

Scattering information from Graz

Henryk Eisenberg

Small Angle X-ray Scattering. Edited by O. Glatter and O. Kratky. Pp.515. ISBN 0-12-286280-5. (Academic: 1982.) £43.60, $81.

FOR SOME years study of the scattering of radiation has been a favoured approach in the investigation of a variety of low molar mass, colloid and biological systems. There are three principal techniques: light scattering which, using an effective wavelength of a few thousand Angstroms, has been revolutionized by the advent of the laser; small angle X-ray scattering, which is restricted to low scattering angles because of the much lower wavelength (around one Angstrom); and neutron scattering, which has recently come to the fore and shows greater flexibility with respect to wavelength (from around one to a few tens of Angstroms). Although the three phenomena share the same basic theory, interesting complementarities result from the specific nature of each of the processes.

Recently, small angle X-ray scattering has received a strong impetus following the introduction of one- and two-dimensional position-sensitive detectors, computerized data acquisition and treatment, and the use of powerful synchrotron radiation sources. These developments have shortened experimental times to the subsecond range, allowing the study of dynamic phenomena. Long viewed with suspicion because of unwieldy and error-prone procedures, and a tendency towards overinterpretation of an essentially information-poor experimental technique, small angle X-ray scattering has now matured into a position of considerably higher respectability.

Although the editors have evidently made efforts to broaden the spectrum of contributors, the book under review represents to a large extent the individual and collective achievements of the Graz school of Kratky and Porod. Porod himself presents a comprehensive and lucid discussion of the general theory, which owes much to his efforts. Statistical fluctuations are mentioned, though not in sufficient depth to relate them to the analysis of multicomponent systems. Instrumental methods, and data treatment and interpretation are covered in detail in the various chapters, as well as contrast variation, a trade-mark procedure in neutron scattering. Although the underlying theory is identical for X-rays and neutrons, no equivalent exists to the contrast variation achieved by manipulation of hydrogen–deuterium compositions in the neutron technique.

Discussions of applications range widely over proteins, nucleic acids and nucleoproteins, lipoproteins and membranes, and natural and synthetic high polymers in the dissolved and solid state, including evaluation of the Kratky–Porod persistent chain, inorganic substances, and aggregates and micellar structure of small molecules in solution.

This volume is a useful though somewhat uneven compilation. Thus, in parts, quantities in equations are not properly defined, some awkward expressions intrude, and references are missing or incomplete. Also it is irritating that different symbols are sometimes used for the same parameter, even in the same chapter.

Altogether, however, the book does provide a good source of information for evaluating both past achievements and future promise in an important field of study. For those wishing to come to grips with most of the theoretical and practical aspects involved it will prove instructive reading. □

The right time for retroviruses

Neil Wilkie

RNA Tumor Viruses. Molecular Biology of Tumor Viruses, Part 3, 2nd Edn. Edited by Robin A. Weiss *et al.* Pp.1,408. ISBN 0-87969-132-8. (Cold Spring Harbor Laboratory: 1982.) $125 (US), $150 (elsewhere).

ALL YOU ever wanted to know (and even more) about retroviruses, contained in one volume. That seems to be the promise of the new Cold Spring Harbor publication *RNA Tumor Viruses,* which together with the companion volume on DNA tumour viruses comprises the second edition of the popular series *Molecular Biology of Tumor Viruses.*

By and large, that promise is fulfilled by a notably clear and up-to-date review of a complex and fast-moving field. The decade elapsed since the publication of the first edition has witnessed remarkable progress in our understanding of the structure and function of retroviruses. It is not surprising, then, that the current volume is massive (it weighs 2 kg and runs to 1,400 pages) or that is essentially a completely new book, rather than a revision of the first edition.

The stated aim of the book is to cater for both the novice and the expert, but novice and expert in what field? The study of

retroviruses has provided insight into many important areas of biology removed from "straight" virology. Retrovirus genomes can be inherited as Mendelian genes as well as spread between and within species by infection; they mimic the effects of mobile genetic elements by mutation and alteration of the expression of chromosomal genes; they activate, recombine with and transduce cellular oncogenes; and they induce defects in the regulation of cell growth. The book is therefore of direct interest to virologists, molecular biologists, geneticists, cell biologists, tumour biologists and clinicians.

Does the book work? The text is divided into 11 chapters which deal firstly with molecular aspects of the genome, its replication and expression, and then with the biological aspects of expression, infection and pathogenesis. The self-contained chapter structure has resulted in considerable repetition and contributes to the overall length of the book. This is anticipated in the preface and on balance the strategy is acceptable; a little reiteration does no harm when the subject matter is so complex. The text has been researched in such formidable detail that complete novices may find some sections hard going. I imagine that undergraduates, for example, would need some guidance in the correct usage of the book. Nonetheless, the writing is generally clear and in most chapters there should be no difficulty in abstracting the information at different levels of complexity. Moreover, where doubt or ambiguity of interpretation is present, this is usually pointed out and the alternatives explained.

I particularly enjoyed the three chapters on the molecular biology of the retrovirus genome. They clearly explain the exquisite mechanisms by which the RNA genome is converted to a DNA copy in which a terminally redundant LTR sequence is created, how this is inserted into the chromosome and expressed using tactical variations on a strategy evolved to permit the synthesis of many gene products from a single genome sequence. The sections covering endogenous viruses also successfully deal with a complex subject while highlighting the evolutionary implications. Of course the pathogenicity, particularly the oncogenicity, of retroviruses is currently a centre of attention and readers will find the chapters on pathogenicity and oncogenes to be of especial interest. These subjects are, in the main, well treated. Just enough (and no more) information on haematopoiesis is given to understand the concepts involved in virus-induced cellular disease. The several current models for the mechanistic interpretation of transformation are fairly represented and the review of oncogenes and their products is also well-balanced and up-to-date.

The final chapter on the identification of human RNA tumour viruses explains the dangers of overinterpreting initial results and introduces the only convincing isolate to date: the lymphoma-leukaemia virus associated with certain forms of adult T-cell leukaemia. A sting in the tail of the book is provided by a compilation of restriction endonuclease maps and primary nucleotide and amino acid sequences of some well-studied viruses.

Students of retrovirology and its practitioners will be not unaware of the clashes which often arise between some dominant personalities with individual and exclusive viewpoints. Although only a small number of authors could be included in the writing of the current volume, my impression is that this has not been allowed to disturb the balance of the text and that the views expressed are reasonably representative of the field (not always the case in other volumes from the same stable).

I also sense that the timing of the book is critical: we are probably ending a phase in which details of the virus structure are the main concern, and beginning one in which the consequences of virus–cell interactions will predominate. This volume comfortably spans these areas. It is exhaustively researched and referenced, and will provide the standard reference text for the field for the foreseeable future.

Neil Wilkie is Head of the Tumour Virus Laboratory at the Beatson Institute for Cancer Research, Glasgow.

An English Lamarck

An English translation of Madeleine Barthélemy-Madaule's *Lamarck ou le Mythe du Précurseur* (Editions du Seuil, 1979) has just been published by MIT Press. The original edition was reviewed in *Nature* **286**, 187; 1980.

The translation (by M.H. Shank) has the title *Lamarck the Mythical Precursor*, and costs $17.50, £12.25.

Looking at comets in Arizona

David W. Hughes

Comets. Edited by Laurel L. Wilkening. Pp.766. ISBN 0-8165-0769-4. (University of Arizona Press: 1982.) $29.95.

TUCSON, Arizona was the place and March 1981 the time of the meeting of 175 scientists for the Sixty-first International Astronomical Union's Colloquium on "Comets: Gases, Ices, Grains and Plasma". The review papers presented at that meeting provide the basis for this book.

Comets have been newsworthy for centuries and scientists are forever using the latest observational techniques and theoretical gambits to delve into their mysteries. The 1980s are no exception. The impending return of Halley's comet in 1986 should see some visits by spacecraft; the successful operation of the International Ultraviolet Explorer has made H and OH observations in the extended coma a commonplace occurrence; the collection of cometary dust in the Earth's upper atmosphere is now routine; and the Pioneer Venus orbiter observations of the interactions of the solar wind with an atmosphere unprotected by a magnetic field gave a preview of what is to be expected in the cometary case.

"New theories and data are collected in this book as an introduction to comets for newcomers as well as a reference volume for specialists" — I quote from Laurel Wilkening's preface. Unfortunately I don't think a book can easily be both and this one certainly is not. It contains 29 papers grouped under headings such as Overview; Nucleus; Dust; Coma, Ion Tails and Solar Wind Interaction; Origin, Evolution and Interrelations; and Basic Information and References. As with all conference proceedings the standard is mixed but there are some real gems — Delsemme on the chemical composition of cometary nuclei, Kresak on statistics and observational selection, Whipple on nuclei rotations, Sekanina on splitting, Wetherill and Revelle on the relationship between comets, meteorites and fireballs, A'Hearn on spectrophotometry, Feldman on the ultraviolet, Everhart on orbital evolution, Marsden and Roemer on astrometry and basic characteristics.

Such papers lift this conference proceedings from the category of "every library should purchase it" to "every comet researcher should have it on his personal bookshelf". If, however, critical comparisons must be made I do think the University of Arizona did a better job on the asteroids in 1979 than they have here on the comets. (For a review of *Asteroids*, edited by T. Gehrels, see *Nature* **287**, 664; 1980.)

Also, when it comes to introducing a topic to newcomers it must be ensured that certain features are not omitted. This is especially difficult for the editor of conference proceedings who is restricted not only by the ease with which scientists raise travel money, and their predilections for Arizona in March, but also by the problems of convincing the participants to write up their papers in a suitable form. There are far too many gaps in this volume to make it a good introduction for the newcomer. ☐

David W. Hughes is a Lecturer in Astronomy and Physics at the University of Sheffield.

Putting Europe's missiles at risk

Next year will be a bad year for European governments, perplexed by strategic problems and bothered by elections. The United States should help them out.

1983 promises to be a rowdy year for nuclear strategists, a testing time for the governments of states belonging to the North Atlantic Treaty Organization (NATO) and one of the most strenuous years for NATO itself since the row about the European Defence Force early in the 1950s and the departure of France at the end of that decade. Although the new year is still some weeks off, the pressure is already building up, principally about the decision taken unanimously by the NATO governments at the end of 1979 to deploy new intermediate range nuclear weapons in Western Europe towards the end of 1983. The plan is that 108 Pershing II ballistic missiles should be sited in West Germany, and that 362 ground-based cruise missiles should be based in West Germany, Italy, the Netherlands and the United Kingdom.

Predictably, the Soviet Union is doing everything it can to frighten governments in Western Europe with the consequences of their decision three years ago. Soviet spokesmen have taken to saying that the short flight-time of the Pershing missiles might force Soviet forces onto the hair-trigger strategy of "launch-on-warning", with all the dangers of accidents that would follow. There have also been heavy hints that it may be necessary to install more of the 5,000-kilometre SS-20 mobile missiles on the Soviet side, that sea-launched cruise missiles might be placed within range of the United States and even that ballistic missiles might again be based in Cuba. The Soviet Union's obvious objective is to undo the 1979 agreement. It is high time that Western governments worked out a resolute response.

The present, unfortunately, is an unpropitious time for working out a level-headed response. Of the principal governments involved in the 1979 decision, only the British government has not been changed, either by the ballot-box or by some other constitutional process. And while it might in ordinary circumstances have been expected that the new West German government of Chancellor Helmut Kohl would have been more able politically to carry through the 1979 agreement than its predecessor, haunted as it was by disagreements on nuclear policy within its own party, Chancellor Kohl is almost as much constrained by his promise to hold a general election next March. Elsewhere in Europe, even the strongest governments have been given pause by the resurgence of opinions dissenting from present strategies. The present British government, for example, has to contend with — and ideally must somehow answer — an increasingly vocal Campaign for Nuclear Disarmament that would abandon the plan to replace the British Polaris submarines with Tridents, decline to provide bases for US cruise missiles and eventually (but not yet) withdraw from NATO, a Labour opposition party now committed to the abandonment of Trident and even an opinion from a Church of England group tending in the same direction. What, in these circumstances, is to be done?

The first need is that embattled governments should remind their people of the reasons for the 1979 agreement and of its terms. The decision to base missiles of intermediate (as distinct from "tactical") range in Western Europe derives simply from the deployment of the Soviet force of SS-20s during the 1970s. With the help of the earlier SS-5 and SS-6 missiles, the Soviet Union could now deliver more than 1,000 warheads on targets in Western Europe using delivery systems that can have no wider strategic role. (The mobile SS-20s are also potentially a threat to China, but most of them just now are based in the central and western parts of the Soviet Union.) To be sure, both sides could carry larger numbers of nuclear warheads to targets some thousands of kilometres away by means of aircraft, but plainly there are technical advantages in a force of ballistic missiles and in the diversity that they bring. If some measure of strict military balance is a legitimate goal of strategic policy, the NATO decision of 1979 was almost unavoidable. On the view, for which there is a rich body of argument in justification, that the nuclear balance has helped to keep the peace in Europe in the past several decades, the decision may also be held to have been prudent.

What has been commonly overlooked, in the arguments between Western governments and their nuclear critics, is that NATO's decision in 1979 was deliberately conditional. The governments concerned said loudly and clearly that intermediate range missiles would be based in Western Europe by the end of 1983 only if, by then, there had been no substantial progress towards arms control in the European region. At the time, the West German government was chief among those that argued that no intermediate range missiles on either side would be preferable to other solutions.

The experience of the past several months at the Intermediate Nuclear Force negotiations (IFN) at Geneva is far from encouraging. So far, the United States has publicly proposed that all intermediate-range missiles should be dismantled, while the Soviet Union has countered in the private meetings with the suggestion that missile launchers should be limited to 300 on each side. Neither of these proposals can be expected to satisfy the other side, especially when account is taken of the complications arising from the substantial fleets of aircraft on each side, and the presence of independent strategic nuclear forces in both Britain and France.

The gap between the two views is not, however, unbridgeable. Technically, the urgent need is for some means of assigning potency to delivery systems of various kinds, and then for settling on appropriate upper limits that should not be exceeded. The political ideal would be to persuade the Soviet Union to withdraw its SS-20s from within striking distance of Western Europe (perhaps to some observable quarantine in Eastern Siberia?) so that the deployment of the Pershing and cruise missiles could be postponed. But that objective entails a paradox: the most effective way of winning an understanding with the Soviet Union is to continue to insist that the deployment of the US missiles will be carried through. On past form, a compromise should then be possible about the middle of 1983.

Long before then, the Geneva talks must be put on a much more rational basis. Two sets of bilateral negotiations, about nuclear missiles of intermediate and strategic range, are being carried on independently of each other. The distinction is absurd. The SS-20s that now potentially threaten Western Europe could be used both in a limited nuclear war in which the United States was not directly attacked (or threatened) or in a strategic all-button conflict. Similarly (Soviet analysts will calculate), Pershings deployed in Europe would be assigned to a variety of targets in the Soviet Union, some of which would necessarily be integral to a strategic attack (no doubt retaliatory), which probably explains why the Soviet Union has reacted so strongly against them. In such a negotiation, the British and French

0028-0836/82/490467-02$01.00

governments should either be participants or effectively be represented.

For Western governments, the implications of this complicated situation are bound to be uncomfortable. In Europe, governments will have to be telling anyone who will listen that they stand by what was agreed in 1979, but that they will refuse house-room for the Pershing and cruise missiles once there is some kind of agreement at Geneva. They will have to give further hostages to electoral fortune by pointing out the inconsistencies in the Soviet Union's insistence that it must be allowed to negotiate from strength. In the United States, however, there is an urgent need that the Reagan government should change tack. More factual and less strident accounts of the Soviet threat would help the Helmut Kohls of this world, while the eagerness of members of the US Administration such as Mr Caspar Weinberger, the Secretary of Defense, to prove that the Soviet Union is "not serious" about arms control is increasingly an impediment to a successful negotiation. Western governments in 1983 should try to persuade their own people that they are equally serious in their intentions both to increase the nuclear striking power in Europe and to negotiate a deal with the Soviet Union.

Max Born's centenary

Quantum mechanics is less than a century old; Max Born belongs to an earlier period.

The accompanying photograph of the late Professor Max Born is a monument to the heroic days of modern physics. Born was born almost exactly a century ago, and his anniversary has been widely celebrated in West Germany in the past few months, the fact of his having been driven out in the 1930s notwithstanding. Max Born is still widely revered as a perceptive and sympathetic teacher, as well as the author of an important textbook on atomic physics. Some may also know that with Jordan and, later, with Heisenberg, he contributed to the construction of quantum mechanics, still the most surprising theoretical construct of the twentieth century. Born's achievement, in the early 1920s, was that or reconciling in his own mind the notion that quantum states can be likened to vectors in some n-dimensional or even infinitely dimensional space, and physical quantities to operators in that space, a triumph of logic over intuition. That Schrödinger eventually stole the show was a kind of accident. And, in any case, Max Born eventually taught physics at the University of Edinburgh as if he had never been a hero.

Can there be excess TV?

Britain has changed from having too little to having too much television.

A few weeks ago, the British were widely regarded as a televisually deprived people, stuck with a meagre ration of three television channels, two run by the British Broadcasting Corporation and one other operated on behalf of commercial interests by a public corporation called the Independent Broadcasting Authority (IBA), financed by those given a licence to broadcast television signals accompanied by advertisements. The late Lord Thomson's remark that a television franchise was a licence to print money has ever since stuck in the public mind and has also been a challenge to the statutory broadcasting authorities: how can the entrepreneurs be kept in their tradesmen's places (chairmen of commercial television companies do not automatically qualify for knighthoods in the British system) while being cajoled into producing better television broadcasts than those that the marketplace would require?

The simple answer, so far, has been to let them make profits, but to take away the cream by means of a levy over and above taxation. More recently, IBA has required that profitable television contractors should contribute towards the cost of an extra television channel. Now, however, the broadcasting authorities are in a fix. The British government, more by accident than design, has decreed not merely that there should be at least two and possibly four extra television channels by 1986, but that there should be a national cable television system even sooner. And then, further to complicate the relief of visual deprivation, the British government has launched a fourth conventionally broadcast set of television signals among the British people, called Channel 4 by English-speaking people, but Canl Pedwar Cymru among those in Wales who are able, linguistically, to insist on speaking Welsh.

The immediate (but admittedly anecdotal) consequence of this development has been that people recently crying for more televisual choice have taken to complaining that they cannot possibly keep up with the output of four channels. Merely reading the menus on offer each day is a sufficient chore; actually watching what is on offer would be death of a kind. This, no doubt, is the reason why Channel 4 has so far been a disaster. It seems to have won the allegiance of a mere four per cent of the British televiewing audience, chiefly (it appears) on the strength of ancient films from Hollywood. What the new channel has so far failed to accomplish is the trick of making what it has to show overwhelmingly captivating for some minority among that section of the population at risk of having no other television signal at which to look. Why, in other words, has not the British Channel 4, the first national television network anywhere to be known by a number greater than three, failed in its first few weeks to live up to the ideals of its prospectus? Because it has not had the courage of its conviction that minority interests should be catered for. Science, for example, has been dealt with shabbily on the fourth television channel. On present form, the sixty-fourth channel will be no better.

The moral for the British broadcasting authorities, the British Broadcasting Corporation and the Independent Broadcasting Authority, is that they should practise what they preach, and in particular agree that as the opportunities for people to choose what they watch expand, the need that statutory authorities should oversee what people watch will inevitably decline. It is understandable but nonetheless unforgivable that the broadcasting authorities should resent the replacement of four by sixty-four channels of video signals. What they do not yet appreciate is that their present audiences are not disloyal but merely dissatisfied; they would like more choice, even if in the end they choose to watch what they have always watched, or nothing at all. If the market will bear that, is there any reason why the customers should be denied?

0028-0836/82/490468-01$01.00

US Public Health Service faces axe

Schweiker urges rethink on OMB cuts

Washington

The Office of Management and Budget (OMB) is proposing broad cuts in health-related programmes for the budget for fiscal year 1984. The National Institutes of Health (NIH) and virtually every public health agency would be affected.

The proposal is contained in OMB's preliminary draft of the President's 1984 budget, which is supposed to be secret until the final budget is published in January. Confidential documents detailing OMB's plans for the health programme, together with a strong protest by Health and Human Services Secretary Richard Schweiker, are now, however, to hand.

According to the documents, OMB wants to limit the NIH budget to $4,013 million; after inflation, this represents a cut from the current level of $3,954 million. The short-fall could be made up by "various 'grant-stretching' mechanisms", OMB suggests, such as reducing direct costs of grants by 4 per cent to 20 per cent, cost-sharing with grantees and limiting "excessive personnel compensation". NIH director James Wyngaarden is known to be concerned about the last of these; NIH are at present conducting their own study of the growing proportion of research money used for principal investigators' salaries.

OMB also wants to revive two old and controversial cost-cutting proposals. One is a reduction in the indirect, or overhead, costs that NIH pay universities receiving grants. These payments go for fixed operating costs, such as office space. NIH last spring provoked a storm of protest from the universities when they proposed cutting indirect cost reimbursement by 10 per cent. Congress has since attached language to the NIH appropriations bill forbidding any such cuts. The other proposal is that NIH should charge patients at their clinical centre for routine hospital costs.

Schweiker's appeal against the OMB plan asks for an additional $229 million for NIH, which would allow the institutes to maintain their present level of 5,000 grants and 10,000 traineeships. The OMB cuts would reduce this to 3,200 grants.

The other Public Health Service agencies appear to fare worse under the OMB plan. The Food and Drug Administration (FDA) would have its budget frozen at the 1983 level and in addition would be required to eliminate 240 full-time positions. The Center for Disease Control (CDC) would have to fire 760 of its 4,162 full-time employees and reduce its budget by nearly one-third, from $318 million to $215 million. The appeal argues that "unless these funds are restored, CDC would lack the capacity to deal with emerging health problems" and would have to "limit research on controlling the 10 leading work-related health problems". It also takes exception to OMB's assumption that FDA could raise $5 million by charging industry for the cost of processing new drug applications; FDA has not yet determined if "user charges can be collected without compromising the mission of the agency", the appeal says.

Schweiker is asking that OMB should add $35 million to the FDA budget and allow the agency to maintain its current staff level, and to limit the CDC cuts to $54 million and 60 full-time positions.

Schweiker is also protesting against organizational changes that OMB included in its budget plan. The most drastic of these would diminish the role of the assistant secretary for health, Dr Edward Brandt, to that of a policy adviser. Brandt, who is considered a powerful advocate of health issues, has operating authority over all of the Public Health Service agencies, including NIH, FDA, CDC and the Alcohol, Drug Abuse and Mental Health Administration; in addition, health promotion and environmental health programmes and the National Centres for Health Statistics and for Health Services Research are run directly from his office. The OMB plan would parcel out these programmes to the various agencies and would eliminate Brandt's authority over the agencies. In effect, the Public Health Service structure would be abolished; each of the agencies would report directly to Secretary Schweiker.

One White House source said "I think Schweiker will be successful in appealing these massive organizationl changes which destroy the Public Health Service". The disposition of OMB and the President towards his other appeals is unknown, although there is strong support for a real increase in NIH funding within the President's Office of Science and Technology Policy.

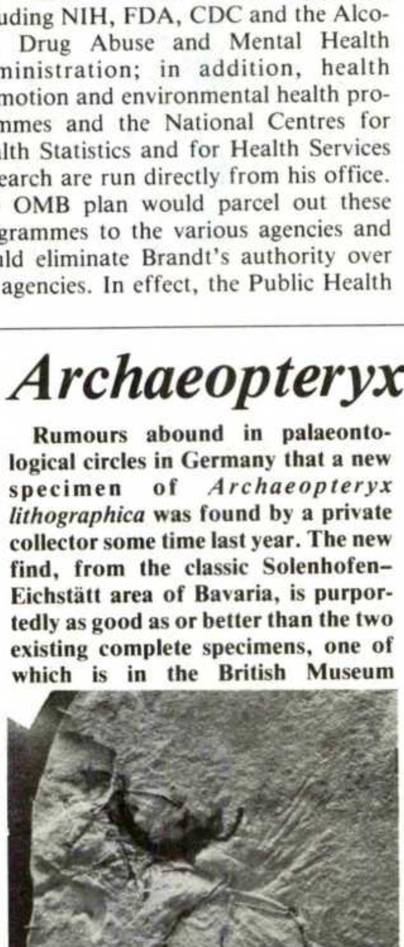
If OMB's proposed cuts do survive Schweiker's appeal, they still face what is likely to be strong opposition in Congress. "Congress would not be very enthused about any of them", said a staff member of the House Appropriations Committee. The support for health research in Congress was demonstrated earlier this year when Congress added $312 million to the Administration's $3,642 million request for NIH.

And a staff member of the House Energy and Commerce Committee, which oversees the Public Health Service, pointed out that the President's budget has tended to carry less weight in recent years owing to the increasing use of continuing resolutions to provide funding. This mechanism is invoked when the new fiscal year arrives and the agency-by-agency appropriations bills have not yet been passed. Continued spending authority is lumped into a single stop-gap bill which a President must sign, or the government ceases operations. This restricts the President's power to impose his version of the budget on Congress.

Stephen Budiansky

Archaeopteryx in hiding

Rumours abound in palaeontological circles in Germany that a new specimen of *Archaeopteryx lithographica* was found by a private collector some time last year. The new find, from the classic Solenhofen–Eichstätt area of Bavaria, is purportedly as good as or better than the two existing complete specimens, one of which is in the British Museum (Natural History) where it is undergoing a further round of extensive preparation.



Of the five known skeletons of *Archaeopteryx* (the sixth example is a single perfectly preserved feather) the "Maxberg exemplar" (see left) found in 1956 is the least known, as the owner is loth to allow specialists even a glimpse of it and only a preliminary description has ever been published.

Whereas the neighbouring state of Baden–Württemberg has legislation which prohibits the sale of finds of scientific importance without special museum authorization, in Bavaria, where no such legislation exists, it is a case of finders-keepers or sale to the highest bidder. And with prices in the hundreds of thousands of deutschmarks for Pterosaur speciments, what price an *Archaeopteryx?*

Mike Howgate

0028-0836/82/490469-01$01.00

Soviet science and technology

Andropov has his say

The Soviet Union will spend 25,500 million rubles on scientific and technological research next year — an increase of 6.2 per cent on 1982. The publication of actual investment figures is somewhat rare in the Soviet media, which prefer to cite increases in percentages only (often referring to inaccessible data-bases). The announcement of this increase — which in real terms represents a rise of some four to five per cent, since inflation in the Soviet Union is running at between one and two per cent annually — was made in a *Pravda* editorial (a traditional Soviet method of announcing a new policy drive) dealing with the speech of Party Secretary Yurii Andropov at last month's plenum of the Central Committee of the Communist Party of the Soviet Union.

According to Mr Andropov, the "great reserves" available to the Soviet Union need to be used "more actively and more consistently". This is basically a reiteration of the Brezhnev policy of modernizing industry by high-priority implementation of research results in industry. This policy, Mr Andropov said, would be continued with even greater impetus — evoking from Academician Anatolii Aleksandrov, president of the Academy of Sciences, the rejoinder that if research results were not being implemented on schedule it was not the scientists but the production ministries which were at fault.

Mr Andropov, however, has some ideas of his own as to how this policy should be pursued. Already the Academy of Sciences carries major responsibility for co-ordinating the research programmes launched to meet the specific needs of Soviet industry and agriculture. Now, it appears, in addition to producing new equipment and "front-ranking work methods", the academy is set to take on a troubleshooting role. Together with the State Committee for Science and Technology and the relevant production ministries, it will be expected to "pinpoint and eliminate" the difficulties hindering technical progress. This approach could be of considerable importance for research planning.

During the past ten years, there has been emphasis on the establishment of local "science centres" (usually created by linking existing institutes in the locality), which were intended to serve the research needs of local industry, frequently on a direct contractual basis. The initiative was normally left to the industrial side, which identified production problems and then sought scientists' help to solve them. The new procedure suggests that scientists will now be expected to identify problems as well as solve them — a procedure which would not necessarily appeal to all enterprise directors. Retooling and redesigning of the production line is a nightmare for Soviet management, since the regular quarterly, annual and quinquennial targets make no allowances for temporary shutdowns. A zealous scientist urging such a closure in the name of long-term improved efficiency might well run foul of a director eager to meet his immediate target figures.

Perhaps to overcome such frictions, the recent plenum urged the importance of material incentives for those involved in modernization projects. People who "boldly go for the introduction of new technology", it noted, should not find themselves placed in a "disadvantageous situation".

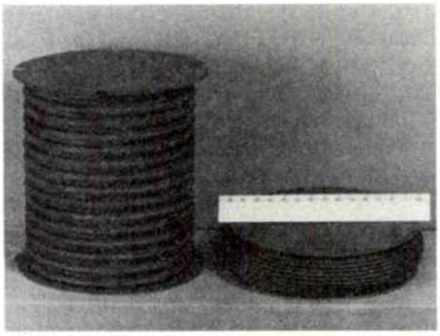
Nuclear waste disposal

Synroc presses on in Australia

The Synroc programme — Australia's synthetic rock alternative to glass for the disposal of highly active nuclear waste — is about to move up a few gears with the construction of a cut-price, "commercial-scale" Synroc plant 20 miles south-west of Sydney. The plant, at the Lucas Heights Research Laboratories of the Australian Atomic Energy Commission (AAEC), will be big enough to cope — in principle — with 600–900 tons of spent fuel a year. But in practice it will not see a jot of nuclear waste.

The objective, according to Dr Keith Reeve, leader of the Synroc project at AAEC, is nevertheless to prove that Synroc is a practical alternative to glass. Tenders closed last week for contract management of the detailed design work, and, says Reeve, the successful bidder is likely to have considerable experience of nuclear plant — for AAEC and the Australian National University (ANU), which is also involved in the project, wish to build a plant which, although non-radioactive, is compact, easily maintained, and demonstrates that active Synroc could be made safely.



A recent 30-kg block of Synroc compressed using the uniaxial bellows hot pressing technique. Primary minerals (and waste) are sealed in evacuated stainless steel bellows, and pressed and heated without side supports. The resulting blocks would then be sealed in a larger can.

Cost precluded the construction of a fully active plant, according to Professor Ted Ringwood, inventor of Synroc and ANU representative on the demonstration plant project. A remotely-controlled active plant might have cost "hundreds of millions of dollars" (A$1.7 = £1), says Ringwood "of the same order as a glassification plant". But AAEC and ANU have only A$2.7 million to spend, the amount of a government grant for the project, plus staff support from AAEC and ANU. A little over A$1 million was released in August, with the rest promised over the next two years, for construction in 1983–84 and operation in 1984–85. "I blow hot and cold on whether these dates are optimistic or pessimistic", says Reeve.

Whenever the plant is ready, it will make Synroc-C, which consists of 60 per cent titanium dioxide, with an admixture of barium oxide, calcium oxide, zirconia and alumina; these react at 1,100–1,170°C and 100–400 atmospheres pressure to create three mineral phases related to perovskite, hollandite and zirconalite. These phases can absorb up to 20 per cent weight of highly active waste oxides, according to Reeves.

At AAEC in Lucas Heights, experiments have concentrated on producing the Synroc in large-scale blocks, rising from a few granules in 1979 to 30-kg hot pressings by the end of 1981. The Synroc itself is able to retain foreign elements much better than glass, the Synroc team maintains; it is also 59 per cent denser and can withstand higher temperatures.

The apparent weakness of the Synroc programme, however, has been the relative lack of work on active Synroc — Synroc actually containing nuclear waste. "We're sensitive to that criticism", says Reeves and in fact next year Reeves plans a "two line" radioactive test programme. One wil involve neutron-irradiated uranium oxide (to stimulate fission products) in smal (½–1 cm diameter) Synroc samples, on which leach tests will be done. The oxide will be fresh from irradiation, Reeve stresses, unlike spent fuel which has been cooled for a few years, and it will b possible to reproduce in two years the tota beta-ray dose expected in a piece of active waste-containing Synroc over its lifetime The samples will then be subjected to leach tests. Alpha irradiation will also b simulated with neutrons.

And in the second line of radioactiv tests, Synroc will be made in a glove bo with "trace" levels of actinides – neptunium, plutonium, americium an curium. The work will start in June.

West German research and technology

Meeting of past and present

The ceremony last week to open the new London premises of the Anglo-German Foundation for the Study of Industrial Society was attended by the unlikely trio of Dr Heinz Riesenhuber, the present minister at the West German Ministry for Research and Technology (BMFT) and two of his predecessors, Dr Andreas von Bülow and Professor Hans Leussink.

Dr Riesenhuber was in London to discuss Anglo-German cooperation in science and technology with the British government, especially in the context of international organizations such as the European Molecular Biology Laboratory and in information technology. He is also interested in joint industry–government collaboration between Britain and West Germany.

Such work might be managed on the West German side by the federally supported Large Research Centres. Riesenhuber reiterated his aim of directing the work of these centres to more industrial projects and his hope that small to medium-sized firms (fewer than 200 employees) will band together to support research at the centres. This may simply mean that these centres impinge on the ground at present occupied by the Fraunhofer Gesellschaft, which supports a number of cooperative research laboratories, and independent contract research centres without increasing the amount or effectiveness of research and development. It remains to be seen, however, what form the as yet undefined "indirect" support of industrial research will take.

Heinz Riesenhuber . . . advocate of collaboration

Last week the minister acknowledged the achievements of West German science under his predecessors and, conscious that research and development is a long-term activity, accepted that change must come slowly. He is, however, concerned about the mediocrity of much basic research and wants to give more support to outstanding scientists. In a constant budget for basic research, this means that money will be less evenly spread. On the other hand, it is not clear how budding geniuses are to be identified before they flower, and with the proposed replacement of student grants by loans (even in secondary education) from 1984 those from modest backgrounds may find it difficult to be recognized. Nevertheless, Dr Riesenhuber believes he knows who the top five in genetic engineering are, and hopes to lure at least one of them to a Large Research Centre.

Dr von Bülow, Riesenhuber's immediate predecessor, was present in his capacity as deputy chairman of the trustees of the Volkswagen Foundation, which has paid for the renovation of the premises taken over from the Pharmaceutical Society. Since leaving office in October, Dr von Bülow has made known his belief that one of the two experimental nuclear reactors should be abandoned. (The costs of completing the fast and high-temperature reactors were a persistent problem for him as they still are for his successor.) In von Bülow's view, the price of uranium is such a small factor in the overall cost of existing light-water reactors that neither reactor can become competitive in the next thirty years, whatever the price of other fuels. This is in sharp contrast with the policy of the present government to complete both reactors. **J.S. Dunnett**

Polish education

New students' association's aims

Poland's new student union, the Association of Polish Students (ZSP), launched last month, has announced a wide programme of action and campaigning to cover virtually all aspects of the higher education process — "the formulation of demands concerning secondary education", equal opportunities of entrance to university, grants, rest and sports facilities, the patronizing of student artistic activities and the "student scientific movement", rationalization of the job market and a loans system for graduates who have difficulties in obtaining housing.

Just how ZSP intends to pursue these aims is not clear — under the new Higher Education Act, which came into force on 1 September, student associations do not have trade union status, and the right to strike is denied them. Some innovations — such as student grants, means-tested on the income of the whole family — have already been introduced by the new act. Other problems, including the disparity of secondary educational standards between urban and rural schools, are already matters of serious government concern. One of the "most important goals" of the association, "exerting influence on matters concerning further education" and the creation of "self-management and democracy" within universities and colleges, is, the statute admits, already covered by the new law, and the association's role will be to lobby for improvements and amendments.

ZSP was founded as a continuation of the old Socialist Association of Polish Students (SZSP), which lost most of its members in autumn 1980, when the Solidarity-type Independent Students Association (NZS) was founded, while many of its functions, including travel and welfare matters, were taken over by "self-government committees" on which both unions were represented. After NZS was banned last January, its members showed no sign of returning to SZSP. Accordingly, shortly before the SZSP Congress (19–20 November), the governing council of SZSP recommended that the word "Socialist" should be dropped, and that the association should be reshaped to draw in as wide a membership as possible. At the same time, the governing council made clear, the experience of the past ten years should be incorporated and a firm commitment made to socialism. Thus the new ZSP statutes not only acknowledge the "leading role" of the party but also pledge the association to fight for the implementation of socialist values in Poland, and to cooperate with "progressive" youth organizations abroad in the "battle for peace and national and social liberation".

The Congress of SZSP/ZSP met against a background of continuing university unrest. A few days earlier, all teaching in Torun University had been suspended for a week after disturbances in one of the halls of residence. At Warsaw University, the department of psychology was closed for three weeks pending an inquiry by a special "Rector's Commission" into the stoppage of lectures and classes on 10 November, the Solidarity "day of action". (Few universities came out fully in support of this "day", although token stoppages and meetings were reported in several universities, including Krakow and Wroclaw; in Warsaw, there was a rally on the main campus of the university, estimated by the party newspaper *Trybuna Ludu* at around 1,200 persons.) The Warsaw psychology department was allowed to reopen last week following the resignation of the dean and sub-dean, although many students still face disciplinary proceedings.

How far the new association will go to help defuse the situation remains unclear. One innovation proposed for the new ZSP seems to have been designed to provide a ballast of older members, who could well act as a calming influence. In addition to the ordinary student members, ZSP is to admit "supporting members" — Polish citizens who support the statute and who take some active part in the work of the association. **Vera Rich**

Stanford graduate students

Clampdown on external links

Washington

Members of the Stanford University faculty will not be allowed to employ their graduate students in jobs in outside companies under a new policy adopted last week by one faculty.

"We felt that this was an area that could be abused", said Dr Gerald Lieberman, dean of graduate studies and research. The concern is that a faculty member may in effect make employment in his outside firm a condition for taking on a graduate student. The new rule forbids employment by a faculty adviser or by a member of a student's dissertation committee. The Massachusetts Institute of Technology has a similar rule.

William Smith, a member of the Graduate Student Association's academic affairs committee, said that he knew of one case where such employment arrangements may have been abused. A graduate student not involved in his research adviser's outside company filed a complaint with the university ombudsman that a fellow student, who was employed by the company, was receiving preferential treatment from the adviser.

The effect of the new rule is unclear. Neither Smith nor Lieberman could say how many students throughout the university are employed by their faculty advisers in outside ventures, although Smith said he knew personally of "about ten" students in that position. But he also said that in any case the rule "won't change anything", because of a loophole that allows exemptions to be granted by department chairmen, so that in effect the rule will be little more than a reporting requirement.

Lieberman, though, said "it puts the burden of proof on the faculty member — I think it's a psychological barrier".

A more controversial proposal will be taken up by the faculty's committee on research this winter; this proposal — recommended by the graduate student association — would require annual reporting by faculty members of all outside activities. A similar requirement was recently proposed by a faculty committee at the University of California at Davis, stemming in part from the controversy surrounding Professor Ray Valentine's involvement with his own company and Allied Chemical that surfaced last spring (see *Nature* 4 March, p.6)

Many members of the Stanford faculty reportedly believe such a requirement to be an intrusion of privacy; Lieberman noted that "the big disadvantage is the feeling that once a faculty member has reported, he's absolved of 'guilt'. That means that if you have reported, someone has to take it seriously", which means reviewing the reports and following up on them where necessary. He questioned whether that would be done.

In the recommendation from the graduate student association, Smith writes that at least ten undergraduates, graduates and postdoctoral students have lodged complaints about conflicts of interest on the part of their advisers that they believed interfered with their education and training. The problem, Smith said, centres in the departments of biochemistry, chemical engineering, computer science, electrical engineering, mechanical engineering and medical microbiology.

Stephen Budiansky

UK nuclear power

Hold on fast reactors

The British government's decision to put its fast reactor programme on ice, made public last week in the House of Commons, has spread consternation throughout the UK Atomic Energy Authority. Although the research establishment at Dounreay in the north of Scotland is not likely to be much affected by the decision, other research establishments at Risley (Lancashire), Harwell (Oxfordshire) and Winfrith (Dorset) are likely to suffer reduced budgets in the years ahead. So too is the team of design engineers maintained by the National Nuclear Corporation on the Risley site, which has been putting the finishing touches to the design of a full-scale fast reactor for the past several years.

According to Mr Nigel Lawson, the energy secretary in the British government, it has been decided that the electricity generating industry will not on economic grounds need to order fast reactors before the early years of the next century, so that the programme of fast reactor development based at Dounreay can prudently be stretched out.

The Atomic Energy Authority has therefore been asked to put forward a revised development programme, taking account of the new time-scale for the commercial application of fast reactors and of the opportunities for international collaboration on such projects. A spokesman said this week that it was hoped to have a new fast reactor strategy by the early spring of 1983.

By all accounts, it has been decided to keep the Dounreay reactor working, chiefly so as to try out novel kinds of uranium and plutonium fuel and to test the efficacy of the pilot-scale reprocessing plant in operation there. The extent to which the Dounreay establishment will become the focal point for research and development on fast reactors will depend on the readiness of others among the authority's establishments to give up their interests in the subject.

In the present programme of research and development by the Atomic Energy Authority, fast reactor work acounts for an annual expenditure of about £100 million. Of this sum, roughly a half is spent in the north of Scotland. Part of Mr Lawson's calculation seems to be that if the authority is told clearly that the programme must be stretched out, the result may be more diligence in looking for partners elsewhere. It seems also however to be understood by those concerned that the National Nuclear Corporation should have a say in the final decision on whatever development strategy is eventually agreed.

The outcome of that process is likely to be uncomfortabe for the authority's research establishments. The chances are that, in the spring, the government will be looking to the authority for savings of about a quarter of its current expenditure on fast reactor development. (It is unlikely that even the present government will follow the opinion of some officials of the National Nuclear Corporation that the Atomic Energy Authority's own future should now be reconsidered.) The best solution would be a deal with some comparable authority elsewhere that would postpone the evil day until fast reactors are clearly economic. ●

Dutch scientific research

Good and bad

Waalre, The Netherlands

The Netherlands' two major scientific research organizations have experienced mixed fortunes during the past week. While the Netherlands Organization for the Advancement of Pure Science (ZWO) was finalizing plans to become the first foreign partner to share the British Synchrotron Radiation Source at Daresbury, on the home front the Dutch national applied science organization, TNO, was announcing 550 job losses as a result of a declining government subisidy and reduced orders from government ministries.

On 2 December Professor W.F. de Gaay Fortman, chairman of ZWO, and Professor John Kingman, chairman of the UK Science and Engineering Research Council (SERC) signed an agreement which means Dutch scientists will have access to the Synchrotron Radiation Source at SERC's Daresbury Laboratory. In addition the Dutch partners are to construct a new beamline at Daresbury in 1983–84, fitted with experimental stations to carry out extended X-ray absorption fine structure (EXAFS) and small-angle diffraction (SAD) studies (see diagram). The Dutch share of construction costs will be around £1 million, in exchange for which the British will provide local support for visiting Dutch scientists as well as the

0028-0836/82/490472-02$01 00

experimental facilities.

The collaboration on the Daresbury facility is the first fruit of an "umbrella agreement" signed between ZWO and SERC in June of this year to promote scientific collaboration between the two countries. Previously a protocol on collaboration in astronomical research was signed in La Palma in June 1981 and the two countries are also cooperating, together with the United States, on the Infrared Astronomical Satellite (IRAS) due to be launched on 27 January 1983.

The number of experiments being performed at Daresbury will double during the next few months. The deal with ZWO is one source of the increased work load, but cooperation between SERC and industrial concerns is also on the increase. A consortium of Shell, ICI and British Petroleum is already working with SERC and Professor Kingman hopes that "more money but also more work" will be forthcoming from industry in the near future. Kingman is also optimistic that further cooperation with the Netherlands will follow within the framework of the recent mutual statement of scientific collaboration.

The industrial sector too is the one small sign of hope apparent in the recent announcement from TNO. Despite an increase in orders from industry, government cutbacks have resulted in an increase in TNO's annual deficit from 7 million guilders in 1981 to an expected 15 million guilders in 1983. TNO is to lay off 350 workers in the next four years and a further 200 vacancies will be left unfilled — this represents a cut of around 10 per cent of the staff of 5,000. Research priorities are to be adjusted in response to the crisis, with less expenditure on nuclear energy but more on energy conservation, less materials research and better integration and reorientation of environmental and health research, all politically welcome goals.

Casper Schuuring

Satellite broadcasting

Digital Britain

The British Goverment, not often distinguished by its openness, seems nevertheless to be ready to tell more than the whole truth about the technology of its plans for the eagerly awaited communications revolution. Last week, the Department of Industry issued a formal recommendation by a technical committee of the standards that should be adopted in the design of direct-broadcasting satellites. The first of these is expected to be in service in the United Kingdom in 1986.

As if to emphasize that the traditional technology of the communications industry has been superseded, the report, which runs to 54 pages, is on sale at Her Majesty's Stationery Office (Cmnd 8751) at a price of £5.20 — almost £0.10 a page.

Technically, the recommendation of the advisory panel (chairman, Sir Anthony Part) is however surprising by its daring. The committee has rejected the technical proposals of the British Broadcasting Corporation (BBC), which will operate the first two of the five direct broadcasting channels available to the United Kingdom.

The BBC, in evidence to the committee, had argued for an extension of present analogue codes for specifying the intensity and colour of picture elements on a television screen. In effect, the BBC's proposal would have been a more sophisticated version of the widely-used PAL system in which the transmission of colour information is confined to a small part of the available band width. The basic PAL patent expires in 1983.

In the event, the committee has plumped for a digital system for transmitting television signals. The system concerned, although devised by the Independent Broadcasting Authority, has been offered free of charge to the BBC. What seems to have swayed the advisory committee is the technical superiority of the new system (known as MAC) and the chance that it might subsume both PAL and SECAM, the two broadcasting standards at present used in Europe.

Royal Society

Break ground

This year's annual report from the Royal Society of London, most notably subversive because of what it says on relations between British and Soviet scientists (see *Nature* 3 December), also describes how the society has polled its fellows in the hope of finding out how their universities are surviving and how it is moving (gingerly it seems) towards an assessment of the consequences of nuclear war. The Royal Society, it seems, is on the move, although its direction is as yet by no means clear.

The society's annual report explains that a questionnaire was sent out in June to all members of the society, asking for comments on conditions in their subjects — not merely in their universities. The general response seems to have been a complaint by established academics that it is no longer possible, in the British university system, to appoint promising young people to permanent or even temporary posts. Replies to this questionnaire seem to have been influential in persuading the Royal Society to urge on the British government the need to recruit more young people to academic posts.

The society has also broken new ground by its decision to contribute to public discussion of the consequences of nuclear warfare. The annual report says that the annual meeting in November 1981 was partly given over to a discussion of this topic, but that the society's council has not yet decided whether to mount a formal study of the question. The significance of that development is merely that it would, if carried through, be entirely without precedent.

For the rest, the Royal Society has a disappointing tale to tell of its success in spending funds on exchange visits by scientists. In relationship to Western as well as Eastern Europe, it seems, the willingness of British scientists to travel has declined. A new scheme to enable exchanges with Australasia may nevertheless take up the slack.

UK manufacturing

Cambridge Instruments upturn

The British-based Cambridge Instrument Co. Ltd (CIC) appears successfully to have weathered the storm that almost drove it out of business three years ago. The latest half-yearly figures show the company to have made a remarkable return to profitability. The company now hopes to capture a major part of the future market for robotic vision systems and for manufacturing equipment for gallium arsenide semiconductor devices. An average annual loss of £3 million in the three years to 1979 has been converted to a pre-tax profit of £1 million on a £22.7 million turnover in the year ending 31 March, and profits for the first half of the current year are double those for the same period last year.

This dramatic change in the company's fortunes is attributed by people in the company to the management skills brought in by Terence J. Gooding, a "company doctor" from the United States who bought a substantial shareholding in 1979. As the Cambridge Scientific Instrument Company, CIC was in the early 1960s the first to produce a commercially viable scanning electron microscope, and this type of equipment remains the largest part of the business. In the late 1970s, however, the company appeared to some to be resting on its laurels and to have lost sight of some commercial realities; it produced a scanning electron microscope which was far in advance of its competitors in specification but which was also so expensive to build that it could not be sold profitably.

The lessons of that expensive error seem to have sunk in. Now, the company is concentrating on feeding back information about customers' requirements to the development teams and is once again increasing its share of the market for scanning microscopes. As an example of customer-inspired development, the company cites its new large-chamber microscopes, used in the semiconductor industry for the examination of large wafers. Now, a US factory is planned to cope with increased demand.

The company has also recently introduced new products in its range of electron-beam microfabricators. The new system, called "Chiprite", promises to double throughput in integrated circuit manufacture, with very high resolution. Together with what the company calls a "revolutionary" new integrated circuit checking system, CIC hopes by these means to expand its already large share of the market for semiconductor manufacturing equipment.

Robotic vision, on the other hand, seems to have arisen as a spin-off from the existing technology of image analysers. By the simple expedient of fitting these machines with zoom lenses, CIC finds itself able to apply existing software to the control of industrial production processes.

Another major market that CIC hopes to exploit is that for machinery for the manufacture of large crystals of gallium arsenide. This semiconductor has the substantial advantages over silicon that circuits can be packed more densely, partly because of the lower power dissipated, and that switching times are up to ten times faster.

Gallium arsenide is at present used largely in military applications, but civil applications are likely to flourish in the coming decade, in satellite television links for example. Gallium phosphide and indium phosphide, two other potentially important semiconductor materials, are also produced on CIC equipment. In this area, the company claims the lion's share even of the coveted Japanese market.

Tim Beardsley

Technology drive

Korea

South Korea is to launch an "aggressive drive" to upgrade its technology to international levels. Reporting to a recent technology promotion conference, chaired by President Chon Tu-hwan, the Science and Technology Minister Yi Chong-o described his ministry's new eleven-point plan, which includes the introduction of foreign technology on a "new scale", the promotion of joint research and development projects by Korean institutions and their foreign counterparts and the encouragement of the private sector to set up small and medium-sized technology-intensive corporations in advanced countries. An "active recruitment" programme will be launched by the ministry to encourage South Korean scientists now working abroad to return home and take part in the technology drive.

Vera Rich

Heavy ion research

France finds niche in GANIL

French heavy-ion physics took a step forward on 19 November when GANIL, the national heavy-ion accelerator at Caen in Normandy, produced its first beam. The accelerator's two principal cyclotrons were coupled and, with the help of a smaller injection cyclotron, accelerated a beam of argon ions to 1.8 GeV (45 MeV per nucleon). The first experiments will begin in January.

The decision to build GANIL (Grand Accelerateur National d'Ions Lourds) was taken in 1975 by the then industry minister, Michel d'Ornano. The project was delayed by an early lack of finance but the now completed facility remains within the initial cost estimates of about FF500 million at current prices. According to the director, M. Claude Detraz, the first experiments should start on 10 January; six months' worth of experiments have been planned.

According to its director, GANIL will carry physicists into an intermediate energy and intensity range of unique interest, making it in some ways complementary to other leading heavy-ion accelerators at Berkeley in California, Dubna (near Moscow) and Darmstadt. The Berkeley Bevalac accelerator is capable of accelerating the heaviest nuclei to energies of 1,800 MeV per nucleon. At such relativistic energies, according to current theories, the 3-quark bags that make up each of the protons and neutrons in the nucleus will, it is hoped, break up, leaving quark matter. At lower but still relativistic energies, collisions between heavy nuclei involve interactions between their constituent nucleons. Models for such collisions are comparatively well developed in West Germany.

The Gesellschaft für Schwerionenforschung (GSI) at Darmstadt in West Germany devotes much of its efforts to lower energy regimes, near the Coulomb barrier at 6–7 MeV per nucleon. In this regime, the nuclei undergoing collisions are left in internal equilibrium. By careful experimental arrangement, the heavy nuclei can be made either to rotate at very high frequency — thus allowing investigation of newly discovered angular momentum states — or to collide gently and form new superheavy elements, the most recent being element 109, which was first synthesized a few months ago. (The accelerator at Dubna is also devoted to such experiments.) Successful models have been established for collisions at these energies that treat the nuclei as "collective" bodies.

GANIL will concentrate on the energy regime between GSI and Dubna, producing sufficient intensity (10^{13} nuclei per second) for rare species such as neutron-rich nuclei far from stability to be investigated (such as ^{20}C). In the next six months, ions of neon, argon and krypton will be accelerated at all energies (the highest for Ar, for example, being 80 MeV per nucleon). Preliminary experiments at CERN in Geneva have given some idea of what may be expected. For instance, there seems to be a limit to the amount of linear momentum that can be transferred to the target nucleus as the beam energy is increased. The reasons for this phenomenon are not known. Such glimpses apart, however, GANIL will be taking nuclear physicists into unknown territory.

Philip Campbell

Intermediate vector boson

No Christmas boon for CERN

The race to discover the intermediate vector bosons, the set of particles supposed to play the role of the photon in the weak nuclear interaction, is in full tilt this week, at the European Centre for Nuclear Research (CERN) near Geneva.

Experiment UA1, the larger of two experiments (a collaboration of 13 institutions involving 128 physicists), already has one or two candidates for the charged boson (the W), but the group cannot be certain yet whether these events are signal or background. The smaller experiment, UA2 (6 institutions and 51 physicists), is being more cautious, and wants time to consider its "public statement".

"Ho, Ho, Ho! You didn't think I'd forget?"

So it seems that unless phenomenal luck strikes the groups this week, and they observe a clear signal for a Z, the neutral boson which is easier to distinguish from background but ten times rarer in the experiment than a W, Christmas may come without the present that CERN director Professor Herwig Schopper was hoping for (see *Nature* 18 November, p.205).

There are two technical problems: low average luminosity and high background. The luminosity is a measure of the frequency of events — collisions between protons and antiprotons producing showers of particles, among which the bosons must be sought. When UA1 was designed, the expected luminosity was 10^{30} cm^{-2} s^{-1}, but the current figure is nearer 4×10^{28} cm^{-2} s^{-1}, 25 times lower. Thus in the total run-time this year, UA1 expects to have collected only about five Ws but to have only a 50 per cent chance of having collected a Z, needles in a giant haystack of the other particles produced in collisions at the collider centre-of-mass energy of 540 GeV (that is, approaching 600 proton masses of available energy).

Even with the strategy being followed at CERN for detecting the intermediate vector bosons, this background is uncomfortably high. The trick is to look for electrons with energy of 40 GeV emerging perpendicular to the direction of the collision.

The argument is as follows. If a boson, WNZ, of mass about 80 GeV were formed at rest in the centre of mass, it would decay into two leptons — electrons, neutrinos, or electron and neutrino — with roughly half the 90-GeV decay energy in each particle. These particles could emerge in all directions, whereas the predominant quark–antiquark interactions in collisions between a proton and an antiproton produce only glancing blows and hence little sideways movement.

The objective is thus to detect the sideways 40-GeV electrons. However, gluon–gluon collisions between the "colour" fields of the proton and antiproton can also produce tracks in the detectors which mimic such electrons, and the trick is to distinguish one from the other. In the case of the Ws, which produce only one electron (and one neutrino), this can be done only by distinguishing the average kinematics of the tracks. And of course, to make distinguishable averages, reasonably high numbers of events are necessary. The rarer neutral Z, however, decays into an electron and a positron, both of which should be detected, so making identification much easier.

Next year the search is to be stepped up, with a projected luminosity of 10^{29} $\text{cm}^{-2}\text{s}^{-1}$ and a three-month run — a plan causing some consternation among other users of the Super Proton Synchrotron (SPS), which was originally intended to fire high-energy protons at fixed targets. When the collider was proposed, there was a proviso that it would never take more than a third of total SPS run-time. Next year the ceiling is to be broken in an effort to get the intermediate vector boson: 43 per cent of experimental time is to go to the collider.

Franco-Indian deal

France and India reached a compromise on the supply of enriched uranium for India's Tarapur reactor near Bombay on 27 November — on the eve of a visit to India by the President of France which may result in major economic and military agreements.

Supplies for Tarapur were originally guaranteed by the United States in a 30-year agreement dating from 1963, and backed up by a tripartite inspection arrangement between the International Atomic Energy Agency and the two countries in 1971. But both deals were invalidated by President Carter's Non-Proliferation Act, which forbade the supply of sensitive materials to non-signatories of the international Non-Proliferation Treaty — of which India is one. Carter, who had forgotten — or ignored — the treaties with India, managed to override the act to supply one load of fuel; but President Reagan has felt unable to continue in this manner. France has accordingly stepped into the breach, but began by demanding inspection rights which Mrs Gandhi was unwilling to accept. These guarantees would have gone beyond the terms of the 1963 and 1971 treaties.

In Paris, it was being argued last week that it would have been more dangerous *not* to sign the present compromise agreement than to stand off and let India reject the 1963 and 1971 inspection terms altogether. India already has a considerable amount of waste fuel at Tarapur, which could be reprocessed to extract the plutonium whenever India felt morally free to do so, the justification goes. The present agreement preempts that possibility.

CORRESPONDENCE

Lead in petrol

SIR — Jasper Becker's report (*Nature* 4 November, p.6) on efforts to persuade the European Community to revise its directive on the lead content of petrol perpetuates a general misunderstanding about the directive by saying that it permits a maximum level of 0.4 grammes of lead per litre of petrol and a minimum of 0.15, thus implying that petrol with less than 0.15 grammes is not permitted. Later the report reinforces this misconception by describing the current campaign to introduce lead-free petrol and saying that "no member state is at present allowed to do this"

In fact the directive does not prevent anyone marketing lead-free petrol. What it does do is to prevent any member state from banning lead in petrol or insisting on any lead level less than 0.15 grammes per litre. Thus if the motor industry and the oil companies could agree, it would be possible for lead-free petrol to be introduced tomorrow. If, however, member states are to intervene and insist on lead-free petrol from a certain date they will have to do so simultaneously by agreeing an amending directive.

Another requirement of the directive that deserves to be better known is that the member states have to supply the EEC Commission, at its request, with information on the "development of the concentrations of lead and polluting substances in the urban atmosphere and their effect on public health". The Commission in turn is to report to the Council and Parliament on the information thus obtained and, in the light of the data compiled, is to make appropriate proposals for developing further Community policy on the lead content of petrol. Thus it was foreseen in 1978, when the directive was agreed, that the levels could and should be changed if new knowledge justified it.

No contest?

SIR — *Nature* is highly valued by the scientific community not only for its scientific content, but also for its unwavering position on matters of scientific moral behaviour — and last but not least, the standing of its advertisments Therefore I would like to draw your attention to an instance which I consider as reprehensible practice, in which, in this case, *Nature* has been unwittingly the vehicle

In *Nature* Vol 285, 26 June 1980, the Malaysian government announced (page xxvii) a world-wide competition to find a speedy and accurate method of determining the dry rubber content (DRC) of latex. I sent an entry to this contest on 18 December 1980.

A letter of the Malaysian Rubber Research and Development Board (MRRDB), dated 3 March 1982 stated: " . . [we] regret the delay in the final judging; this has been due to the good response [63 entries, *note M.B.*] received and the need to test out some of the entries".

Without news for several months from the MRRDB, I wrote them a letter on 26 October 1982, from which I quote: "I presume this final judging has taken place. Sincere scientific curiosity, besides the sportsmanship of having participated, prompts me to ask the communication of the optimal method having been selected. Perhaps it could be published. . ."

From the answer of the MRRDB (10 November 1982): "Judging of the Dry Rubber Content determination competition took place on 28 October 1982 and regretfully, of the 63 entries received from all over the world, including the one entered by you, there has been no outright winner as none of the entries met the criteria of an ideal method for DRC determination."

Conclusion: for the price of an advertisment — and the vague promise of the sum of about $10,000, which is a mere trifle as research budgets go — the MRRDB did perhaps not obtain the dream-method, but it may be estimated that a significant fraction of the entries yielded enough valuable ideas, elements and propositions to obtain, through very little further expense, the ideal method, provided that one exists. Really, the MRRDB got quite cheaply a great deal of intellectual effort.

Had the advertisment in question appeared anywhere else than in *Nature*, I at least, and perhaps more of the 62 colleagues who sent entries would have perceived beforehand the unilaterality and the arbitrariness behind such a "contest".

Vitamin C reviewed

SIR — In reviewing our book "Vitamin C in Health and Disease" (*Nature* **299**, 760), Dr Rivers has had to contend with the problem of assessing three books at once and the self-inflicted difficulty of having apparently pre-judged the debate on vitamin C. Rivers's view appears to be that the vitamin's only function in man is to prevent the symptoms of overt clinical scurvy. He may be right, but as we emphasize this possibility in the concluding paragraph of our book, it is surprising that he accuses us of having an "atrophied critical faculty". However, he apparently draws this conclusion from a series of comments about the book which are simply not true, and it is these I wish to refute.

He does not exclude our book from his general observation that all three texts claim that vitamin C will not only cure scurvy but colds, cancer and cardiovascular disease. We make no such claim. We include in our evidence on vitamin C and the common cold the statement that randomized, blind, clinical trials have indicated that megadose vitamin C therapy has almost no effect on either the frequency or length of the cold. However, there is some evidence that there are decreases in the severity of the symptoms. For cardiovascular disease and cancer, we suggest that although vitamin C deficiency may be implicated in the aetiology of these conditions, only long-term, large-scale, randomized, controlled trials can confirm or refute such roles for the vitamin.

Rivers makes a more detailed criticism of one section of the book and again he is in error. In the figure he refers to, there is both a highly significant difference between the two groups and a significant correlation in one of the groups alone, a finding that he was unable to see by eye. To us, this indicates an association between hepatic vitamin C and rate of cholesterol transformation, without suggesting that a cause and effect relationship has been proven. The section which includes this graph makes no claim, as Rivers states, that changes in vitamin C status are central to fluctuation in mortality from ischaemic heart disease. Indeed, we warn that such evidence is only circumstantial and indirect.

In our book on vitamin C in health and disease we have attempted to summarize the available evidence. Dr Rivers may honestly feel that we have leant too far towards those who support a role for vitamin C in the prevention of a whole variety of diseases and he is entitled to his opinion, but he should have supported his views by statements which are correct.

Jungle law

SIR — J. Fleuris (*Nature* 18 November, p.212) is correct in stating that *orang* is Malay for man (though *person* is more accurate, as orang has no sense of gender), but *orang utan* has orang-utan only as a secondary meaning. Its literal meaning is man (or person) of the jungle (*utan* being the common word for jungle, as opposed to *ulu* which means up-river and has come to mean jungle by extension).

J.R. GOSDEN

Eskbank, Midlothian, UK

Chinese names

SIR,— M.C. Mckenna (*Nature* 18 November, p.212) oversimplifies when he states that Chinese given names are now hyphenated and the second syllable is not capitalized in English transliteration. While the use of the hyphen to link given names is widespread, it is by no means universal and the use of a capital for the second syllable is at least as common as lower-case.

Moreover it is now common in journals from Mainland China for the given names to be written as one word, for example Chen Yurong. This practice still enables the surname (usually one syllable) to be distinguished easily from the given names (usually two syllables) but the single-syllable given name (such as Pei, in Wang Pei) may still cause difficulty. It is not unknown, either, for "helpful" journals from Chinese and other ideographic language sources to present transliterated names in a Western order, without an obvious indication of their practice.

NEWS AND VIEWS

Oncogenes in solid tumours

One of the most obvious quibbles about the recently isolated clutch of human oncogenes should be quenched by the paper on page 539 of this week's issue. Since most of the oncogenes, including the first to be sequenced (see *Nature* 11 November, pp.143 and 149), have been derived from tumour cell lines cultured over many generations, the question has naturally been raised whether the supposed oncogenes might be an artefact of cell culture. But data now reported from the Laboratory of Cellular and Molecular Biology of the National Cancer Institute show that oncogenes can be found in cells taken from a variety of solid tumours surgically removed from human patients some time ago and since kept in a deep freeze. The point is important because it reinforces confidence in the pathological relevance of the discovery reported last month that cells cultured from a human bladder carcinoma contain an oncogene whose structure (described by R.A. Weinberg's group at the Massachusetts Institute of Technology and by Mariano Barbacid's group at the National Cancer Institute) differs from that of a normal human gene by a single substitution of one nucleotide by another. What now also emerges is good (if circumstantial) evidence for at least a second human oncogene. And oncogenes of some kind have turned up in several different types of human carcinoma — the lung (one), the pancreas (one), the colon (two) and an infantile sarcoma known as embryonal rhabdosarcoma.

The human oncogenes whose existence has been demonstrated in these solid tumours (and in a number of cell lines derived from a variety of other tumours) are, however, not the same as that reported last month by the Weinberg and Barbacid groups. They showed by sequencing nucleotide bases of an oncogene in a human bladder carcinoma that the oncogene differs from a naturally occurring normal gene only in a single base substitution, the effect of which is to substitute the amino acid valine for glycine in the twelfth position along the length of a protein molecule called p21. (The nondescript name is a sign of how little is known of the normal function of this material: "p" stands for "protein", "21" for the molecular weight, approximately 21,000). On this occasion, the nucleotide sequences of the oncogenes have not been determined directly, but have instead been inferred from the readiness with which cloned stretches of the DNA concerned will combine with the oncogenes of a variety of retroviruses.

The striking result is that most of the human oncogenes now found are related to the oncogenes carried by the retrovirus known as the Kirsten murine sarcoma virus. Indeed, in the malignant human cells, whether from tumours or by cell-culture, the version of the p21 protein produced is often antigenically similar to that produced in mouse cells transformed (or made malignant) by the Kirsten virus. From the known structure of the virus genes, the consequences for p21 should consist of another substitution for the glycine at position twelve. Nobody will be surprised if, in the human cells as in the virus, the glycine is this time replaced by serine, not valine. And given that the retrovirus known as the Harvey murine sarcoma virus is known to produce an altered p21 protein in which the same critical glycine is replaced by arginine, it will no doubt be only a matter of time before some human cancer associated with that mutation turns up. It is also, however, clear that mutations of the p21 gene are not a sufficient explanation of the malignant condition.

One of the intriguing features of this week's report by Barbacid's group is that cells from the two fresh colon carcinomas tested have oncogenes differing both from each other and from the Kirsten version of the p21 gene (which, nevertheless, turns up in a cell line derived from another colon carcinoma). It will be fascinating to see what are the nucleotide sequences in these genes, as it will be to know why the gene product of the single case of pancreatic carcinoma studied appears to have a molecular weight of 27,000, not 21,000. Meanwhile, Barbacid and his colleagues have taken advantage of the availability of normal as well as cancerous tissue from the patient with the pancreatic carcinoma to demonstrate that DNA from the normal tissues will not convert mouse cells of the NIH line known as 3T3 from their usual (nearly malignant) condition into cells that are frankly malignant. That has an obvious bearing on the question still to be settled of whether human oncogenes of the two types now characterized occur in apparently non-malignant cells, which in turn bears on the question whether in real cells (as distinct from those of the 3T3 cell line) the presence of an oncogene is a sufficient cause of cancer.

Already, however, it is clear that the two human oncogenes now defined are only a small part of this unfolding story. Thus the oncogenes known to be involved in tumours of the white blood cells, leukaemias, lymphomas and the like, but mostly in other than human animals, are quite different. Two important papers on that subject appeared last month in *Proc. natn. Acad. Sci. U.S.A.* (79, 6971 and 6999; 1982), even if their relationship with oncogenes is apparent only in the light of more recent information. Both papers are concerned with plasmacytomas, tumours of B lymphocytes secreting immunoglobulins. In the mouse, it is commonly observed that the end of a chromosome 15 has moved, in malignant lymphocytes, to the region of chromosome 12 where the gene for the heavy chain of immunoglobulin is located. Alternatively, a piece of chromosome 15 may finish up on chromosome 6, where the κ-chain genes are based. Jerry Adams and his colleagues in the Walter and Eliza Hall Institute of Medical Research have now cloned from a plasmacytoma a transcriptionally active segment of chromosome 12 which appears to have been derived from elsewhere, conceivably chromosome 15. And Kathryn Calame (from the University of California School of Medicine at Los Angeles) and her colleagues have identified in two plasmacytomas secreting immunoglobulin A the physical conjunction of a segment of chromosome 15 with part of the gene for the immunoglobulin A constant region gene of chromosomes 12 (to be precise, it is joined to that one of the two chromosomes 12 which is not actively involved in immunoglobulin A production).

From results reported from a recent meeting (see *Nature* 2 December, p.403), it now seems that these two groups — and Marcu *et al.* before them (*Proc. natn. Acad. Sci. U.S.A.* 79, 6622; 1982) — have been observing the translocation of the oncogene known as c-*myc* from chromosome 15 to an active region of chromosome 12 or, alternatively, the transfer of this active region to the site of c-*myc* on chromosome 15. Either way the proposal is that the c-*myc* gene thereby becomes expressed and that this is associated with the oncogenetic process.

As a service to readers, the staff of *Nature* will attempt at intervals in the weeks ahead to draw attention to papers appearing elsewhere which are judged to be important contributions to the quickly developing oncogene story. The assistance of readers and of the authors of papers published elsewhere would be appreciated. Communications (by letter or telephone) should be addressed to Dr Peter Newmark in the London office.

Safe with Cepheids?

from David A. Hanes

MEASUREMENTS of the period of oscillation of the pulsating supergiant Cepheid variable stars have underpinned our estimates of the cosmic distance scale and thus of the age of the Universe for more than half a century. If a study[1] recently published by M.J. Stift and first brought to the attention of astronomers at the General Assembly of the International Astronomical Union in August is correct, however, this application will have led to serious errors.

By astrophysical good fortune, Cepheids combine several properties which make them potentially excellent indicators of distance: they are intrinsically luminous supergiants, and so can be seen even in external galaxies; their luminosity varies with considerable amplititude, so that they draw attention to themselves in crowded star fields; and they vary with well defined periods which are proportional to their intrinsic luminosities. Thus a simple determination of the period of an individual Cepheid allows the intrinsic luminosity to be calculated — comparison with the observed mean apparent luminosity of the star then yields a direct distance estimate; provided that the period–luminosity (PL) law has been correctly calibrated with reference to Cepheids whose distances are independently known.

The importance of the PL law was recognized shortly after its discovery[2] in 1912 in a sample of Cepheids at a common distance in the Large Magellanic Cloud, the nearest galaxy outside our own Milky Way. The subsequent identification[3] of Cepheid variables in the Andromeda nebula (M31) and the Triangulum nebula (M33) resolved the controversy over the nature of the spiral nebulae, proving that our Galaxy is not unique, and set the stage for the discovery[4] of the expansion of the Universe. The succeeding half century has seen many revisions[5,6] of the extragalactic distance scale and inferred age of the Universe, but that scale still depends in large measure on the distances implied by the Cepheid variables (see *News & Views* **299**, 297; 1982).

It is in the calibration itself that difficulties arise. Cepheids are young massive stars in short-lived late stages of stellar evolution; thus they are rare. None is close enough to permit a straightforward measurement of distance (say, by parallactic triangulation) and the calibration relies largely on the identification of a handful of Cepheids in clusters or associations whose distances can be derived by other often less precise means. Moreover, Cepheids are found preferentially in the plane of the Galaxy, and may be considerably obscured and reddened by interstellar dust. This problem is exacerbated by the youth of the Cepheids: they may be found still embedded in the locally dust-rich environments from which they formed. Thus it is difficult to assess with what precision we know the absolute luminosities and colours of the calibrating Cepheids.

In external galaxies, further problems arise. There is some evidence[7] that the PL law differs from galaxy to galaxy, perhaps as a consequence of different heavy-element abundances. Measurements of stellar brightness are difficult in crowded fields near the limits of big telescopes. Perhaps most important, only the extremely luminous Cepheids (those of the longest periods) can be detected in remote galaxies; such stars are not found among the calibrating sample, and extrapolations of the locally calibrated PL law are required. A clear understanding of the law is therefore essential.

What form does it take? It has been argued[8] that a simple PL law is an incomplete description of the phenomenon. With age, evolving stars change their radial distributions of mass, composition, rate and source of energy generation, temperature and opacity. At certain critical phases, manifested observationally by characteristic intrinsic luminosities and surface colours (or, equivalently, surface temperatures), stars may become unstable to pulsational vibrations. The region of the luminosity–colour plane within which such variations occur is referred to as the 'instability strip'. Elementary physical considerations suggest the necessity for a three-argument period–luminosity–colour (PLC) law — at a given period Cepheids may exhibit a range of mean luminosities, with the intrinsically brighter at that period being the hotter (bluer) stars, while their fainter counterparts are cooler (redder) — or vice versa. No such relation will arise if the instability strip is very narrow, or if some compensating structural difference fortuitously cancels the dependence on colour. An analysis of available data did, however, originally seem to support the three-parameter PLC formulation — although that analysis[8] has subsequently been hotly criticized[9,10].

Supporters of the full PLC law argue that its use improves the Cepheid distance estimates to the fundamental limit permitted by the measuring uncertainties of the observational data themselves. However, there are difficulties. It is disquieting that the colour coefficient ($\beta = 2.7$) derived[8,11] for the PLC relation so nearly matches the effect ($\beta \sim 3$) which would be produced by a component of interstellar obscuration; that is, for Cepheids of given period the fainter (obscured?) stars are redder by almost exactly the amount that would be produced by normal interstellar dust giving rise to the observed dimming. While this may be mere coincidence, it suggests that differential obscuration may be largely responsible for the apparent PLC law, in which case the subsequent technique of determining distance may be erroneous, especially as it depends in certain applications upon lengthy extrapolations of the law.

The recognition of this problem recently sparked two separate critical assessments, by J. Brodie and B. Madore[12] in Cambridge and by V. Clube and J. Dawe[10] in Edinburgh. The Cambridge study was based on Monte Carlo simulations of randomly generated data sets, obeying underlying perfect PLC laws but variously affected by reasonable random errors of photometry and by plausible randomly assigned amounts of obscuration. The conclusion was that the coefficient could be in excess of $\beta = 5$, but that in the presence of moderate amounts of differential obscuration the intrinsic PLC relation is completely masked by the dominant extrinsic trends. On the other hand, the Edinburgh study, which criticized (*inter alia*) the original[8] semitheoretical determination of the colour term, concluded that near-zero or negative values were favoured.

M. Feast and L. Balona published a swift rebuttal[13] of the Cambridge study, with the distinction between the analyses being one of mathematical methodology: in the rebuttal, maximum likelihood techniques of arguably greater reliability were shown to reconfirm the original PLC derivation. It is this conclusion that is now under spirited attack by M.J. Stift[1]. Like Brodie and Madore, he uses extensive numerical simulations and introduces all conceivably relevant effects: the photometric measuring errors; the effects of obscuring material, randomly assigned; the presumed true physical width of the instability strip; a spread in Cepheid properties caused by

0028-0836/82/490478-02$01.00

mass loss among a sample of originally identical stars; and so forth. His analyses show that the maximum likelihood method systematically overestimates β, whether the data are affected by correlated (obscuration-induced) or uncorrelated errors. Indeed, Stift concludes that it is impossible in such analyses to distinguish between $\beta = 0$ — the irrelevance of a colour term — and $\beta = 2.7$, the generally accepted value: the maximum likelihood estimate is indeterminate. His own analyses merely suggest that β must lie in the broad range 0-3. More importantly, he concludes that the inclusion of the colour term is irrelevant and generally erroneous in the use of Cepheids; he recommends the complete abandonment of the PLC relationship as an indicator of cosmic distance.

Such a conclusion is particularly damaging for the Sandage–Tammann construction[6,14] of the universal distance scale, which is already under critical attack[9,15,16] for other reasons, because their entire scale is predicated on the use of the PLC relationship for Cepheids in nearby galaxies — the first stepping-stones in a hierarchical construction. The present study is more supportive of an alternative treatment[17] of the Cepheid variables by de Vaucouleurs, which, when coupled with other indicators, yields a cosmic distance scale half that proposed by Sandage and Tammann. Thus Stift's provocative results may help (if correct in all particulars) to resolve this outstanding controversy, a subject of often heated and occasionally acrimonious debate for the last decade. Observational cosmologists are eagerly awaiting the next instalment. ☐

Microbial galley slaves

from Ralph A. Lewin

SOME of the weirdest and most wonderful microorganisms are to be found in termite guts, veritable zoos of strange protozoa, and among these a devescovinid flagellate is especially notable for having enslaved bacteria to move it around. Some recent papers by Tamm[1,2] provide revelations on this subject, trumping science fiction with science facts.

Devescovinids are fairly large, as microbes go; their cells are 100–150 μm long and 30 μm wide. They occur in the digestive systems of certain Florida termites (*Cryptotermes cavifrons*), where they slither around in continuous motion. Each cell has a pointed front end tipped with a sort of nose-cone or conning-turret, which is constantly rotating at about 30 r.p.m. (Look at it face-on, and you see that it always turns clockwise. How a single lump of protoplasm can have a swivel like this is one of its mysteries; it must have no microtubules in its 'neck' regions, or they'd soon get screwed up.) At its front end the animal has four whip-like cilia, about as long as the cell and some 400 nm wide, with the usual arrangement of 9 + 2 microtubules found in other eukaryotes. Three of them lash to and fro, forwards and back, while the fourth trails backwards like a sort of rudder. However, the three beating cilia are not the main mechanism of locomotion for this (as yet unnamed) devescovinid, since most of the work is apparently accomplished by some two or three thousand rod-shaped bacteria, 2–3 μm long, attached to its surface. These little galley slaves lie end to end in more than a hundred single files, firmly embedded in helical grooves. On its outer side each bacterium bears a dozen flagella. These are 4–5 μm long but only 18 nm wide, and are composed of longitudinal rows of flagellin molecules like those of, say, *Escherichia coli* (though in *E. coli* they are borne on all sides of the cell). Some of the flagella from each bacterial cell trail backwards and join those of the cell behind to form a helical bundle about 24 flagella thick. Hydromechanical forces are evidently responsible for aligning and synchronizing their movements. As the individual flagella rotate, so do the helical bundles, and this is what propels the protozoan on its way. (Other ectosymbiotic bacteria — longer, thinner and without flagella — are attached along the ridges between the grooves; their role is so far completely unknown.)

A devescovinid slithers along at a rate of about 100 μm s^{-1}. As large protozoa go — *Paramecium*, for instance — that's not very fast, but since the motors are basically bacterial it isn't a bad speed at all. The protozoan vessel is propelled three or four times as fast as a free-swimming *E. coli* cell, even though its flagella are of similar size and rotate at much the same speed (50–150 Hz). Tamm attributes their celerity to the fact that devescovinids glide over solid substrates — probably bits of wood ingested by the termites — and that less energy is dissipated at a phase interface than free in a fluid.

Can one be sure that it is really these bacteria that are responsible for the motility of the protozoan? Two lines of evidence, at least, indicate that this is so. First, many fragments of protozoan cells — crushed, for example, under a coverslip — rotate actively if they bear bacteria, although they may completely lack any of the four devescovinid cilia: the more bacteria they bear, the faster they spin. Bacteria liberated from crushed host cells can swim, too. Second, a proton ionophore such as dinitrophenol (10 mM), which interferes with the motility of bacterial flagella, reversibly arrests the movement of the devescovinid though not the beating of its own cilia. On the other hand, certain polyene antibiotics, toxic to most eukaryotic cells, inactivate the four cilia of the protozoan but have little effect on its gliding activity. (A specific inhibitor of the ATP mechanism of protozoan cilia would presumably not interfere with the gliding movements of the devescovinids, but Tamm did not mention having tried this.)

How and why could such a system have evolved? We might start by asking what benefit the protozoa could derive from being able to move at all. Perhaps such slithering around enables them to keep making new contacts with the bits of wood on which they are presumed to feed. (Many symbiotic protozoa digest lignocellulose

Electron micrograph of a rod bacterium (rb) isolated from the surface of a devescovinid. The flagella arise from what would be the exposed surface of the bacterium and are shown in comparison with the douoblet microtubules (dmt) from the devescovinid's own flagellum.

with the aid of hyper-symbiotic intracellular bacteria, but that's another story.) Perhaps motility, with some kind of orientation mechanism located in the conning-tower apparatus at the pointed end, helps to ensure that the devescovinids stay cozily ensconsed inside the termite's gut and are not excreted or shed when their insect host casts its skin. Maybe the general stirring of the intestinal contents helps to keep gut fermentations operating effectively. But why don't these protozoa depend entirely on their own ciliary apparatus, and 'go it alone' as do most other motile microbes? Are the three beating cilia too weak to move such relatively large cells around? Apparently so; or perhaps it is cheaper, energetically, to enslave or enlist bacteria to do the rowing than to row oneself. However, as any trireme skipper knows, even slaves have to be fed if they are to continue to man oars effectively. Presumably some nutrients are transferred through the cell membranes of the protozoan grooves to keep the hard-working bacteria going, but so far this subject seems not to have been investigated.

As for the steps by which such a system of microbial enslavement might have evolved, we can only hazard a guess. Many animals are covered with bacteria; in some invertebrates they seem to be highly specific. Little flagellate cells may shift bigger things around, sometimes fortuitously (witness the rotating eggs of seaweeds such as *Fucus*, spun by the crowds of spermatozoids attracted to their surfaces) and sometimes in an apparently purposeful fashion (as in the green alga *Prasiola*, where the fertilized egg gains the ability to swim by adopting one of the flagella of its successful male partner[3]). As Tamm reminds us, there is another genus of protozoa related to the devescovinids, *Myxotricha*, found in the gut of another kind of termite, from Australia, which has rows of bracket-like processes along its sides, each bracket bearing a motile spirochaete; by means of these symbiotic cells, it can swim in much the same way as the devescovinid described above, although at only about one-fifth of the speed. This remarkable symbiotic system, in *Myxotricha*, has been known and studied for about 20 years, but Tamm's observations on devescovinids are much more recent and quite as fascinating. ☐

Bird coloration and parasites — a task for the future?

from Paul H. Harvey and Linda Partridge

NATURAL selection for defence against parasites may have more significance for evolutionary biology than has often been supposed. Increasing awareness of host-parasite interactions has led to suggestions that they have a key role in population regulation[1,2], in the maintenance of genetic polymorphism[3], in social organization[4,5] and even in the evolution of sex[6–8]. Now, W.D. Hamilton and Marlene Zuk of the University of Michigan have come up with the hypothesis[9] that parasite resistance is even important in the evolution of bird coloration. The idea is that birds choose mates with bright plumage and complex songs because these characters are correlated with heritable resistance to parasites.

For a character to be heritable genetic variation must exist. Ever since Haldane[10], population geneticists have known that defence against different parasites could lead to the maintenance of such variation in a host species. Most models of the process assume that increased protection against one type of parasite leads to increased susceptibility to another; this has been verified in several cases (see ref. 3), though mainly among plants and their parasites. However, not all models make this assumption. For example, if defence mechanisms against parasites are costly in terms of potential reproductive success, then when parasites are common genes for defence may be favoured, but when parasites are rare those same genes may be at a disadvantage[3].

Genetic variability in the host species can be maintained without there being a single equilibrium point: limit cycles and other patterns of temporally changing gene frequencies are features of some models. If cycles are long, then genes for parasite resistance which are favoured by natural selection in one generation are, on average, those likely to be favoured in the next generation. As a consequence, when cycles are long, genes for choosing mates that have high parasite resistance will be favoured by sexual selection.

But how can animals recognize that potential mates possess the correct genes? One way would be to assess their parasite loads directly: when an animal has few parasites, it means it has high resistance. A more indirect measure might be via plumage characteristics. That, at least, is the suggestion made in the recent paper by Hamilton and Zuk[9]: "The methods used should have much in common with those of a physician checking eligibility for life insurance . . . the choosing animal should unclothe the subject, weigh, listen, observe vital capacity, and take blood, urine and faecal samples". Although they cite no relevant evidence, they go on to argue that "general good health and freedom from parasites are often strikingly indicated in plumage and fur, particularly when these are bright rather than dull or cryptic". Within bird species, they predict that the most brightly coloured animals should have low parasite loads, and, *ceterus paribus*, be favoured mates. In contrast, across species, bright coloration should be found associated with high species-specific parasite loads — species subject to a wider variety of parasites will have experienced stronger selection. They were only able to test the latter prediction, although the former is probably the more telling.

Data on four or five haematazoa and on microfilarial worm infestations of passerine birds from five sites were extracted from the literature. Both sexes of 109 different species were scored for degree of 'brightness', and in those same species the songs of the males were scored for 'complexity'. Male brightness (1), female brightness (2), male song (3), male showiness (1 + 3) and bisexual showiness (1 + 2 + 3) show weak but highly significant increases with recorded parasite load across species. The one exception is negative associations of brightness, song and showiness with the generic 'disease' *Toxoplasma*. A footnote to the paper points out that, although these same general patterns of increased brightness, song and showiness with parasite load are found in grouse, the opposite correlations hold for owls.

Hamilton and Zuk conclude that the results conform to their model, although "evaluation of the many plausible and overlapping theories about display and sexual selection, including our new one, is a daunting task and must be left to the future". That is true, but it is unfortunate that their report was not presented at a greater length. Then they could have presented more than summary statistics of their data and they could have considered other correlates of bright coloration among bird species. Two were mentioned and considered to be in agreement with their theory: bisexual brightness and sexual dimorphism are lower on islands[11] (there are fewer parasites on islands), and larger-bodied species tend to be more brightly coloured[12] (larger birds provide a bigger target for vectors, and can tolerate more insect bites). But what of the other correlates pointed out by Baker and Parker[13] in their detailed study of coloration in 516 species of Western Palaearctic birds? For example, diurnally active birds are more conspicuous than nocturnally active birds, gregarious birds are more conspicuous than solitary birds and concealed nesters

Paul H. Harvey is a lecturer in the School of Biological Sciences, University of Sussex, Brighton BN1 9QG and Linda Partridge is a lecturer in the Department of Zoology, University of Edinburgh, Edinburgh EH8 9YL.

0028-0836/82/490480-02$01.00

are more conspicuous than exposed nesters. Baker and Parker conclude that "in every case the more colourful category is likely to be a less profitable prey to a predator than the more cryptic category" and "that it is possible to explain variation in the coloration of adult birds largely in terms of the selective pressures generated through predation risk". We can also make *post hoc* explanations for why each of those same categories should be subject to higher parasite infestations.

The time has come to make predictions which will enable us to distinguish between these and alternative hypotheses. Surely, after taking possible taxonomic effects into account, different hypotheses should make different predictions about other ecological, behavioural or morphological correlates of bright coloration? □

Vaccination programmes and herd immunity

from Robert M. May

VIEWED from the level of the population as a whole, immunization programmes have two primary effects.

The more obvious, or 'direct', effect of vaccinating some fraction of a population against a particular infection is that most of the vaccinated individuals are thereby protected. The ideal vaccine or toxoid is one which produces immunity in all treated individuals (100 per cent efficacy), and where this immunity is lasting. Current measles vaccines, for instance, approach this ideal, apparently inducing lifelong immunity with about 95 per cent efficacy.

Less obviously, the immunization of some fraction of the population is likely to have the 'indirect' effect of diminishing the 'force of infection', defined as the probability that an unvaccinated individual will contract the infection within a specified time interval. If fewer people are candidates to run around coughing or sneezing at you, your chances of acquiring infection are likely to be smaller. One consequence of the existence of such indirect effects is that it is not necessary to immunize everyone in order to eradicate an infectious disease; once a sufficiently large fraction of the population has been protected, the associated indirect effects can drive the reproductive rate of the infection — the average number of secondary cases produced by an infected individual — below unity, so that the infection cannot be maintained[1,2] (except by immigration). It is the intuitive appreciation of these facts that lead many people to decide their best vaccination programme is one where almost everyone else is vaccinated while they are not, so that they are indirectly protected without incurring any of the risks or inconveniences associated with direct protection. Such dissonance between the interests of the individual and the interests of the group arises, of course, in many areas of evolutionary biology and elsewhere. In what follows, we shall meet some subtle variations on this theme.

Bearing in mind both direct and indirect effects, we may ask what happens to the population as a whole — to 'herd immunity' — as a result of immunizing, say, 50 per cent of the population.

One answer comes from the extensive mathematical literature dealing with the transmission and maintenance of infectious diseases. Essentially all such theoretical work is based on the assumption of 'homogeneous mixing', whereby new infections appear at a rate directly proportional both to the number of infectious individuals and to the number of susceptibles. That is to say, school and family associations, and all other kinds of social groupings, are averaged out; infections result from binary encounters within a homogenized population. Under this assumption, implementing a vaccination programme that is not sufficiently intense to eradicate an infection will lead to a new steady state in which the number of susceptible individuals is exactly the same as in the unvaccinated population[3]. At first sight, this result may seem surprising; intuition suggests the proportion susceptible should decrease as vaccination coverage increases.

The theoretical result is, however, easily proved. First, let R_0 denote the basic reproductive rate of the infection, the average number of secondary cases produced when an infected individual is introduced into a wholly susceptible population[4-6]; R_0 depends on the basic biology of the infectious agent, and on all manner of social and environmental factors that affect transmission. Next, suppose that only a fraction x of the population is susceptible, the other individuals having acquired immunity either by vaccination or by recovery from natural infection. In a homogeneously mixed population, the average number of secondary infections produced by each infectious individual is then $R = R_0x$. But at equilibrium each infection must produce on average exactly one secondary infection, $R = 1$. Hence, for an infection that is established at some endemic steady state, the fraction susceptible is $1/R_0$. The answer depends only on R_0, and is independent of the proportion vaccinated.

To make the result a bit more concrete, consider the example of an infection with $R_0 = 10$ (which is very roughly the case for many childhood infections in Western countries). The equilibrium state before any vaccination has 10 per cent susceptible, with essentially all the remaining 90 per cent having acquired immunity following recovery from infection (the typical infection runs a relatively short course, so the remaining fraction that are actually infectious at any one time is very small although, of course, crucial for maintenance of the infection). Suppose now that we move to a new steady state in which 50 per cent of the population are immunized by a vaccine or toxoid. If there were no indirect herd effects of immunization, the remaining 50 per cent of the population would be divided between susceptibility and acquired immunity in the same proportions as in the original population, to give a total of 5 per cent susceptible and 95 per cent immune (50 per cent from the control programme, 45 per cent following natural infection). The existence of indirect effects, however, leads under the assumption of homogeneous mixing to there still being 10 per cent ($1/R_0$) susceptible and 90 per cent immune (50 per cent from the control programme, 40 per cent following natural infection). By the same token, immunization of more than 90 per cent of the population (or, more generally, more than a fraction $1-1/R_0$) leads to eradication of the infection, by virtue of the indirect effects[7]. In the absence of such indirect effects, almost 100 per cent immunization would be required to eradicate infection from a very large population.

Many people have observed that real populations are rarely, if ever, 'homogeneously mixed', with susceptibles and infecteds bouncing around like the molecules of an ideal gas. The assumption may nonetheless give a good description of what happens on the average; as Bartlett[8] has written: 'even if a multiplicity of detailed causes is operating to produce the observed broad classes of events, it is often

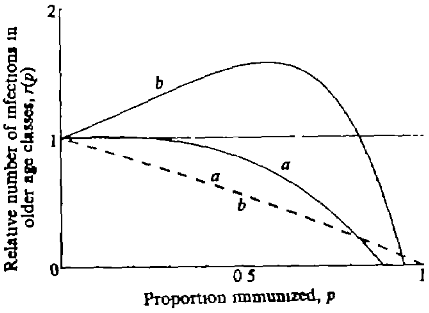
an economy of thought in the sense of Mach to ignore these and appeal merely to the operations of chance and the laws of averages'. This issue cannot be resolved in the abstract. What we need are good empirical tests of the validity of the predictions made by the simple theory.

One especially interesting such test has recently been made for measles by Fine and Clarkson[9]. Analysing the data that are available for age-specific incidence and immunity levels for measles in England and Wales since 1950, they find the 'total number of individuals susceptible to measles has remained relatively constant', at around 4 to 4.5 million. This corresponds to about 9 per cent of the population being susceptible, implying R_0 is around 11–12; this accords with other independent estimates[10]. As Fine and Clarkson emphasize, there are biases and deficiencies in the available data (having to do mainly with the notification of cases), and methods of correcting for such biases depend to a degree on the assumption of homogeneous mixing. Thus their test of this assumption is not altogether free of some circularity. I think, however, that Fine and Clarkson's analysis is important, showing that homogeneous mixing represents a useful working approximation for measles in England and Wales, and therefore possibly for broadly similar infections elsewhere.

Weighing risks

In practice, immunization programmes must take account of additional complications arising from age-specific aspects of the vaccination schedules and of the infection processes. If the bad effects of infection are the same at all ages, then any vaccination programme (no matter how low the coverage) will reduce suffering to some extent, provided only that the vaccine is safe. In this situation, it is in principle a relatively simple matter to weigh the health benefits of a vaccination programme against the risks of vaccination itself (although an economic cost–benefit analysis is likely to be more complex, involving the familiar difficulties of assigning monetary values to physical disabilities). The current controversy over vaccination against pertussis (whooping cough) is a case in point. Here the debate is clouded by uncertainties about the risks of vaccination, by the possibility that immunization protects against the symptoms of pertussis but not against becoming infected and infectious (so that no indirect benefits are realized by vaccination) and by a certain amount of emotionalism. I shall not deal further with this vexed subject, lest this article get out of hand.

Such calculations become trickier when a disease has been eradicated from a particular region or country, so that incidence of the disease depends on chance episodes of importation. Becker[11] has shown how to estimate the number of fatalities to be expected from such an episode in an unvaccinated population, before quarantine and vaccination get things under control, and how to weigh this against the number of fatalities to be expected in association with a vaccination programme. This general kind of calculation underlay the UK and US decisions to discontinue routine vaccination against smallpox in 1971: in the UK, the years 1951–1970 saw around 100 deaths from smallpox vaccinations (roughly one death per million primary vaccinations) and approximately 37 from smallpox itself[1].



The number of infections among females in older age groups (specifically, between 18 and 35 years) when a proportion p of the females are protected by vaccination; the number of infections are calculated as a ratio, $r(p)$, to the corresponding number without any vaccination. The solid curves are for a vaccination policy in which a proportion p of both males and females are immunized at age 2, and the dashed curves are for a policy in which only females are immunized at age 12. The solid and dashed curves a are for $R_0 = 7.5$, and the curves b are for $R_0 = 13$.

Age-dependent effects

For many viral infections, the chance of serious complications arising is greater if the infection is acquired at an older age. For example, although the probability of encephalitis occurring as a complication of measles is low, this probability rises roughly linearly with age at infection[12] (at least through the first 20 years of life). In such circumstances, it is important to note that indirect effects of immunization or other factors that diminish the 'force of infection' within a population will correspondingly increase the average age at which infection is acquired. There is evidence to this effect from vaccination programmes against measles and rubella (German measles)[9,12].

In short, under a vaccination programme stopping short of eradication, fewer individuals will get sick, but those who do will do so on average at an older age. If fatalities or other complications are more likely at older ages, it is thus conceivable that certain vaccination programmes could actually increase the incidence of serious cases. The likelihood of such a perverse outcome is not easily guessed, but rather requires a close analysis of the detailed interplay among several factors: the way serious illness depends on age, the details of the vaccination programme and the basic biology of the transmission process (summarized by R_0).

It is probable that the history of poliomyelitis represents a 'natural experiment' of this general kind. The argument runs that, in earlier times, most people contracted this infection in the first few years of life, when it very rarely has serious consequences. Increasingly high standards of cleanliness in Western societies in the middle decades of this century led to lower values of R_0, and thence to a diminished force of infection and a consequent rise in the average age at which infection was acquired (albeit by fewer people, in total). Since paralysis and other complications are apparently much more likely for infections in teenage or older individuals, poliomyelitis paradoxically became more troublesome as its transmissibility declined. More recently, in a notable success story, the advent of safe, effective and cheap vaccines has effectively eradicated poliomyelitis in Western countries.

Rubella is a particularly striking example of an infection whose seriousness depends on the age at infection. Usually a mild infection, rubella can cause the damaging congenital rubella syndrome (CRS) in the offspring of women who acquire the infection in the first trimester of pregnancy. In a seminal paper, Knox[11] has shown how the incidence of CRS may indeed increase under some vaccination programmes.

The solid curves in the figure (which represents a slightly modified version[12] of Knox's simpler analysis) show the number of individuals who are infected between the ages of 18 and 35 — the main childbearing years in Western countries — when a proportion p of the total population (boys and girls) are successfully immunized at age 2, as a ratio to the number of individuals acquiring infection in this age range before vaccination was introduced. This ratio, $r(p)$, provides a rough estimate of the relative incidence of CRS to be expected for different values of p; more accurate calculations integrate over the product of the reported age-specific fecundity times the age-specific incidence of infection[12,13]. Curve a is for an infection with $R_0 = 7.5$ (roughly corresponding to rubella in the US and UK), and curve b is for $R_0 = 13$. In both cases it is assumed that the population is homogeneously mixed, and that everyone lives to age 75 and then obligingly dies (which is a reasonable approximation to the real survivorship function). From these solid curves a and b, we see that the incidence of infection among older individuals can increase under a vaccination programme with moderate levels of coverage (p not too large), and that this propensity becomes more pronounced as R_0 increases.

The dashed curves a and b (which are effectively indistinguishable) correspond to the solid curves a and b respectively, with the one difference that now a proportion p of girls, and only girls, are immunized at age 12. For given p, the two immunization policies provide the same amount of direct protection against CRS. The 'girls at age 12' policy has little effect on the overall force of infection within the population, and thus produces little in the way of indirect protection; hence the ratio $r(p)$ is roughly just $1-p$. The 'everyone at age 2' policy, on the other hand, does substantially affect the force of infection, producing indirect effects that both increase the average age at infection and eventually, for large p, lead to eradication. Hence, as shown in the figure, the former policy is better at low p and the latter at large p. For rubella, the cross-over point is for p in the range 75–85 per cent[12-15].

The solid curve, or 'everyone at age 2' vaccination policy against rubella, is essentially that followed in the US where immunization levels are in the 90 per cent range or above. Conversely, the dashed curve, or 'girls at age 12' vaccination policy, is essentially that adopted in the UK, where p is currently around 70–80 per cent. Each country thus appears to have chosen the correct policy for its particular level of vaccination coverage[16].

This analysis of vaccination strategies against CRS can be elaborated and made more realistic in many ways. In particular, Dietz[14] and Hethcote[15] have included the costs of the different policies in more exhaustive studies.

Most mathematical work on herd immunity and the effects of vaccination concentrates on comparing the initial and final steady states. The dynamics of the transition process, however, can be of great significance, expecially as programmes often undergo changes in midstream. Analysis of the age-specific dynamical effects is made complicated by the existence of several characteristic time scales, ranging from around 10 days or so for infection to run its course in an individual, to the 70 years or so that characterize the lifespan and turnover in a population at equilibrium. In some of the large and avowedly realistic computer models for these dynamical phenomena, apparently harmless approximations (such as updating the force of infection once a year instead of every few days) have led to spurious results because the intricacies associated with the different time scales are not fully understood. I think elaborate numerical studies can only be trusted if they are grounded on a clear understanding of the basic dynamical processes.

On the other hand, the most mathematically impeccable studies of the dynamics of vaccination programmes are largely fruitless unless tested against factual evidence. There is very little such work, and a clear need for more studies of the kind undertaken by Fine and Clarkson.

Very high-energy gamma-ray astronomy

from P. V. Ramana Murthy and Trevor Weekes

THE high-energy region from 10^{11} to 10^{14} eV is the last window in the electromagnetic spectrum to be exploited by ground-based astronomers and one of particular relevance to high-energy astrophysics. Practitioners in the field met at a recent workshop* in Ootacamund, India to discuss their results: although there have been experiments in four continents over two and a half decades, the techniques used have been somewhat different and there has not always been agreement on the results obtained.

The flux of photons with energies above 10^{11} eV is very small so that detection by satellite, even with larger detectors than at present, would be extremely difficult, if not impossible. At energies greater than 10^{14}eV photons cannot be observed as they undergo photon–photon interactions with the universal 3° black body radiation and are absorbed over distances greater than 10 kiloparsecs. Fortunately for the ground-based astronomers, though, photons in the 10^{11}–10^{14} eV range are sufficiently energetic that when they interact with the upper atmosphere they produce an electromagnetic cascade that can be detected by its atmospheric Cerenkov radiation using simple light collectors. The great advantage of this technique is that the effective area for detecting γ rays is a few orders of magnitude larger than the geometrical area of the detectors themselves. Although attempts have been made to detect cosmic γ-ray sources using this technique since 1958, it is only in the past decade that sources have been detected.

Cygnus X-3, a binary X-ray source, first came into prominence when it underwent a massive radio outburst in 1972. Within a few days, γ rays of 10^{12} eV were detected from the source. Every year since then the flux, although variable, has been detected (Stepanian, Crimean Astrophysical Observatory). The emission shows two modulations, with 4.8 hour and 34.1 day periodicity, which also occur at X-ray wavelengths. The 4.8 hour light curve has been seen at energies $\gtrsim 10^{12}$eV for some time and is quite different from that seen at lower energies; the 34.1 day modulation has only recently been detected (Turver, Durham University) and appears to be out of phase with the X-ray variation.

Since high-energy γ-ray emission has been detected from the young pulsars in Vela and the Crab, it has been suggested that the Cygnus X-3 system may contain a young pulsar. A search for pulsations in the high-energy γ-ray signal in the range 4–40 ms has so far been unsuccessful (Porter, University College, Dublin).

An alternative model based on an analogy with SS433, a source with known jets of relativistic material, requires a black hole or neutron star to be in orbit with a helium star; the rotation axis of the compact object makes an angle with the plane of the system (Grindlay, Harvard-Smithsonian Center for Astrophysics). The analogy is attractive since SS433 is the most powerful source in the Galaxy and Cygnus X-3 may be the most powerful source yet detected.

There is no real problem in producing high-energy γ rays in pulsars; the difficulty arises in getting them away from the pulsar without absorption. Variability in the pulsed γ-ray emission is evidence for this difficulty and suggests that the pulsars that are regular emitters at X-ray and optical wavelengths may be quite different at these extreme energies. Previous reports of transient emission of 15-min duration from the Crab pulsar have been extended by the observation of 1-min variability in the pulsed signal from the Crab pulsar and 15-min variability from the Vela pulsar (Vishwanath, Gupta, Tata Institute of Fundamental Research).

The atmospheric Cerenkov technique finds application in another area — study

---

*The 'International Workshop on Very High-Energy Gamma Ray Astronomy' was held at Ootacamund, India on 20–25 September 1982 and was jointly sponsored by the Smithsonian Institution, USA and the Tata Institute of Fundamental Research, Bombay, India

P. V. Ramana Murthy is a professor at the Tata Institute of Fundamental Research, Colaba, Bombay 400 005, and Trevor Weekes is an astrophysicist at the Harvard-Smithsonian Center for Astrophysics, Whipple Observatory, PO Box 97, Amado, Arizona 85640.

of extensive air showers produced by ultra-high-energy cosmic rays. By studying air Cerenkov pulse profiles and amplitudes along with other observations, it is becoming possible to understand the charge composition of primary cosmic rays at energies greater than 10^{15} eV (Rao, Tata Institute; Tanahash, University of Tokyo; Clay, University of Adelaide; Turver).

Further progress in this discipline requires the development of new and more sensitive detection techniques. Improvement in angular resolution will lead to improved minimum flux sensitivities; such improvement may come from the imaging systems being developed independently at the Crimean and Whipple Observatories. Since the sources so far detected include an X-ray binary, pulsars and a radio galaxy, a small improvement in sensitivity could lead to a dramatic increase in the number of detected sources (Gursky, Naval Research Laboratory). With the development in this decade of more sensitive detectors at satellite γ-ray energies and of new experiments in neutrino astronomy, the role of the atmospheric Cerenkov technique in covering this window in the electromagnetic spectrum will become all the more important. □

Greek fireworks

from M.H. Day

THE Third European Congress of Anthropology was held in Greece at Petralona, near Thessalonika, at the end of September. Two main themes — the pre-*sapiens* stage of human evolution and the biology of migrating populations — attracted great interest and over 200 delegates from around thirty countries took part. One individual dominated the whole gathering, however, and that was Petralona man himself; unfortunately he was not present at the Congress since his fate was then still in the hands of the Greek courts of law. Until the courts decide whether to accede to Aris Poulianos's request that the skull be transferred to his museum at the Petralona cave, the Petralona skull remains aloof and incarcerated in its present resting place at the University of Thessalonika museum.

The first two days of the meeting were held at the Petralona site itself, in the splendid new facilities that have been provided by the energy and dedication of Poulianos, including a new tarmac road, a conference hall, a museum and laboratories. The Petralona cave nearby must be one of the most beautiful caves in Europe with hundreds of metres of vaulted galleries with stalactites and stalagmites; the cave is well illuminated and now engineered with walkways. Delegates wandered in and out of the cave freely and were shown anything that they wished to see.

The problems and the scientific disputes over Petralona man are of long standing and now rest principally upon the dating. Indeed, the conference was preceded by a brisk exchange of views on this subject in the pages of this journal[1-5]. The skull itself, billed as 'The Oldest Europaeoid' has features that make it crucial to establish its evolutionary position.

So muddy have the waters become that almost everything ever stated about the find and the site has been questioned, yet there are some facts that seem to have a solid consensus of support. First, there seems no doubt that at Petralona in 1960 a virtually complete fossil skull was found adherent to the cave wall. Second, the cave is a Pleistocene cave containing an extinct fauna. Third, it does have a stratigraphy that is long and complex. Fourth, there are numerous supposed 'tools' made of bone, limestone, bauxite or quartz. The vast majority of these 'tools' cannot be proved to be artefacts — but some of the quartz tools are undoubtedly humanly worked. Lastly, the cave has clearly been closed for a long time but it is unlikely that any cave would remain closed for 500,000 yr as has been claimed.

This brings us face to face with the problem of dating. Most now agree that the initial estimate of 70,000 yr BP is too young and that on a variety of grounds a date in excess of 200,000 yr BP is more likely. The dating claimed by Poulianos of over 700,000 yr BP for the skull is very hard to accept on the evidence produced at this meeting. Perhaps the most impressive speakers on dating were M. Ikeya, the originator of ESR dating, and Dr Yokoyama. The consensus of their views would seem to be that 400,000 yr BP would be an appropriate date for Layer 11, the layer said by Poulianos to correlate with the deposits associated with the skull; but this stratigraphical correlation is difficult to prove over the distance involved in the cave. Various other claims relate to the occurrence of fire at one million years BP, the discovery of the true entrance to the cave used by Petralona man and the recovery of fragments of the Petralona man's postcranial skeleton from the 'Mausoleum' area. Of the latter claim, I can speak personally, having been allowed to examine, with several others, the supposed postcranial fragments. We agreed that there was no single identifiable fragment of this sample that was human. The remaining fragments were too small for either identification or attribution.

In anthropological terms, the quarrels that this site has provoked have all the makings of a Greek tragedy as harrowing and as long as the *Medea* of Euripedes performed so well for the delegates at the open-air theatre at the site. Indeed, the site and the situation now require a cool and informed assessment, perhaps by a commission under the chairmanship of Jan Jelinek, the newly elected President of the European Anthropological Association. Such a commission could consist of an internationally respected small group including a palaeontologist, a palaeolithic archaeologist, a palaeoanthropologist, a cave stratigrapher and a geochronologist. Their task could be to examine the bones, the tools, the cave and the claims made for them.

Make no mistake, however, Aris Poulianos and his son, Nickos Poulianos, are to be congratulated on the progress that they have made at the site, but they must also accept that today such a tremendous enterprise must be a team effort. No single researcher can encompass all the disciplines that the rigorous investigation of a site demands today, neither can one man have the time and resources to 'go it alone' successfully.

The view that emerged from the conference was quite clear in that the Petralona specimen is an extremely important skull, almost certainly of Middle Pleistocene age, and of critical importance in documenting the transition from the *Homo erectus* stage of human evolution to the *Homo sapiens* stage in Europe. We owe it to Petralona man, therefore, to gain from the skull and the site every scrap of evidence available to us by the use of modern methods and scientific cooperation. □

Mysteries of the ringed planets

from J. N. Cuzzi

THE colloquium* on planetary rings recently held at Toulouse was designed as a cross-disciplinary meeting of planetary scientists and astrophysicists that would discuss what is known about ring systems and evaluate theoretical understanding of flattened rotating systems in general. The observational material was, not surprisingly, spacecraft-dominated, but the contributions of ground-based observations have been, and will continue to be, of fundamental importance. Theoretical work comes predominantly from gravitational mechanics, and is now moving towards an understanding of collective effects via both fluid-mechanical and statistical-mechanical pathways. Studies of electromagnetic phenomena are also of great importance.

Voyager observations of Saturn's rings and accumulating data from stellar accultations by Uranus's rings provided most of the new observational material. Jupiter's faint ring, first suspected to exist after Pioneer 10 and 11 encounters in 1973 and 1974, was last closely examined by Voyager in 1979. The three known ring systems exhibit certain family resemblances, such as in their proximity to their parent planet and magnetospheric environment; Saturn and Uranus both possess narrow, eccentric rings with abrupt boundaries, and both Saturn and Jupiter possess broad diffuse low-capacity rings composed substantially of short-lived micrometre-sized particles. There are, however, important differences in the composition and sizes of the constituent particles. The rings of Jupiter and Uranus are composed of quite dark, distinctly non-icy material (Nicholson, Cornell University), whereas the bulk of Saturn's much more extensive rings is composed of water-ice. One reported observation of a ring around Neptune remains unconfirmed, there being uncertainty in the position of Neptune's pole (Elliot, MIT). New results on an even larger 'ring' — the asteroid belt — show it to consist of several distinct sub-rings with differing amounts of dry and water-bearing material (Tedesco, JPL).

One fascinating question is that of the relationship of planetary rings to associated 'moonlets', or objects of 1–100 km size. The observed close association and structural influence of such objects, observed for Saturn and inferred for Uranus, have important implications for the origins of the various rings and, perhaps, for the origin of the Solar System as a whole. The Saturn system is generously endowed with moonlets outside the rings. Charged particle data from Pioneer 11 (Van Allen, University of Iowa) and Voyager imaging data (Terrile, JPL) suggest that two of the larger moonlets, the satellites 1980S26 and 1980S27, which apparently confine or 'shepherd' the curiously kinked and stranded F ring, may be only the largest of many smaller moonlets lying in a broad band about 1,000 km wide. It is probably close encounters with some of these moonlets which kink and braid the F ring, but the details of the process are not fully understood either observationally or theoretically (Showalter, Cornell University).

So far no moonlets have been discovered within the main rings, despite careful searches of promising, but limited, regions by Voyager imaging. The presence of large numbers of 1–10 km-sized objects in the rings would clear gaps of comparable width, which seem to have been ruled out by stellar accultation measurements (Esposito, LASP). Furthermore, radio accultation measurements of ring-scattering properties (Marouf, Stanford University) show directly a fairly sharp upper-size cutoff at 5 m, with a broad, possibly power law-size, distribution extending down to about 1 cm. However, the rings may still contain mountain-sized chunks of matter in numbers far less than the upward extension of the power law would indicate. Several have recently been inferred to lie within the 320 km-wide Encke division. This practically empty region is known to contain a few discontinuous clumpy ringlets similar in appearance to the 'kinky' F ring, and gravitational effects by other hypothetical moonlets have been invoked by analogy. New analysis of Voyager images has also revealed azimuthal waves running along the inner and outer edges of the division in orderly patterns which may reflect recent passage by (still unseen) small moonlets (Cuzzin and Scargle, Ames). This is, of course, also indirect evidence but it has a firmer theoretical base. Confirmation of the existence of such moonlets in the rings would help decide between alternative theories of the origin of the rings.

It is becoming increasingly apparent that the large-scale structure of the rings (A, B, C and so on) is highly meaningful, independent of the detailed behaviour of fine internal structure discussed below. In studies of typical length scales from stellar occultation data, Esposito has found no scales preferred over noise with the possible exception of the very largest scales, and has suggested that the significant dynamical processes act on scales far larger than any discussed so far. Combinations of radio opacity (Tyler, Stanford University) and visible-wavelength opacity show that the particle size distribution is significantly different in the A and B rings from that in the optically thinner C ring and Cassini division; this is in addition to the already known regional differences in particle colour and brightness. Although little attention was given at the meeting to the various origin scenarios, R. Hart (Johns Hopkins University) drew attention to the formative role of the initial energy and momentum of the material, which might also have determined the overall distribution of matter in the planetary system. However, significant dissipative processes may have obscured initial conditions, and ongoing formative processes must be better understood before more detailed inferences as to origin may be drawn.

The question of the fine structure in the rings is yielding to study, but only slightly. The strongest gravitational resonances in the rings are readily identifiable with structure. The two strongest are responsible for the outer edges of the A and B rings, which are radially very sharp ($\leqslant$ 100m), and may be comparable in scale with the vertical height or ring thickness. The sharpness of these edges can be understood in terms of local resonant distortion of the particle rotation law from Keplerian, which may allow diffusive transport of angular momentum to vanish (Goldreich, CalTech).

Further detailed calculations (Borderies, CalTech) verify the amplitude of the distortion of the edge of the B ring as due to distortion of resonant streamlines by self-gravity. Weaker resonances produce Lin-Shu spiral waves of either density or vertical displacement at dozens of locations in regions of moderate optical depth, much as predicted by Goldreich and Tremaine several years before Voyager. Almost all the fine regular structure in the outer A ring is probably due to similar, but unresolved, features in excellent positional agreement with predicted resonances with 1980S26 and 1980S27, with the notable exception of the narrow gap near 2.26 Rs, now named Keeler by the IAU. Spiral waves enable the local mass density to be determined and their damping may be used with caution to measure the local viscosity (Lissauer, Berkeley), yielding an estimate of the local vertical scale height of tens of metres in the outer A ring. The question of ring scale height continues to generate controversy; however, a scale height of tens of metres, in a ring composed of centimetre-to-metre-sized particles, would satisfy the 'many-particle-thick' concept favoured by remote-sensing observations such as the opposition brightening (Irvine, University of Massachusetts), radar backscatter (Pettengill, MIT) and radio occultation (Marouf, Stanford University).

In the optically thinner C ring, strong resonances produce very different structure, for reasons not understood. Optically thick ringlets seem to form,

usually within or adjacent to fairly clear gaps. Both the ringlets and the gaps show intriguing and unexplained fine structure down to kilometre scale (Lane, JPL). Resonances with Jupiter in the optically even thinner asteroid belt appear to have acted primarily to clear the Kirkwood gaps, but only following the clearing of any massive primordial nebula (Murray, Cornell University). More detailed attempts to assign resonances to the many other features in the C and B rings have been less successful. The enormous number of features calls for comparison with much more numerous, but much weaker, resonances (Wiesel, USAF Institute of Technology). It has been argued alternatively that the uncounted, randomly distributed narrow features in, at least, the B ring may result from a local 'diffusion' or viscous instability, and not from resonances at all. However, early versions of this theory predicted more dramatic fluctuations than observed. Recent refinements have used theoretical understanding gained from dynamical studies of the evolution of particle disks, pioneered by Safronov and recently extended numerically by Brahic, Casanave (CNES) and Clairemidi (Besançon), and analytically by Hornung and Pellat (Ecole Polytechnique). Such results generally indicate different random velocities for particles of different sizes; a sort of 'thermal equilibrium' with the less massive particles being hotter. This refinement appears to smooth the instability-predicted optical depths into better agreement with the observations (Ward and Harris, JPL). However, the problem of the myriad ringlets appears to be a long way from solution.

The narrow eccentric ringlets of Uranus are being explored in increasing detail by occultation measurements in the near-IR where suitable stars are more plentiful and scattered light is limited by methane absorbtion in the planet's atmosphere. The information has made it possible to determine not only ring eccentricities but also inclinations of comparable amplitude. The eccentricities and inclinations both show a large systematic decrease with increasing distance from the planet, with the exception of the unusually broad and eccentric or outer ring (French, MIT). The observations are, in fact, accurate enough for satellite perturbations of Uranus itself from the system barycentre to be detectable, and direct detection of the influence on the rings of shepherding satellites (Tremaine, MIT), such as, perhaps, distortion of the type seen along the edges of the Encke division, should soon be possible. Certainly the many stellar occultations which will be obtained during Voyager 2 encounter will be extremely illuminating. It is becoming increasingly difficult to make confident assignments of the uranian rings themselves to any three-body resonances once thought appropriate (Aksnes, University of Trömso; Tremaine). Postulated shepherding moonlets could, however, be locked in nearby resonant orbits. Because most known narrow ringlets have nearly the maximum eccentricity allowed before orbits start to cross, and because collisions in the rings are common and dissipate angular momentum, postulated shepherding satellites must be nearby to maintain the eccentricity (Tremaine).

In an extensive discussion of gravitational torques and angular momentum transfer, Greenberg stressed the importance of damping processes, which are implicitly assumed in current shepherding formalisms, but which may require special attention in limiting cases of low optical depth or strong interactions. Goldreich also discussed the role of dissipation from the perspective of streamline distortion, and of the tendency of strong perturbations to modify the rotation law sufficiently to cause the normal outward flow of angular momentum to cease or even reverse. Further progress towards understanding the true 'efficiency' of strong resonances and gravitational torques in general may help us to understand at least one puzzle — why the close-in 'ringmoons' are not being hurled away from the rings by their own resonances.

The importance of electromagnetic effects is well established for Saturn's rings, and probably for Jupiter's ring as well. The activity of the 'spokes' in Saturn's rings has been shown to display the periodicity of Saturn's magnetic field, and maximum activity is more specifically associated with the anomalous magnetic longitude on the planet which is, for reasons unknown, also responsible for Saturn's own kilometre-wavelength radiation (Porco, CalTech). Although most spoke features rotate at the local orbital rate, certain sharp nearly radial edges seem to be more nearly co-rotating with the magnetic field (Terrille), perhaps implying ongoing formation. Theoretical work is sketchy but promising, generally focusing on instabilities in current loops running between the rings and the ionosphere (Goldreich), perhaps with subsequent development of propagating clouds of plasma which serve to levitate pre-existing dust grains away from particle surfaces (Morfill, Max-Planck Institut, Garching). Whether the mysterious static, or SED, discovered by the Voyager Planetary Radio Astronomy experiment is connected with the rings (Warwick, Radiophysics, Boulder) or planetary lighting (Burns, Cornell University) remains a subject of lively debate; further observational constraints on power spectrum and periodicity are being obtained (Zarka, Meudon), ground-based detection is being sought (LeCacheaux, Paris Observatory) and radio occultation results will eventually be capable of addressing the question of a gap at the proper location identified by one, but not both, Voyager stellar occultation experiments. Theoretical studies of electromagnetic effects on the behaviour of micrometre and smaller ring particles (Grün, M-P, Heidelberg; Mendis, UCSD) indicate that they have a significant role in the Jupiter ring, perhaps determining the morphology of its 30,000 km-thick 'halo', and probably also in the outer tenuous E, F and G rings of Saturn. The E ring is unlike its neighbours in colour and apparently consists largely of short-lived micrometre-sized particles. This broad ring is centred very close to the orbit of the 250 km-radium moon Enceladus, which itself shows unique surface evidence of recent geological activity, suggesting Enceladus provides the source of ring particles in some way (Johnson, Pang; JPL). The E and G rings are more vertically extended than the main rings, about 1,000 and 100 km respectively (Wassermann, Lowell; Grün, Pedersen), which may be due to electromagnetic effects. However, the problem of the behaviour of charged grains in all of these ring processes is complicated by the stochastic and fluctuating nature of grain charges, both in magnitude (Lafon, Meudon) and in sign (Meyer-Vernet, CNRS).

Many of the processes illustrated in existing ring systems may have been active during the formation of the planets. Safronov (Schmidt Institute) reviewed recent work on nebular evolution. The essence of the problem is transfer of angular momentum as the interstellar medium collapses to form a solar system. The role of viscosity is central; slightly different assumptions as to its source and nature producing qualitatively different results in evolution calculations. Controversy remains as to whether planets formed through such gradual accumulation of planetesimals in a viscous collisional disk or by gravitational instability of nebular gas and dust with subsequent loss of light components. Even electromagnetic effects may have had their day very early in the game. Safronov believes that the very existence of planetary rings, each 'frozen' within its parent planet's Roche zone, attests to the once-ubiquitous presence of a particulate protoplanetary disk.

In summary, although observational and theoretical progress is impressive, there are still many outstanding and intriguing problems. Connections between various ring systems are becoming more apparent. Theoretical studies initiated to understand observed phenomena are aiding basic research into the behaviour of protoplanetary disks. It became clear at the meeting that considerable progress both in theory and observation, could take place in the near future. Further in-depth analysis of Voyager data and a strong continuing programme of ground and orbit-based observations are necessary, and it is hoped that the time will soon again be ripe for further close observation by spacecraft. □

REVIEW ARTICLE

Molecular mechanisms of general anaesthesia

N. P. Franks* & **W. R. Lieb**[†]

* Biophysics Section, Blackett Laboratory, Imperial College of Science and Technology, Prince Consort Road, London SW7 2AZ, UK
† Department of Biophysics, King's College, 26–29 Drury Lane, London WC2B 5RL, UK

Important constraints on possible molecular mechanisms of general anaesthesia are derived from a quantitative reappraisal of data on the potency of general anaesthetics on whole animals. Despite their popularity, theories that invoke lipids as the prime target do not look at all promising, and available data point much more plausibly to a direct effect on particularly sensitive proteins. Structural changes of proteins on binding general anaesthetics are probably small but may be sufficient to perturb normal function; alternatively, anaesthetics may compete with an endogenous ligand. The phenomenon of pressure reversal of anaesthesia may simply be due to anaesthetics being squeezed away from their target sites.

MODERN surgery would be inconceivable without general anaesthetics. Yet, after more than a century of research, there are very few points of agreement about how and where they act. The extraordinary diversity of theories which have been proposed over the years is matched only by the diversity of molecules which can induce reversible loss of consciousness. Indeed, general anaesthetics form no single chemical class but include substances as dissimilar as xenon, chloroform and thiopentone. This apparent lack of specificity, together with the remarkable observation that general anaesthesia can be reversed by high pressure, poses a unique pharmacological problem.

Unfortunately, rather than converging to a solution, the field at present seems to be diverging along a number of mutually incompatible lines, with various groups becoming entrenched in the defence of particular theories. It therefore seems timely to review the field critically and examine which ideas, in the light of recent data, are really tenable. We hope to show that, despite the present lack of consensus, there are real grounds for optimism.

In this review, we will first discuss what inferences can be made about the molecular nature of the general anaesthetic site(s) from a quantitative consideration of data on the potency of general anaesthetics on whole animals. With this information in mind, we will then assess the relevance of the numerous studies on simple systems and discuss whether lipid or protein provides the most plausible molecular target for general anaesthetic action. (We will not review the literature on isolated nerve preparations, partly because few unifying themes have emerged but mainly because expert and extensive reviews[1-3] have recently appeared.)

Whole animals

The induction of general anaesthesia must involve a site or a number of sites in the brain. (This is in contrast to local anaesthesia, which results from the blockage of nerve pathways outside the brain.) Because it is not known where in the brain general anaesthetics exert their primary effect, potencies can only be determined using the whole animal. Various behavioural end points, reflecting complex central nervous system activity, have been used and give potencies which usually agree to within a factor of two. Potency is defined as the reciprocal of that concentration (ED_{50}) at which 50% of the animals are anaesthetized, and most quantitative work has rightly focused on the importance of obtaining and analysing accurate ED_{50} values.

Concentrating on anaesthetic end point data effectively means ignoring the large variety of side effects which different general anaesthetics produce and which are of crucial importance to the clinician. The assumption that side effects do not interfere with the anaesthetic end point is, of course, only an approximation; however, a quantitative interpretation of potency data is possible only if this simplifying assumption is made.

What property of the anaesthetic molecule accounts for its potency?

As early as the 1890s, it was known that the potency of an anaesthetic increased roughly in proportion to its partition coefficient (concentration ratio) between olive oil and water[4-6]. We have shown that an even better correlation is obtained using the slightly more polar solvent octanol, whereas very poor correlations are found with apolar alkane solvents[7]. Although there have been many attempts to correlate potency with various other physical properties of the anaesthetic molecule, none of them has been as complete or successful as the correlations with partition coefficients[1,8].

The attraction of these solubility correlations is that they provide a simple physical picture. Since a log–log plot of potency in the aqueous phase versus octanol/water partition coefficient has a unit slope[7], then, if the general anaesthetic site has solubility properties similar to octanol, all anaesthetic molecules would be equally potent at the site. One must be very careful, when comparing potencies, not to get confused between observed values and the potency at the site itself. For example, in air, ether is roughly five times more potent than cyclopropane[9], whereas in water it is about ten times less potent[7]; at an octanol-like site, however, both anaesthetics would be equally potent. It is not necessary to postulate that some anaesthetics are intrinsically more effective than others at the site, due, for example, to their relative abilities to break hydrogen bonds[10] or to their relative molecular volumes[11]. It is also worth pointing out here, while discussing potencies, that a common mistake is to compare[12-14] potencies in one phase (such as air) with partition coefficients between a solvent and another phase (such as water). The remarkable fact that anaesthetic potency can be predicted from such a simple parameter as the octanol/water partition coefficient not only shows that potency is essentially independent of the detailed size, shape and chemical nature of the anaesthetic molecule, but also strongly suggests that the site is amphiphilic, having both polar and apolar characteristics[7,15].

0028-0836/82/490487—07$01.00

Some drugs could not be considered in the above correlations because their potencies have not been determined. For example, it is very difficult to determine equilibrium potencies for intravenously administered anaesthetics, because of their complicated pharmacokinetics and the fact that (in contrast to inhalational anaesthetics) an effectively infinite reservoir of drug is not present. Other molecules are excluded for potentially more interesting reasons. As one ascends an homologous series, a point is reached beyond which higher members of the series are not anaesthetic—the so-called 'cutoff' effect[11]. The most obvious explanation for this finding is that the site has a finite size and simply excludes molecules which are too large. While this may reasonably account for decane and tetradecanol being inactive, it is not so immediately obvious why a saturated vapour of C_3F_8 does not anaesthetize mice[16], even after allowing for the much larger volumes of fluorinated compounds[17] compared with their hydrogenated counterparts. What all the 'cutoff' molecules do have in common are very low aqueous solubilities. Indeed, it has recently been suggested[18] that because of the low aqueous solubility, it is impossible, in principle, to deliver enough drug to the site, even at equilibrium. However, the final equilibrium concentration at the site must be independent of path; nonetheless, the time taken to reach equilibrium may be so long that, in practice, the drugs appear inactive. We feel that more work is needed before one can say for certain whether or not the observed 'cutoff' phenomena reflect fundamental properties of the general anaesthetic site.

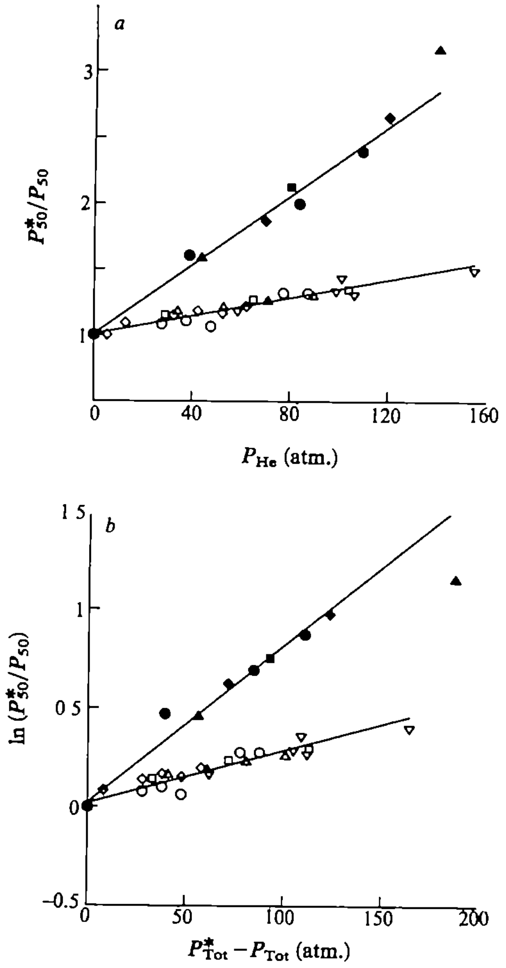

Fig. 1 Pressure reversal data for mice and newts interpreted according to *a*, the critical volume hypothesis[21] and *b*, a simple binding model. P^*_{50} and P_{50} are the anaesthetic partial pressures needed to anaesthetize 50% of a population of animals at total pressures P^*_{Tot} and P_{Tot}, respectively, and P_{He} is the partial pressure of helium used to increase the total pressure. Open symbols are for the mouse, and filled symbols are for the newt. The anaesthetic gases are: N_2O (○, ●); SF_6 (◇, ◆); Ar (▽), CF_4 (□, ■); and N_2 (△, ▲). The data were taken from refs 21 and 22. In *a*, the data are plotted according to the prediction[21] of the critical volume hypothesis $P^*_{50}/P_{50} = \text{constant} \cdot P_{He} + 1$, where the constant factor (the slope of the lines) depends upon the compressibility and molar volume of the site, the fractional volume expansion needed to induce anaesthesia, and the partial molar volume and mole fraction solubility of helium at the site. In *b*, the data are plotted according to the prediction of a simple binding model (see text), derived as follows: Let the equilibrium between concentrations of unoccupied site [S], free anaesthetic [A], and inactive complex [SA] be described by the equilibrium constant $K_{eq} = [SA]/([S][A])$. The thermodynamic relationship between K_{eq} and total pressure P_{Tot} is given[23] by $\partial(\ln K_{eq})/\partial P_{Tot} = -\Delta V/(RT)$, where R is the gas constant, T is the absolute temperature and ΔV is the increase in volume of the system when anaesthetic binds to the site. If we assume that anaesthesia occurs when the ratio [SA]/[S] of occupied to unoccupied sites reaches some critical value, then, by integrating the thermodynamic relationship and assuming ideal gas behaviour, we obtain the prediction that $\ln(P^*_{50}/P_{50}) = (\Delta V/RT) \cdot (P^*_{Tot} - P_{Tot})$.

How does potency vary with pressure?

Few pharmacologists would expect high pressure to be a particularly useful tool when trying to elucidate the mechanism of action of a drug. However, the intriguing observation[19,20] that general anaesthesia can be reversed by high pressures (of the order of 150 atmospheres) provides what might be an important clue as to how anaesthetics act. If pressure exerts its effect at the anaesthetic site, then, since pressure can only act by reducing volume, this implies that the total volume of site plus anaesthetic increases when they interact. Although such an increase in volume may be secondary to the anaesthetic mechanism, there are those[21] who postulate that it is the primary cause. The most self-consistent and best known of these volume expansion theories is the critical volume hypothesis: "Anesthesia occurs when the volume of a hydrophobic region is caused to expand beyond a certain critical amount by the absorption of molecules of an inert substance. If the volume of this hydrophobic region can be restored by changes of temperature or pressure then the anaesthesia will be removed"[8]. According to the theory[21], as the total pressure is raised, more anaesthetic is needed, simply to counteract the reduction in volume caused by pressure. Figure 1*a* shows that the quantitative predictions of the critical volume hypothesis are well satisfied using a range of gaseous anaesthetics, for both newts (filled symbols) and mice (open symbols). The slope can only be interpreted if certain unknown properties of the anaesthetic site are assumed; the different slopes for the two animals are said to be due to different site compressibilities and critical volumes[21,22].

The impressive agreement between the predictions of the critical volume hypothesis and the pressure reversal data for gaseous anaesthetics has been the main reason for its popular acceptance. However, such agreement is only a necessary but not a sufficient condition for the validity of the hypothesis, and other, more molecularly plausible, theories might fit the data equally well. Perhaps the simplest molecular model is one in which a single anaesthetic molecule binds to the site and inactivates it. This model can be quantitatively tested with the same data used to support the critical volume hypothesis. When this is done (see Fig. 1*b*), we find, remarkably, that this simple binding model accounts for the pressure reversal data as convincingly as the critical volume hypothesis (see Fig. 1*a*).

An advantage of this simple binding model over the critical volume hypothesis is that the slopes of the lines in Fig. 1*b* can be interpreted directly in terms of a single molecular parameter (ΔV), the average partial molar volume of the anaesthetic gases at the site. (Had the potencies been expressed in terms of aqueous concentrations, then ΔV would be the *difference* between the volumes at the site and in water.) We calculate $\Delta V \simeq 190\ \text{cm}^3\ \text{mol}^{-1}$ at the newt site and $\Delta V \simeq 65\ \text{cm}^3\ \text{mol}^{-1}$ at the mouse site. These values can be compared to an average partial molar volume of about $65\ \text{cm}^3\ \text{mol}^{-1}$ for these anaesthetics in a simple solvent such as benzene[21,22]. The larger value for the newt may indicate that, in addition to the expansion caused by simple solvation of the anaesthetic molecule, there is some additional volume increase due to a small change in the structure of the site itself. (If the site were a protein of weight 100,000 g mol^{-1} which undergoes a conformational change on binding[24], an expansion of only about 0.2% would be sufficient to account for the newt data.) Alternatively, the larger volume could be due to more than one anaesthetic molecule combining with the newt's site. For the mouse, on the other hand, the value of ΔV for these gases is about the same as their average partial molar volume in simple solvents and can thus be accounted for by simple solvation, with little or no additional volume change due to disruption of the site.

It is very often stated that pressure reversal cannot be due to simply squeezing the anaesthetic molecule away from its target site. Our above analysis shows that this simple notion *should not be dismissed.* Indeed, when one considers the mouse data in Fig. 1*b*, it is difficult to imagine any site—be it protein or lipid—in the mouse (or presumably in man) for which this would not be the major factor!

The appealing simplicity of the pressure reversal data with gaseous anaesthetics has not been matched by more recent results obtained using nongaseous anaesthetics injected into mice and rats. For these compounds, the decrease in potency with increasing pressure is usually greater[25] than that observed with the gases in Fig. 1, can vary significantly from drug to drug[26] and can even be nonlinear[26]. However, we feel that the experimental complications associated with the use of intravenous agents should not be underestimated, and perhaps these results would have been on a surer footing had they been obtained with animals (such as tadpoles) having simpler pharmacokinetics[25,27].

Finally, although it is possible to explain most of the pressure-reversal data by assuming that pressure and anaesthetics act at the same site, the possibility that they act at different sites must be seriously considered. For example, pressure reversal could be due to pressure causing a general increase in excitability, which counteracts a general decrease in excitability caused by anaesthetics[28,29].

How does potency vary with temperature?

Temperature is a much more familiar experimental variable than pressure, and the effects of temperature on anaesthetic potency have been measured for a number of animals. Nonetheless, the importance of these results has often been underestimated, due, we feel, to the fact that they do not agree with the predictions of most current theories of general anaesthesia.

In 1901, Hans Meyer[5] found that the aqueous potencies for tadpoles sometimes increased and sometimes decreased with temperature, depending upon the anaesthetic, but that these changes could be largely accounted for by corresponding changes in the oil/water partition coefficients. Later, Kurt Meyer and Hemmi[30] reached the same conclusion. More recent work with goldfish[12] showed that potencies expressed in terms of partial pressures decreased markedly with increasing temperature, in line with similar, but somewhat smaller, changes in oil/gas partition coefficients[31,32]. (It should be stressed that, although oil/water partition coefficients can either increase or decrease with rising temperature, oil/gas coefficients usually decrease[31].)

In agreement with the goldfish results[12], Eger and his colleagues[32–34] found that gas phase potencies for dogs also consistently decreased with increasing temperatures. An obvious problem when working with dogs, or indeed with any warm-blooded animal, is that deviations from the normal body temperature may well produce physiological effects which interfere with the anaesthetic endpoint. At extreme temperatures, this was clearly the case. Over a moderate temperature range, however, this did not appear to be a major complication. Not only were relative changes in potency quite different for different anaesthetics, but for the least soluble anaesthetic (cyclopropane) the change was minimal and could be almost entirely accounted for by changes in solubility. Furthermore, potency changed in the same manner both above and below the normal body temperature (see Fig. 2).

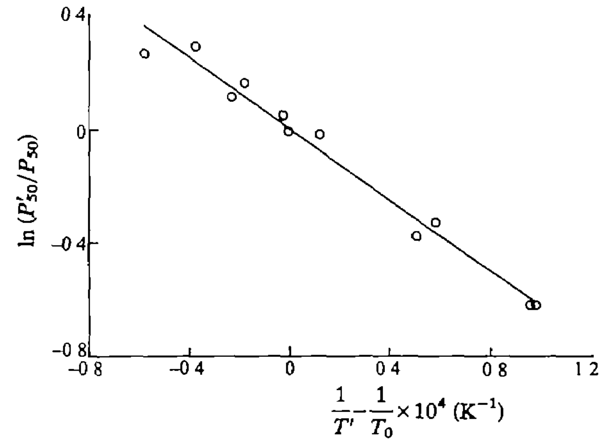

Fig. 2 The effect of temperature on the potency of halothane for dogs, interpreted according to a simple binding model. P'_{50} is the partial pressure of halothane needed to induce anaesthesia at a body temperature T', and P_{50} is the partial pressure at the normal body temperature $T_0 = 310$ K (37 °C). The data[32–34] are for dogs with body temperatures T' between about 28 and 43 °C. According to a simple binding model, in which a single anaesthetic molecule binds to the site and inactivates it, the equilibrium between concentrations of unoccupied site [S], free anaesthetic [A], and inactive complex [SA] can be described by the equilibrium constant $K_{eq} = [SA]/([S][A])$, which will vary with temperature according to[23] $\partial(\ln K_{eq})/\partial T = \Delta H/(RT^2)$, where ΔH is the enthalpy of binding, that is, $-\Delta H$ represents the heat released when anaesthetic binds to the site. If we assume that anaesthesia occurs when some constant fraction of sites are inactivated, then integration between T' and T_0 yields the prediction that $\ln(P'_{50}/P_{50}) = (\Delta H/R)\cdot(1/T' - 1/T_0)$. For these data, the slope of the line gives $\Delta H = -52$ kJ mol^{-1}.

The temperature results pose a serious problem for some popular theories (for example the critical volume hypothesis and lipid bilayer fluidity and phase transition theories), which predict that a rise in temperature should contribute positively to the anaesthetic end point. They can, however, be readily explained in terms of the simple binding model introduced in the previous section. This is shown quantitatively in Fig. 2, where we have plotted the most extensive set of published data (for halothane and dogs). From the slope of the line, we calculate that 52 kJ mol^{-1} of heat is released when halothane binds to the dog site from the gas phase. Heats of binding for various inhalational anaesthetics lie in the range 16 to 56 kJ mol^{-1} for the dog[32,33] and goldfish[12], with good agreement for a given anaesthetic. The heat released is comparable with, but consistently larger than, that released when binding to olive oil[31–33] and, although the values for oil are not particularly accurate, the difference is probably real. It might represent some interference with the anaesthetic end point by temperature itself or, more interestingly, it might reflect a genuine difference in binding, indicating that an anaesthetic is more tightly bound at the site than in a simple solvent. Whatever the precise details of the thermodynamics, it is clear that binding models quite naturally account for the consistent experimental observation that gas phase potency decreases with increasing temperature, because of the tendency of heat to drive the anaesthetic off the site into the gas phase.

Molecular models of the anaesthetic site

In a field in which there is so much controversy, it is perhaps comforting to find at least one point of almost universal agreement. Most workers feel that the *ultimate* effects of general anaesthetics are on proteins. The question is: do anaesthetics act directly on proteins, or do they act indirectly by first affecting membrane lipids? An attraction of the idea that membrane lipids may be the primary site is that anaesthetic potencies would be easy to account for[35], since both aqueous potencies[7] and lipid/water partition coefficients[36] correlate well with octanol/water partition coefficients.

Lipid bilayer fluidity. Soon after the introduction of magnetic resonance techniques to the study of membranes, it was shown[37] that anaesthetics could increase the fluidity of membranes and lipid bilayers. These results led to the popular theory that anaesthetics act by increasing the fluidity of membrane lipids, which, in turn, perturbs the normal functioning of some crucial membrane protein, such as a nerve channel. A large number of subsequent studies, using a variety of techniques, apparently lent support to this idea. In retrospect, however, it is clear that, almost invariably, very high concentrations of anaesthetics were used to obtain the observed increases in fluidity[7,38]. More recent work[7,38–41] has shown that, at clinically relevant concentrations, changes in lipid bilayer structure and fluidity are virtually undetectable. The few reports that fluidity is significantly altered at surgical concentrations are either contradictory[42,43] or else have been obtained at higher than the minimum alveolar concentrations[44].

Thus purely quantitative considerations argue against changes in bilayer fluidity being important. Nonetheless, it has been argued[45] that measurements at high concentrations, where clear effects are seen, are relevant and can be extrapolated back to clinical concentrations. This is a risky procedure, since it is extremely difficult to demonstrate linearity of response at low anaesthetic concentrations, where barely measurable effects occur. Interesting information can, however, sometimes be obtained. Such experiments have shown that high concentrations of anaesthetics can sometimes order and sometimes disorder, depending upon the anaesthetic and spin-probe used as well as on the composition of the lipid bilayer[18,45–47]. While this diversity of observed effects has been used[46] to argue against fluidizing theories, it has also, on the other hand, encouraged proponents of such theories to 'fine-tune' their systems so that consistent responses are observed with all anaesthetics. Following the latter philosophy, Miller and Pang[45] concluded that a suitable bilayer must contain at least 10% (molar) cholesterol and have a charge density of between 0.12 and 0.46 charges per phospholipid.

At surgical concentrations, however, fluidity increases in such bilayers (estimated by extrapolation) would be exceedingly small. Indeed, equivalent increases in fluidity occur in cholesterol-containing bilayers which have been warmed only a few tenths of a degree[41,48]. Needless to say, such small changes in temperature do not induce anaesthesia in whole animals.

$$\begin{array}{ccc} (a) & & (b) \\ \mathrm{E} \underset{}{\overset{K_1}{\rightleftharpoons}} \mathrm{E_I} & \begin{array}{c}\text{Thermal}\\ \text{inactivation}\end{array} & \mathrm{E} \overset{K_1}{\rightleftharpoons} \mathrm{E_I} \\ \mathrm{E_I} + n\mathrm{A} \overset{K_2}{\rightleftharpoons} \mathrm{E_I}n\mathrm{A} & \begin{array}{c}\text{Anaesthetic}\\ \text{binding}\end{array} & \mathrm{E} + n\mathrm{A} \overset{K_3}{\rightleftharpoons} \mathrm{E}n\mathrm{A} \end{array}$$

$$\text{where } K_1 = \frac{[\mathrm{E_I}]}{[\mathrm{E}]}, \qquad K_2 = \frac{[\mathrm{E_I}n\mathrm{A}]}{[\mathrm{E_I}][\mathrm{A}]^n} \quad \text{and} \quad K_3 = \frac{[\mathrm{E}n\mathrm{A}]}{[\mathrm{E}][\mathrm{A}]^n}$$

Fig. 3 Two alternative schemes to explain the inhibition of luciferase by inhalational anaesthetics. In both schemes, the active form (E) of the enzyme is in reversible thermal equilibrium with an inactive form ($\mathrm{E_I}$). The schemes differ only in regard to which of these forms the n anaesthetic molecules (A) are assumed to bind. In *a*, binding occurs only to the thermally denatured form[107], while in *b*, binding occurs to the active form of the enzyme. Both schemes fit the data[107] equally well and give reasonable values for the enthalpy increase ($\Delta H_1 = 320\ \mathrm{kJ\ mol^{-1}}$) and entropy increase ($\Delta S_1 = 1075\ \mathrm{J\ K^{-1}\ mol^{-1}}$) upon thermal denaturation, and they show that about one anaesthetic molecule ($n \sim 1$) binds to each luciferase molecule. Scheme *a* yields extremely large changes in enthalpy ($\Delta H_2 = -335$ to $-376\ \mathrm{kJ\ mol^{-1}}$) and entropy ($\Delta S_2 = -1{,}160$ to $-1{,}340\ \mathrm{J\ K^{-1}\ mol^{-1}}$) upon binding of the various anaesthetics from the gas phase. It is easy to show that $\Delta H_3 = \Delta H_1 + \Delta H_2$ and $\Delta S_3 = \Delta S_1 + \Delta S_2$, so that scheme *b* yields much smaller and more reasonable values ($\Delta H_3 = -15$ to $-56\ \mathrm{kJ\ mol^{-1}}$ and $\Delta S_3 = -85$ to $-265\ \mathrm{J\ K^{-1}\ mol^{-1}}$), consistent with simple binding.

Moreover, fluidization theories predict an increase in anaesthetic potency with rising temperature (since fluidity increases markedly with temperature), whereas, as we have seen above (Fig. 2), the reverse is observed experimentally. At first sight, one of the attractions of these theories is that pressure might reasonably be expected to counteract the fluidizing effect of anaesthetics, so that pressure reversal seems easy to explain. While qualitatively this prediction is supported by experimental observations, quantitatively the agreement is very poor. The fluidity increases at concentrations which cause general anaesthesia would be counteracted by about 25 atmospheres or less[39,49,50], whereas pressures of the order of 150 atmospheres are necessary to overcome anaesthesia in the whole animal. In summary, it seems to us most improbable that changes in lipid bilayer fluidity play any significant role in general anaesthesia.

Phase transitions in lipid bilayers. Another class of lipid theories supposes that certain bilayers in nerve membranes are poised near a chain-melting phase transition, and that anaesthetics induce a cooperative structural change. Most general anaesthetics do in fact significantly depress the temperature T_m of the gel to liquid crystalline phase transition in pure lipid systems at clinical concentrations[51–53]. However, the observed effects are equivalent to those produced by a temperature increase of less than a degree[51–53] and can be reversed by only a few tens of atmospheres of pressure[52,53]. Also, some anaesthetics (the higher alcohols) can actually increase[46,54,55] T_m. Thus these theories suffer from most of the shortcomings of the fluidization theories. An attempt has been made to 'fine-tune' phase transition theories, by introducing lipid mixtures which undergo lateral phase separation[56]. However, not only do difficulties with temperature remain, but two equally potent anaesthetics have been shown[18] to shift solid/fluid phase equilibria in opposite directions.

Finally, it should be remembered that there is little convincing evidence for the existence of significant regions of solid-phase lipids in mammalian membranes. Indeed, in view of the high concentrations of unsaturated hydrocarbon chains in these membranes and the high concentrations of cholesterol in nerve plasma membranes in particular, one would need a large measure of faith to remain convinced that the answer to general anaesthesia lies in the study of lipid phase transitions.

Changes in membrane dimensions. When anaesthetics partition into membranes, some geometrical changes are almost certain to occur. Early workers[57–59] found that clinical concentrations of general anaesthetics produce sizeable changes in the surface pressure of lipid monolayers held at a constant area at an air/water interface, and these correspond to smaller but still significant increases in area (of about 0.5%)[60] at constant pressure. More importantly, very similar increases have been observed in the area of intact red blood cell membranes[61].

The effect of anaesthetics on membrane thickness is much more controversial. Using X-ray and neutron diffraction, we could detect no significant change in the structure or thickness of lipid bilayers exposed to surgical concentrations of nitrous oxide, halothane or cyclopropane[7,38]. Haydon and his colleagues, on the other hand, showed that high concentrations of the lower alkanes cause significant decreases in the electrical capacitance of black lipid films[62] and squid axon membranes[63], which they reasonably interpreted as thickness increases. Alkanes have also been observed to increase bilayer thickness in multiwalled lipid vesicles[64]. A large increase in thickness (a capacitance decrease) was also reported to occur in solvent-containing black films exposed to benzyl alcohol[65]. However, this report now appears to have been misleading, since later workers[66–68] have shown that, when 'solvent-free' films are used, benzyl alcohol, octanol and chloroform actually increase the capacitance. While this might suggest that these agents decrease bilayer thickness, the observed increases in capacitance could be largely due to increases in dielectric constant[68]. Looking at all available results, on fluid lipid bilayers[7,38,40,66], 'solvent-free' black films[66–68], and myelin membranes[69], and extrapolating where necessary to low concentrations, we are forced to conclude that any changes in membrane thickness at general anaesthetic concentrations must be very small.

There has been considerable confusion about the size and importance of the volume changes that occur when anaesthetics enter membranes. On the basis of area expansion and mass density measurements[61,70,71], Seeman calculated that while lipid bilayers expand by only the van der Waals volumes of the occupying drug molecules, biological membranes expand by about 20 times this amount. We have recently reinvestigated this problem and find that, in fact, the volume expansion caused by a molecule of halothane is essentially the same in both red cell membranes and lipid bilayers, and little different from that in liquid halothane or water[72]. Kita *et al.*[73] have also measured these volumes for a number of different lipid bilayers and anaesthetics and found values close to those in the pure liquid anaesthetics but slightly greater than those in water. In terms of total membrane volume, both red cell membranes[72] and lipid bilayers[72,73] expand by only a few tenths of a per cent at clinical concentrations.

In summary, small increases in both area and volume have been detected at clinical concentrations of general anaesthetics, but whether or not changes in thickness occur is uncertain. An estimate of the thickness change can be made, since a small fractional change in volume must equal the sum of the fractional changes in area and thickness. For red cell membranes and halothane, the observed volume expansion[72] of about 0.1% and area expansion[61] of about 0.4% imply a thickness decrease of about 0.3% (less than 0.2 Å). The possibility of anisotropic changes in membrane dimensions of this sort has been discussed by others[21,74]. What is important, however, is that changes in membrane dimensions at clinical concentrations are very small indeed. (Comparable changes are produced by only slight increases in temperature: area[75], thickness[76] and volume[77] all change by $\geqslant 0.1\%$ per degree.) Thus we feel that changes in membrane dimensions do not provide a very plausible basis for theories of general anaesthesia.

Permeability changes in lipid bilayers. Probably the most promising line of argument for those who believe that anaesthetics act primarily on lipids would rest on the effects observed on bilayer permeability. Bangham and his co-workers[59,78,79] showed that the leakage of cations from lipid vesicles is markedly enhanced by general anaesthetics and that these changes can be reversed by high pressure. At clinical concentrations, these permeability increases can be as large as 20–50% for cations[80], but, interestingly, appear to be much smaller for anions[68] and non-electrolytes[68,79]. Although the permeability of lipid bilayers to inorganic cations is very small, and orders of magnitude less than that observed in biological membranes, similar effects of anaesthetics and pressure have been observed on the much larger cation fluxes found with ionophore-containing bilayers[78–80].

While these results are certainly tantalizing, it is not obvious that cation fluxes mediated by ionophores such as valinomycin and gramicidin A are appropriate models for ionic movements across natural membranes. Recent experimental results[81], however, suggest that proton permeabilities across pure lipid bilayers may be anomalously high, and Bangham and Mason[82] have proposed that anaesthetics act by affecting these proton movements. They suggest that anaesthetics act by collapsing *p*H gradients across catecholamine-containing synaptic vesicles. This in turn neutralizes the catecholamines (which had been charged in the acidic interior and thus effectively trapped[83]) and allows them to escape, thereby inhibiting synaptic transmission. Convincing experimental evidence in favour of this new and ingenious theory is still rather sparse, and whether or not lipid bilayers are highly permeable to protons is an extremely controversial point[84,85].

Proteins. At first sight, the idea that anaesthetics act directly on protein might seem improbable, since the well constrained structures of most proteins would not be expected to provide the sort of binding environment necessary to account for the simple correlation of anaesthetic potency with octanol solubility[7]. On the other hand, it might be argued that if the anaesthetic site were an integral membrane protein, its necessarily intimate association with membrane lipids might well provide an octanol-like environment at the protein/lipid interface. However, a major experimental problem which arises when working with integral membrane proteins is that it is difficult to disentangle effects on protein from those on the surrounding lipids. While negative results are meaningful, positive results can be difficult to interpret. To avoid these difficulties, we will focus our attention here on the evidence that has been obtained using simple, relatively pure protein systems, where the observed effects can be interpreted reasonably unambiguously in terms of direct protein/anaesthetic interactions.

Quantitative data on the binding of general anaesthetics to proteins are, unfortunately, not very extensive. However, certain anaesthetic alkanes[86,87] and alcohols[87] have been reported to bind to bovine serum albumin (BSA). In addition, Hansch and his colleagues have accumulated a large amount of data on the binding of small organic molecules (including some anaesthetics) to BSA[88] and haemoglobin[89] and have shown that the binding of a molecule can be simply correlated with its octanol/water partition coefficient; although not directly relevant to anaesthesia, these data do illustrate that a diverse range of molecules can bind to a protein in a manner relating to their solubilities in a simple organic solvent. Further, using what data[86–88] are available for the binding of anaesthetic molecules to BSA, we calculate that at concentrations which cause general anaesthesia there would be one or more anaesthetic molecules bound to each protein molecule.

In some cases, organic molecules apparently bind at the interfaces between protein subunits[89] or subunit-like domains[90]. For example, a number of molecules which bind strongly to haemoglobin do not bind measurably to myoglobin[89]. On the other hand, the small anaesthetics xenon, butane and pentane bind strongly to both haemoglobin and myoglobin[91], apparently in the well-defined pockets which have been identified crystallographically by Schoenborn[92]. β-Lactoglobulin[93] and adenylate kinase[94] are other examples of proteins which fortuitously bind anaesthetics in localized pockets. That such pockets will accept molecules only up to a certain size is illustrated by the alkane-binding site of β-lactoglobulin, which can accept two butane molecules equally well, two pentane molecules unequally well, but only one molecule of iodobutane[93]. Although all of these binding studies have been performed on proteins which are obviously not directly involved in general anaesthesia, they do illustrate that the solubility properties of the general anaesthetic site, including the 'cutoff' effect, could be quite plausibly mimicked by a protein.

Binding of an anaesthetic to a protein and inhibition of its function are, of course, two very different things. For example, when anaesthetics bind to haemoglobin, the resulting structural changes are very small[92,95] and the oxygen dissociation curve is unaffected[96]. In contrast to the paucity of data on the binding of anaesthetics to proteins, there is no shortage of reports of direct effects of anaesthetics on protein function. However, if these results are looked at critically, it is clear that in most cases they have little relevance to general anaesthesia: the effects that are or would be observed at clinical concentrations are either very small or undetectable, or else clear effects are seen with some anaesthetics but negligible or opposing effects are seen with others. This is true in most studies with soluble proteins, organized protein assemblies, and membrane proteins[96–102].

One class of proteins, however, which do appear to be particularly sensitive to general anaesthetics are the light-emitting luciferase enzymes. Work with whole cells[103–105] has shown inhibition at low anaesthetic concentrations and even, in some cases, pressure reversal. Although these results are seductive, molecular interpretation is difficult, and there have been too few studies using cell-free systems. A membrane-free preparation of bacterial luciferase has been shown to be inhibited by low concentrations of ether, which apparently competes with the binding of an aldehyde necessary for luminescence[106]. Using a cell-free extract from firefly tails, Ueda and Kamaya[107] showed that firefly luciferase is inhibited by surgical concentrations of halothane, methoxyflurane, chloroform, enflurane and fluroxene. They measured gas-phase potencies at different temperatures but, unfortunately, interpreted their results in terms of a scheme (Fig. 3*a*) inherited from earlier workers[103], in which anaesthetics could only interact with a thermally inactivated form of the enzyme. This scheme gave extremely large decreases in enthalpy and entropy on binding, from which they concluded (we think erroneously) that anaesthetics cause a major conformational change when they bind to luciferase.

However, the luciferase data[107] can be interpreted much more reasonably in terms of a simple binding model (Fig. 3*b*) similar to that introduced in previous sections, in which the anaesthetic binds to the active enzyme and inhibits it. We find that, not only are the enthalpy and entropy changes modest and easy to account for by simple binding (comparable enthalpy changes are observed when these anaesthetics partition from the gas phase into oil[31–33]), but the heats of binding are now similar in magnitude to, and of the same sign as, those found when applying the model to whole animal data. In other words, the temperature dependence of anaesthetic potency in whole animals can easily be accounted for in terms of anaesthetics binding to protein.

Thus, although the data on anaesthetic interactions with proteins are rather sparse compared with those available for lipids, examples of proteins can be found which satisfy most of the properties required of a successful molecular model of the general anaesthetic site.

Conclusions

There are many who would argue that it is premature to search for the molecular mechanisms underlying general anaesthesia. Nonetheless, when one focuses on quantitative data on anaesthetic potencies for whole animals and considers how these potencies vary with pressure and temperature, certain clear trends emerge, which do provide important information on the molecular interactions involved and impose severe constraints on the molecular nature of the target site. For the relatively inert anaesthetics, for which unambiguous potency data exist, these trends are surprisingly simple. In contrast, complications arise with the intravenous agents. While this may indicate that some anaesthetics act differently from others, it may only reflect the more complex pharmacokinetics of these compounds.

Using the constraints imposed by the whole animal potency data, we have assessed the relevance of simple lipid and protein model systems. Despite the vast literature on anaesthetic/lipid interactions, those theories which postulate that anaesthetics exert their primary effects on lipids do not look at all promising, although changes in lipid bilayer permeability remain a possible candidate. In most cases, the results obtained with proteins look equally unpromising; nevertheless, some proteins do exist which are sensitive to surgical levels of general anaesthetics and are inhibited at anaesthetic concentrations which not only correlate well with whole animal potencies, but also show analogous dependencies upon pressure and temperature. Taken as a whole, the data available point much more plausibly to protein rather than lipid as the primary site of action.

We feel that the simplest working hypothesis, best supported by available data, is that general anaesthetics act by binding directly to a particularly sensitive protein (which may or may not be membrane-bound) and inhibiting its normal function. The fact that potencies correlate with octanol, but not hydrocarbon, partition coefficients suggests that the binding site on the protein is amphiphilic. The anaesthetic could inhibit either by interfering directly with catalytic or transport activity (for example by disrupting subunit–subunit contacts) or by competing for the binding of some endogenous ligand (such as a neurotransmitter). In either case, the structural perturbations which occur on binding are probably small, since the volume and enthalpy changes, derived from the effects of pressure and temperature, are modest. Contrary to popular belief, pressure reversal may well be due to pressure simply 'squeezing' the anaesthetic molecules away from their target sites, while the decrease in gas-phase potency with increasing temperature may similarly be due to heat driving the anaesthetic off these sites.

We thank Dr C. D. Richards for helpful comments and the MRC and the British Oxygen Corporation for support.

ARTICLES

Sr isotopes in interstitial waters of marine sediments from Deep Sea Drilling Project cores

H. Elderfield[*†] **& J. M. Gieskes**[*‡]

* Department of Earth Sciences, University of Leeds, Leeds LS2 9JT, UK
‡ Scripps Institution of Oceanography, University of California San Diego, La Jolla, 92093, USA

Sr isotopic compositions of interstitial sea waters have been documented in detail with cores from 37 Deep Sea Drilling Project sites. The ^{87}Sr/^{86}Sr ratios are sensitive indicators of diagenetic reactions involving alteration of volcanic matter dispersed in sediments and recrystallization of carbonates. Effects of basalt alteration reactions, except possibly for hydrothermal signals, and of alteration of continental debris are minimal. Carbonate recrystallization has a significant effect on the geochemical mass balance of Sr but diffusion of unradiogenic strontium from interstitial waters has only a small effect on the ^{87}Sr/^{86}Sr ratio of ocean water.

IN the study of geochemical cycles much recent attention has been given to evaluating differences in the isotopic compositions of the various geochemical reservoirs. ^{87}Sr/^{86}Sr ratios of marine deposits have been reported extensively and have proven to yield useful isotopic indicators of the provenance of marine sediments[1], the involvement of seawater in the geochemistry of hydrothermal sediments[2], in basalt alteration[3] and in mineral formation[4]. In particular, ^{87}Sr/^{86}Sr ratios have been used to evaluate the carbonate record of seawater evolution through time[5–7].

Less attention has been given to measuring the ^{87}Sr/^{86}Sr ratio of sea waters. Because the current oceanic residence time of Sr ($\sim 10^6$ yr) is much longer than the mixing time of the oceans ($\sim 10^3$ yr) it has been generally assumed that the Sr isotopic composition of seawater is the same everywhere[7]. The value for modern ocean water is close to 0.7092.

However, there are two areas in the marine realm where considerable variability in the dissolved ^{87}Sr/^{86}Sr ratio can and does occur. One is in seawater hydrothermal systems[8,9]. The other is in the interstitial waters of marine sediments[10,11]. Sea waters buried with sediments are subject to major compositional changes because they reflect the diagenetic evolution of the sediments and alteration reactions in underlying basalts[12,13]. Earlier measurements[11] of profiles of the Sr isotopic composition of the interstitial waters at two Deep Sea Drilling Project (DSDP) sites showed decreases in ^{87}Sr/^{86}Sr ratio with burial

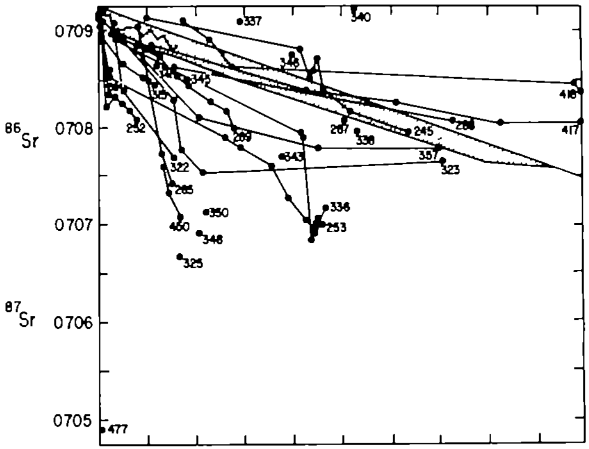

Fig. 1 Plots of ^{87}Sr/^{86}Sr ratios of DSDP interstitial waters versus the age of the sediment sections from which they were extracted. Numbers refer to DSDP sites (Table 1) and the shaded area shows the inferred variation of the ^{87}Sr/^{86}Sr ratio of sea water with time and is defined by: (upper) the linear equation of Hawkesworth and Elderfield[11] and (lower) the fourth order polynomial of Hart and Staudigel[14], the solid line for 0–16 Myr is from ref. 18.

---

depth down to ~0.7069. That study prompted a comprehensive programme of measurement of $^{87}Sr/^{86}Sr$ ratios in interstitial waters based on samples from, to date, 37 DSDP sites (Table 1) covering the major oceans and a wide range of sedimentary types. Here we summarize the results, the chief generalizations and the inferences which may be made from the whole data set in terms of processes affecting $^{87}Sr/^{86}Sr$ ratios, temporal changes, and the geochemical mass balance of Sr isotopes in the oceans.

$^{87}Sr/^{86}Sr$ ratios

The Sr isotopic compositions, summarized in Table 1, are plotted in Fig. 1 as a function of the age of the sediment sections from which the interstitial waters were recovered. Examples of the depth profiles are shown in Fig. 2.

Overall, the ratios range from 0.70920 to 0.70904 within 10 m of the sediment surface, values similar to those of contemporaneous sea waters, to a minimum value of 0.70490 in the deepest sample (173 m) obtained from Site 477 in the Gulf of California. With few exceptions the general trend of the data is for $^{87}Sr/^{86}Sr$ ratios to decrease from modern-day values as a function of burial depth and age. However, this decrease does not reflect the changing Sr isotopic compositions of seawater[11,14] because most of the interstitial water values are less radiogenic than contemporaneous sea waters. Such differences cannot be explained purely in terms of diffusive mixing of Sr isotopes within profiles because in many cases the inferred 'age' of the deepest interstitial water sample (using the seawater versus time curve) is greater than the age of the oceanic crust at that site. Even in situations where the age curve for the interstitial waters approximates to that for contemporaneous seawater (for example, Site 245) the Sr isotopic profiles cannot reflect burial of sea waters and no reaction because Sr^{2+} is enriched in the interstitial waters (Fig. 2). Therefore, the Sr isotopic data must reflect geochemical reactions affecting the compositions of the interstitial waters.

Sources of strontium

The $^{87}Sr/^{86}Sr$ ratios in potential source materials responsible for the Sr^{2+} enrichment and isotopic compositions of the interstitial waters are[11]: (1) continental detritus: $^{87}Sr/^{86}Sr \sim 0.716$; (2) biogenic carbonates: $^{87}Sr/^{86}Sr = 0.7092$ to 0.7075 over 0 to 100 Myr, that is the range for contemporaneous seawaters; (3) volcanic materials (basalts and volcanic ash and glass): $^{87}Sr/^{86}Sr = 0.7027$ to ~0.705, the low values for fresh basalts and the high values for materials previously altered by reaction with seawater.

None of the more than 160 interstitial waters analysed have $^{87}Sr/^{86}Sr$ ratios which are significantly higher than the ratio for modern seawater, and few samples have ratios which are more radiogenic than contemporaneous sea waters. This rules out continental detritus as a dominant source of the interstitial Sr^{2+} anomalies at most sites. In contrast, the low $^{87}Sr/^{86}Sr$ ratios of many samples relative to the seawater curve (Fig. 1) show that reactions involving the alteration of volcanic materials must have a major role at many sites.

Geochemical reactions

The chemical and isotopic compositions of the interstitial waters at each site give integrated signals of the combination of diagenetic reactions which, in turn, reflect the mixed lithologies and multiple origins of the sediments. In addition diffusion processes through the interstitial water column will tend to smooth out concentration gradients. Nevertheless, it is possible to identify sites where particular geochemical reactions are dominant.

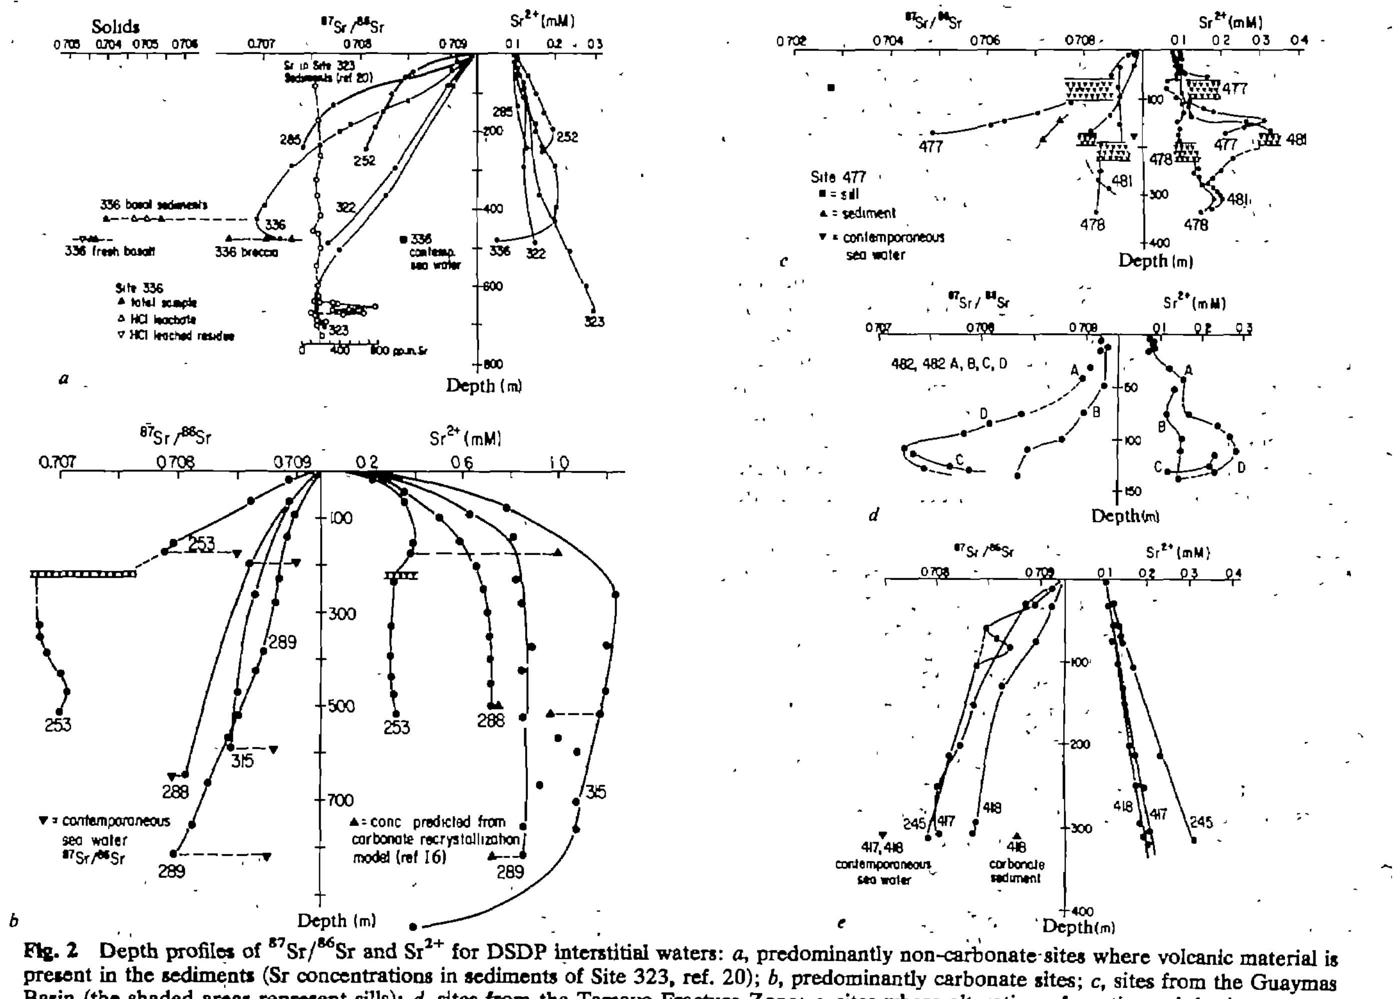

Fig. 2 Depth profiles of $^{87}Sr/^{86}Sr$ and Sr^{2+} for DSDP interstitial waters: *a*, predominantly non-carbonate sites where volcanic material is present in the sediments (Sr concentrations in sediments of Site 323, ref. 20); *b*, predominantly carbonate sites; *c*, sites from the Guaymas Basin (the shaded areas represent sills); *d*, sites from the Tamayo Fracture Zone; *e*, sites where alteration of continental detritus may be occurring.

We now wish to identify the principal types of reaction that can be inferred from the ^{87}Sr/^{86}Sr results when considered alongside the Sr^{2+} and other interstitial water data and the locations and lithologies of the sites.

Alteration of volcanic matter: A major feature reflected in Fig. 1 is that in many sites the ^{87}Sr/^{86}Sr ratios of dissolved strontium are much less radiogenic than those of contemporaneous sea waters. The cause of this phenomenon must be sought in substantial contributions to the dissolved strontium pool by reactions involving volcanic matter.

Figure 2*a* shows profiles from non-carbonate sites containing volcanic matter throughout the sediment column[11,15,16]. Relatively small enrichments of Sr^{2+} in the interstitial waters are accompanied by large decreases in ^{87}Sr/^{86}Sr ratios with depth. At Site 323, the moderate enrichment of Sr^{2+} with depth, ~0.2 mM over ~700 m, was modelled by McDuff and Gieskes[17] in terms of conservative mixing of Sr^{2+} produced from a localized deep source, assumed to be a zone of Danian nanno-chalk and surrounding Sr-rich claystones. The minimum at ~650 m in the Sr isotopic profile defines the deep source as this Sr-rich zone and gives a ^{87}Sr/^{86}Sr ratio of ~0.7075, slightly lower than that for 65-Myr old seawater. The dissolved strontium source, therefore, appears to be derived chiefly from carbonate recrystallization with a small contribution from volcanics. At Site 336, the major Sr^{2+} source is also near-basal sediments. These sediments contain volcanic glass and ash layers are quite common. Comparison of the sediments and associated interstitial waters shows that they are not in Sr isotopic equilibrium.

In all sites presented in Fig. 2*a* it is apparent that at all depths large deviations occur in the ^{87}Sr/^{86}Sr ratio when compared with contemporaneous seawater (see also Fig. 1). The implication of this is that during alteration of volcanic material dispersed in the sediment column extensive exchange of strontium isotope occurs, without a concomitant large effect on the dissolved Sr^{2+} distribution.

The important question arises whether alteration of basalts of Layer 2 of the oceanic crust also contributes to the Sr^{2+} and ^{87}Sr/^{86}Sr signals. Such alteration reactions are held responsible for the often observed large increase in Ca^{2+} and decreases in Mg^{2+}, K^{+} and ^{18}O in the overlying interstitial waters[12,13]. Evidence from dissolved Sr^{2+} profiles (see Fig. 2*a*) indicates reversals in the ^{87}Sr/^{86}Sr and Sr^{2+} gradients where near basement was sampled. Results from the base of Site 336 show that Sr isotopic equilibration of the interstitial water and a basaltic breccia zone has occurred whereby the altered rocks have been severely contaminated by seawater Sr. From the Sr contents and ^{87}Sr/^{86}Sr ratios it seems that the alteration occurred with an effective water–rock ratio of about 20. Thus, although the hydrolysis reaction imparts a Sr isotopic signal to the interstitial water, the resulting ^{87}Sr/^{86}Sr ratios are not strikingly unradiogenic because of the water-dominated exchange reaction. We surmise that no clear basement signal in ^{87}Sr/^{86}Sr is observed as a result of high water–rock ratios, and that the major process leading to the low ^{87}Sr/^{86}Sr ratios in interstitial waters is the alteration of volcanic matter dispersed in the sediment column. This, of course, makes this isotopic ratio particularly useful in studies of sediment diagenesis.

Carbonate recrystallization: Although a volcanic Sr signal is undoubtedly present in many of the profiles, the isotopic data cannot be explained simply in terms of the input of strontium to the interstitial waters by dissolution from an unradiogenic source. This is because the profiles which show the least extreme ^{87}Sr/^{86}Sr gradients show the greatest Sr^{2+} enrichments and vice versa (Fig. 2*b*). The sites showing large Sr^{2+} enrichments (for example, Sites 315, 289, 288, 253) are all carbonate sites. In these sites, interstitial Sr^{2+} concentrations increase to a concentration maximum, up to over 10 times normal seawater levels (Fig. 2*b*) and the ratios of Sr^{2+} and Ca^{2+} concentrations, in excess of those of seawater (that is $>7\times10^{-3}$) are larger than Sr/Ca in basalts, clays and biogenic carbonate ($\sim2\times10^{-3}$). These enrichments are caused by the release of Sr^{2+} during diagenetic recrystallization of inorganic calcite producing Sr-depleted chalks and limestones[18,19,22]. In such cases the interstitial ^{87}Sr/^{86}Sr ratios will remain close to contemporaneous seawater values provided that active recrystallization is occurring so as to minimize the effect of diffusion.

Site 253 indicates a case where a strong volcanic signal is superimposed on the profile expected from pure carbonate recrystallization. Sedimentation rates in the upper 150 m have been relatively low (~4 m Myr^{-1}) and the volcanic sediments below the basaltic sill at 150 m serve as a sink for Sr^{2+} as well as a source of low radiogenic strontium.

Hydrothermal activity: A thermally induced signal in ^{87}Sr/^{86}Sr has been observed in the interstitial waters at sites in regions of high heat flow on young oceanic crust (Fig. 2*c*, *d*). At site 477, located on a large heat flow anomaly (≥20 heat-flow units (h.f.u.)) in the southern rift of the Guaymas Basin, Gulf of California, where the bottom-hole temperature is thought to have exceeded 200 °C there is an extremely strong negative ^{87}Sr/^{86}Sr depth gradient in the interstitial waters down to 0.7049, similar to values for basalt-Sr. The low ^{87}Sr/^{86}Sr ratios are associated with excess ^{3}He values reflecting hydrothermal processes involving basement rocks[21]. At Site 481, in the northern rift of the basin (~4 h.f.u.) the hydrothermal activity must have been associated with the intrusion of a dolerite sill complex which heated the surrounding sediments to as high as ~165 °C (ref. 23) and has now cooled to 45 °C.

Though it is tempting to suggest that the low ^{87}Sr/^{86}Sr ratios in these sites are due to hydrothermal alteration of basalts, it is equally possible that alteration of volcanic debris has caused the ^{87}Sr/^{86}Sr decreases near the sills. This is demonstrated well in Site 482 in the Tamayo Fracture Zone[24], where the high heat flow (12 h.f.u.) has apparently accelerated the rate of alteration of volcanic matter in the sediments producing

Table 1 Summary of Sr isotopic compositions

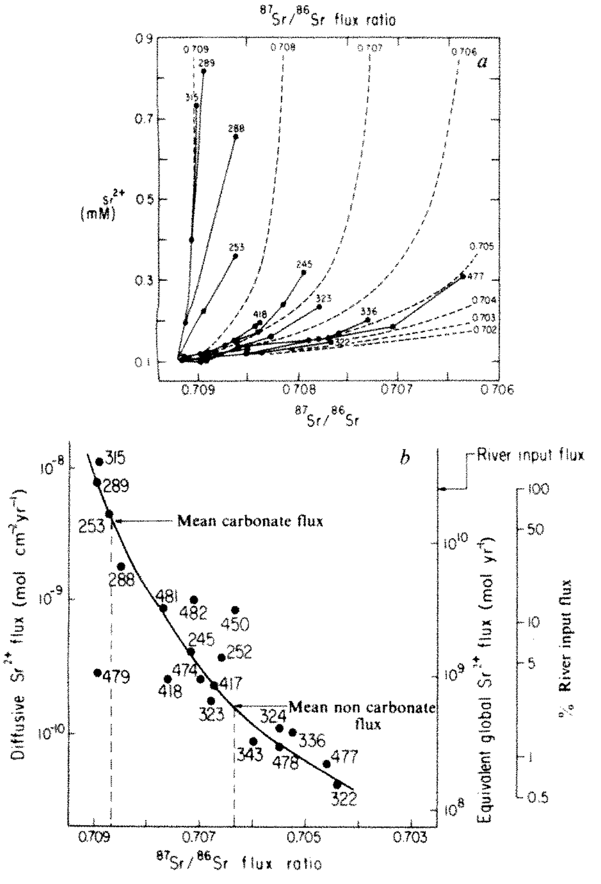

Fig. 3 *a*, Plots of Sr^{2+} against $^{87}Sr/^{86}Sr$ for uppermost sections of interstitial water profiles. Numbers refer to DSDP sites and the curves labelled with $^{87}Sr/^{86}Sr$ ratios are the ratios of fluxes of ^{87}Sr to ^{86}Sr, calculated from: flux (^{87}Sr)/flux (^{86}Sr) = $D(\Delta^{87}Sr/\Delta \text{ depth})/D(\Delta^{86}Sr/\Delta \text{ depth})$, where D is diffusion coefficient. *b*, Diffusive Sr^{2+} flux against $^{87}Sr/^{86}Sr$ flux ratio. Sr^{2+} flux calculated from: $D\Delta Sr^{2+}/\Delta$ depth where $D = 2\times10^{-6}$ cm^2 s^{-1} (ref. 27); flux ratio calculated as above. Numbers refer to DSDP sites. Also shown are average carbonate and non-carbonate fluxes (see text) and river input flux[7]. The equivalent global flux is obtained using the oceanic area of 361×10^{16} cm^2.

pronounced extrema in $^{87}Sr/^{86}Sr$ and dissolved strontium. The isotopic signal is stronger in Holes 482C and D where the thermal influence is thought to have been greater than in Holes 482A and B and, overall, the isotopic changes occur at shallower depths and during earlier diagenesis than at the sites shown in Fig. 2*a* where high temperatures were not experienced. Such $^{87}Sr/^{86}Sr$ changes appear to be associated with temperature-dependent silicification reactions involving the alteration of volcanic matter in the sediments and the diagenesis of opaline silica giving rise to 'diagenetic fronts' in the sediments at depths which relate to the thermal influence at each site[24–26].

Diagenesis of continental debris: Rarely do the $^{87}Sr/^{86}Sr$ profiles show evidence of reaction which may be attributed to material of continental origin having radiogenic Sr isotopic compositions. At Site 245 (Fig. 2*e*) the interstitial waters at ~75 m are distinctly more radiogenic than contemporaneous seawater which may indicate exchange reactions involving continental debris. At Sites 417 and 418 the $^{87}Sr/^{86}Sr$ ratios of the interstitial waters are everywhere significantly higher than for contemporaneous seawaters (Fig. 2*e*) and persist to close to basement into a narrow zone of impure Cretaceous carbonates contaminated with continental detritus which appears to be the main Sr^{2+} source. However, these sites are characterized by very slow sediment accumulation rates (~3 m Myr^{-1}) and diffusive communication with the overlying ocean will exist throughout the pore water profiles. Thus, the high $^{87}Sr/^{86}Sr$ ratios may reflect diffusive mixing of Sr-isotopes. Similar arguments could made for Sites 337 and 340 (Fig. 1). Therefore, no sites yet studied show unequivocal evidence of a Sr-isotopic signal reflecting diagenesis of continental debris.

The above discussion reveals that the major processes affecting the $^{87}Sr/^{86}Sr$ distribution in interstitial waters of deep sea sediments are the alteration of volcanic matter dispersed in the sediments and the recrystallization of carbonates. Even in drill sites consisting almost of pure carbonate sediments a volcanic signal is often superimposed on that expected from carbonate recrystallization processes. Effects of alteration reactions involving basalts of Layer 2, with the possible exception of hydrothermal signals, and of the alteration of continental debris are minimal.

Geochemical mass balance

One of the major aims of the DSDP interstitial water programme has been to evaluate the exchange of chemicals between the oceans and the sediments and basalts of oceanic crust. It has been shown that the diffusive fluxes of the major constituents Ca^{2+}, Mg^{2+} and K^+, as deduced from interstitial waters concentration gradients, do not have a significant role in the geochemical mass balance of the oceans whereas the oxygen isotopic flux may be of importance[12,13].

The Sr^{2+} concentration gradients shown in Fig. 2 are about 0.5–1.0 mM per 100 m for carbonate sites and about 0.02–0.03 mM per 100 m for non-carbonate sites where volcanic matter is undergoing alteration. With an average diffusion coefficient of 2×10^{-6} cm^2 s^{-1} (ref. 27), and neglecting advection, the values are equivalent to integrated global fluxes of the order of $1\text{–}2\times10^{10}$ mol yr^{-1} for carbonate sites and $5\text{–}7\times10^{8}$ mol yr^{-1} for non-carbonate sites, as compared with the river input flux of 2.5×10^{10} mol yr^{-1} (Fig. 3*b*). Assuming that carbonate sediments occupy 25% of the sea floor one calculates an average Sr flux from carbonate sites of ~20% of the river flux. The flux from non-carbonate sites is trivial, globally ~2% of river input.

The effect of these interstitial Sr^{2+} fluxes on the Sr isotopic balance of the oceans is small. This is because the largest interstitial Sr^{2+} gradients (and, hence, the largest fluxes) are associated with smallest $^{87}Sr/^{86}Sr$ depth gradients and vice versa. A combination of Sr^{2+} and $^{87}Sr/^{86}Sr$ data allows the diffusive flux ratios of ^{87}Sr to ^{86}Sr to be defined using the ratios of their concentration gradients versus depth (Fig. 3). Figure 3*b* shows a very consistent pattern for nearly all sites with high values of the $^{87}Sr/^{86}Sr$ flux ratio associated with high Sr^{2+} fluxes and low values of the isotopic flux ratio associated with low total fluxes. The large average Sr^{2+} flux from carbonate sites has an average $^{87}Sr/^{86}Sr$ ratio of ~0.7087, close to the modern seawater ratio as compared with non-carbonate sites which have an average $^{87}Sr/^{86}Sr$ ratio of ~0.7064. However, the latter have a lesser effect on the oceanic Sr isotope budget because the associated Sr^{2+} flux is an order of magnitude smaller. Overall, the effect is small and of minor significance in the oceanic budget of Sr-isotopes[8,9]. This evaluation does not, of course, include the transport by advection of interstitial waters with anomalous $^{87}Sr/^{86}Sr$ ratios. It has been suggested[8,9] that the flux of hydrothermal fluids supplied to the ocean by advection plays a significant role in fixing the $^{87}Sr/^{86}Sr$ ratio of seawater. The advection of interstitial waters with low $^{87}Sr/^{86}Sr$ ratios because of the influence on hydrothermal processes would add to this flux.

Oxygen isotope evidence for shallow emplacement of Adirondack anorthosite

J. W. Valley

Oxygen isotopic analysis of wollastonites from the Willsboro Mine, Adirondack Mountains, New York reveals a 400-ft wide zone of ^{18}O depletion at anorthosite contacts. Values of $\delta^{18}O$ vary more sharply with distance and are lower (to −1.3) than any yet reported for a granulite facies terrain. Exchange with circulating hot meteoric water best explains these results and implies that the anorthosite was emplaced at relatively shallow depths, <10 km, in marked contrast to the depth of granulite facies metamorphism (23 km). These ^{18}O depletions offer the first strong evidence for shallow emplacement of anorthosite within the Grenville Province and suggest that regional metamorphism was a later and tectonically distinct event.

MASSIF-TYPE anorthosite is an important rock type in the Grenville Province and in many other deeply eroded Precambrian terrains of US–Canada. Most of these bodies were metamorphosed in granulite facies conditions that imply burial depths of 20–30 km (refs 1–3). This observation is commonly used as evidence that anorthosite selectively intrudes and solidifies in the lower crust and thus may be a major constituent of a mafic layer below the Conrad seismic discontinuity.

In the Adirondack Mountains, New York and elsewhere petrological evidence has been used to suggest that anorthosite intruded at shallow depths before deep burial and metamorphism. Buddington[4] interpreted the borders of the Adirondack Massif as a chill margin with massive contact skarns and therefore proposed that it intruded shallowly into comparatively cool country rocks. The presence of wollastonite, an index mineral of the sanidinite facies[5,6], supported this view[7]. However, wollastonite has now been recognized in many amphibolite and granulite facies terrains[2,8–11] indicating that the classical assumption that $P_{\text{lithostatic}} = P_{CO_2}$ is not valid for the metamorphism of all marbles[2,11,12]. Thus the petrological evidence is ambiguous, permitting either shallow or deep intrusion[13–15].

We have studied the C–O–H stable isotope geochemistry and phase equilibria of contact skarns in the Adirondacks. While phase equilibria are inconclusive as to depths of emplacement, oxygen isotope studies at the Willsboro Mine, a massive skarn, provide new data that bear on this important problem.

The Willsboro Mine

The Willsboro Mine, an important source of wollastonite since 1940, is located in a 0.25-km thick skarn belt at the contact of the Port Kent–Westport unit of the main Adirondack anorthosite massif. This skarn belt extends over 7 km in the Willsboro quadrangle and may continue an additional 8 km into the Au Sable quadrangle, connecting two other wollastonite deposits at Deerhead and Lewis, New York. The anorthosite forms a structural trough in the region of this belt and shows evidence of extensive magmatic assimilation of metasediment, including common xenoliths of marble and evolved anorthosite compositions[4,16]. Similar features are found on mountain tops in adjacent quadrangles, indicating that originally overlying metasediments were engulfed in the roof zone of the anorthosite body.

The wollastonite ore-rock is distinctively similar throughout these three deposits, consisting of parallel layers of three coarse grained minerals: wollastonite, clinopyroxene, and grandite garnet. Compositional variation is limited and of major-element solid solutions, only Fe/Mg and Fe/Al vary among the pyroxenes and garnets of different layers. At Willsboro two major and many minor layers of ore-rock dip 30–55° NNE with anorthosite forming the footwall of the deposit. Surrounding and between these layers of ore-rock are layers of mixed gneisses including mafic gneiss, amphibolite, and granitic gneiss.

All rocks in the Adirondacks, except a few late dykes, show the effects of a pervasive metamorphism that occurred during the Grenville orogeny. At Willsboro and elsewhere in the north-east Adirondacks, the maximum pressure and temperature of granulite facies equilibration are estimated from many mineral thermometers and barometers to be 7±1 kbar and 700±50 °C (refs 1, 3, 17, 18). U/Pb, Rb/Sr and Nd/Sm ages indicate that metamorphic recrystallization overprinted earlier igneous events[19–21]. Various age estimates suggest that the anorthosite intruded at 1,200 Myr, at least 100 Myr before the peak of metamorphism, but it cannot be resolved whether igneous activity was a precursor of metamorphism with intruding magmas contributing heat to raise the geotherm, or whether intrusion and metamorphism represent two discrete, unrelated events.

The Willsboro skarn belt gives clear evidence of a metasomatic origin. The wollastonite ore-rock consistently contains three phases and five components for 4 degrees of freedom, and it is commonly reported to be totally devoid of any calcite or quartz[22]. We have located a few thin layers containing calcite at Willsboro (see Table 1), but these amount to only a few centimetres out of thousands of metres of drill core that were examined. If wollastonite formed through isochemical metamorphism (with only fluid components added or subtracted) through the reaction:

$$\text{Calcite} + \text{Quartz} = \text{Wollastonite} + CO_2 \qquad (1)$$

the entire original limestone unit would have had to contain an impossibly perfect molar ratio of 1 calcite to 1 quartz. Thus large amounts of material were either removed or added in solution, indicating that massive fluid circulation was involved in the ore genesis.

Stable isotope results

Analysis of mineral separates from 18 samples of drill core from a 700 ft traverse of the Willsboro Mine (at 7,600 W, mine coordinates) shows that unusually low values of $\delta^{18}O$ (2.9 to -1.3) are restricted to localities within 400 ft of the anorthosite contact. Taylor[23] reported a similar low value of -0.9 for one sample of wollastonite from Willsboro. These low values form a steep-sided trough (Fig. 1) with sharp gradients to higher $\delta^{18}O$ in the gabbroic anorthosite of the footwall and in the mafic gneisses of the hanging wall. The magnitude of this trough is normalized in Fig. 1 by a line connecting wollastonite analyses or, in the case of rocks not containing wollastonite, through the value of a fictive wollastonite, calculated assuming equilibrium isotopic fractionations at 700°C (refs 24, 25).

Other wollastonite samples from the main layers of ore-rock at Willsboro as well as from Lewis and Deerhead (Table 1) have similarly low $\delta^{18}O$ values (3.1 to -1.2) suggesting that the entire 15-km skarn belt is ^{18}O-depleted near the anorthosite contact. We are making further analyses to test this hypothesis, as it would indicate that the ^{18}O-depleting event affected many cubic kilometres of rock.

Three coexisting minerals were analysed from a sample of Willsboro ore-rock (82-W-1) to test that equilibrium isotopic values[24,25] have been preserved from the peak of regional metamorphism (Table 1). These mineral analyses approximate the values that are expected at 700 °C considering that the fractionations and chemical compositions are not well known. The large ^{18}O anomaly cannot have formed by retrograde exchange with post-metamorphic fluids as such an exchange would differentially affect the different minerals.

The gradients in this isotopic trough are the sharpest yet reported for non-carbonate-bearing rocks from any granulite facies terrain. In drill hole DDH 50, $\delta^{18}O$ values vary by 8.0‰ in 14 ft between ore-rock and amphibolite and by 6.0‰ in 3 ft within ore-rock. Additional sampling and analysis will elucidate the details of these gradients. In this respect the apparently parallel layers of the Willsboro deposit cause probelms. In spite of extensive drilling and mining it is not now known to what extent these gradients are due to tectonic juxtaposition through faulting, recumbent folding, or deformation. Faulting, in particular, could cause gradients in $\delta^{18}O$, and the coarse regional metamorphic recrystallization of the deposit must be considered, as it could effectively conceal evidence of such movements if they were premetamorphic. We have not seen any textural evidence of faulting in the zones of high $\delta^{18}O$ gradient, nor are indications of faulting reported by previous workers. Thus if tectonic processes are responsible for these gradients, they operated during an earlier event before peak metamorphic recrystallization, and these gradients were then preserved through the granulite facies metamorphism.

Seven samples of amphibolite were also anlysed for hydrogen isotopic composition. Unfortunately the measured δD values of -86 to -68 fall in a range commonly observed in igneous, metamorphic and sedimentary rocks and are not indicative of the origin of fluids involved in the genesis of this deposit.

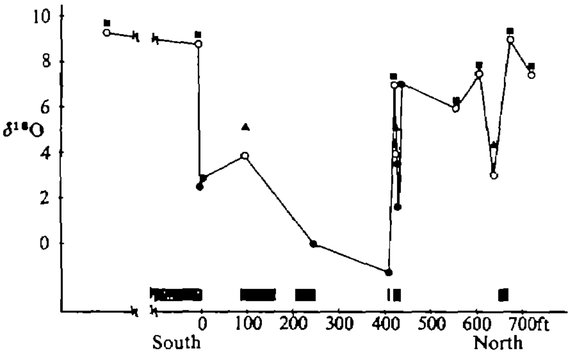

Fig. 1 Values of $\delta^{18}O$ for minerals from a 700-ft traverse of the anorthosite contact with wollastonite skarn at the Willsboro Mine. The 400-ft wide trough of ^{18}O depletion includes the lowest $\delta^{18}O$ (-1.3) and the sharpest $\delta^{18}O$ gradients known from a granulite facies terrain. Plagioclase in the hanging-wall anorthosite (south) is isotopically similar to other Adirondack anorthosites. ●, Wollastonite (measured); ○, wollastonite (calculated); ■, plagioclase; ▲, calcite; solid shading, wollastonite ore-rock; and hatching, anorthosite.

Cause of the ^{18}O depletion

Large ^{18}O depletions occur at igneous contacts by only two processes: metamorphic volatilization and exchange with hot meteoric water. Estimates of the effects of volatization, however, indicate that they are insufficient to account either for the extreme magnitude of ^{18}O depletion (up to -20‰) or the extreme size (cubic kilometres) of the Willsboro skarn belt.

Unusually low $\delta^{18}O$ values have also been reported from granulites of widely separated portions of the Strangways Range, Australia (1.8‰ for hypersthene, 2.8‰ for cordierite)[26]. Additional mechanisms for ^{18}O depletion have been proposed for these rocks including premetamorphic diagenesis and high temperature metamorphic exchange with deep-seated mafic reservoirs. These processes cannot have been important at Willsboro as the ^{18}O anomaly is restricted to the skarn belt and is not seen in any of 85 regionally distributed marble samples that have normal values of $\delta^{18}O$ (ref. 27).

Volatilization can be considered as the slow release of CO_2 due to the reactions such as (1). The magnitude of ^{18}O depletion is then largest for reaction in shallow terrains, in spite of the pressure independence of equilibrium isotope fractionations, because temperatures of reaction will be lowest at low pressures, resulting in higher enrichments of ^{18}O in the escaping CO_2. We have made equilbrium calculations at 300–600 °C based on the stoichiometry of well-known, idealized reactions for the complete decarbonation of a siliceous marble. These calculations suggest that the extremes of ^{18}O depletion for regional and contact metamorphism are approximately 5 and 7‰, respectively. These ^{18}O depeletions would be even less if decarbonation is not complete, if non-reacting minerals are present in the rock, if H_2O or CH_4 dilute the metamorphic CO_2, or if degassing is not controlled by Raleigh distillation[28] with equilibrium fractionations. If isotopic fractionations are not equilibrium fractionations, then the magnitude of ^{18}O depletion due to volatilization will again be reduced. Experiments on the rapid, non-equilibrium, thermal decomposition of dolomite show that the evolved CO_2 is only slightly enriched in ^{18}O relative to dolomite[29].

Results from the Mottled Zone, Israel, should represent an extreme case of volatilization depletion. In response to heat from naturally burning organic matter, calcite completely reacted with silicates at depths of <100 m, and the measured ^{18}O depletions are generally <7‰ (ref. 30). Similar results are observed for low pressure contact metamorphism at Marble Canyon, Texas, where a difference of 9‰ (normalized to wollastonite) was found between adjacent zones of calcite+wollastonite and spurrite[31]. Some ^{18}O depletion in these areas could have been caused by hot circulating groundwaters, and thus these values may be viewed as upper limits. Numerous other contact aureoles have been shown to be less affected by volatilization[31–35].

In the Adirondacks analyses of 85 carbonates average $\delta^{18}O = 20$ (ref. 27). This is in keeping with the average $\delta^{18}O$ value of 21 for worldwide unmetamorphosed carbonates of the same 1,200 Myr age[36]. In contrast the Willsboro wollastonite is depleted by >20 ‰. This ^{18}O depletion is 3–5 times larger, depending on depth of metamorphism, than is found at other documented localities or than our calculations indicate is possible through volatilization.

Table 1 Values of $\delta^{18}O$, δD and $\delta^{13}C$ for mineral separates from the Willsboro Skarn Belt

Sample no.	Description	$\delta^{18}O$	$\delta^{13}C$	δD
AUS 78-1	Plagioclase megacryst from anorthosite, Lewis Quarry	9.7		
AUS 78-4	Wollastonite from ore-rock, Lewis Quarry	−1.2		
81-AUS-1	Wollastonite from ore-rock, Deerhead Quarry	1.2		
W 2-3b	Calcite from marble 2.5 km ENE of Willsboro Mine	21.9	1.1	
DDH W 50-1′	Wollastonite from ore-rock in main ore zone, DDH 50 at 1-ft level, Willsboro Mine	0		
DDH W 50-163′	Wollastonite from ore rock, 3-ft layer within amphibolite	−1.3		
DDH W 50-177′	Plagioclase from amphibolite	6.7		
	Hornblende from amphibolite			−69.6
DDH W 50-178′	Calcite from 2-cm thick layer of calcite+clinopyroxene+scapolite	5.5	−1.4	
DDH W 50-181′	Wollastonite from ore-rock, 19-ft layer within amphibolite	3.5		
DDH W 50-183′	Wollastonite from ore-rock	1.0		
DDH W 50-186′	Wollastonite from ore-rock	7.0		
DDH W 50-216′	Biotite from amphibolite			−75.4
DDH W 50-287′	Biotite from amphibolite			−73.3
DDH W 50-307′	Plagioclase from amphibolite	6.3		
	hornblende	4.8		
DDH W 50-351′	Biotite from amphibolite			−68.5
DDH W 50-357′	Plagioclase from amphibolite	7.9		
DDH W 50-391′	Calcite from 10-cm thick layer of calcite+garnet+clinopyroxene	4.4	−2.2	
DDH W 50-425′	Plagioclase from amphibolite	9.3		
	whole rock			−86.2
DDH W 50-475′	Plagioclase from amphibolite	7.8		
	biotite from amphibolite			−78.0
W 77-100	Plagioclase from foot-wall mafic gneiss in outcrop at no. 4 portal at Willsboro Mine	9.8		
W 77-103	Plagioclase from hanging wall amphibolite in outcrop at no. 2 portal at Willsboro mine	8.6		
	hornblende	5.8		−86.0
DDH W 81-3-5′	Calcite from 5-cm thick layer of calcite+clinopyroxene+garnet	5.1	−3.6	
DDH W 81-3-88′	Wollastonite from 1.3-m thick layer of ore-rock	2.9		
DDh W 81-3-91′	Wollastonite from same layer as −88′	2.5		
DDH W 81-3-101′	Plagioclase phenocryst from gabbroic anorthosite	9.3		
DDH W 81-7-1′	Wollastonite from ore-rock in foot wall 1,200 ft ESE of DDH W 81-3	3.1		
DDH W 81-9-94′	Plagioclase phenocryst from gabbroic anorthosite 200 ft WNW of DDH W 81-3	7.8		
81-W-21	Plagioclase phenocryst from anorthosite 2 km E of the Willsboro Mine	9.1		
82-W-1	Coexisting minerals from ore rock, Willsboro Mine			
	wollastonite	−0.7		
	clinopyroxene	0.3		
	garnet	−0.5		

If the ^{18}O depletion at Willsboro resulted from volatilzation of CO_2 then a complimentary ^{13}C depletion should be seen. Carbonates from contact aureoles that have undergone variable amounts of volatilization often show a direct correlation between $\delta^{18}O$ and $\delta^{13}C$ for this reason[30–35]. The ratio of ^{13}C depletion to ^{18}O depletion is controlled by the relevant CO_2-mineral fractionations and the mechanism of volatilization, but ^{13}C depletion is always at least one-third that of ^{18}O. Three calcites from thin lenses (2–10 cm thick) within the Willsboro ore-zone have an average $\delta^{13}C = -2.4$. This is 2.5‰ less than the average of 75 Adirondack calcites (0.1)[27] indicating that the magnitude of ^{18}O depletion at Willsboro is ≤7.5‰, in accord with our estimate based on calculations and other field studies.

Exchange with heated meteoric waters is a well documented process, causing massive depletions of up to 15‰ to $\delta^{18}O$ values below −10 at the margins of cooling plutons where convective fluid flow facilitates high water-to-rock ratios[37]. Exchange with meteoric water is thus the most probable cause of ^{18}O depletion, especially given the association of wollastonite with the roof zone of the anorthosite massif.

It is common for hot circulating meteoric waters to lower the ^{18}O content of the solidified margins of a pluton as well as the surrounding country rock. In the Adirondacks, the $\delta^{18}O$ values of plagioclase in anorthosite (8.9–11.2) are generally 3‰ higher than anorthosites and gabbros elsewhere. However, five unusually garnet-rich anorthosites have low $\delta^{18}O = 4.3$ to 5.7 (ref. 23). Regardless of whether the general ^{18}O enrichment occurred during the metamorphic[23] or magmatic[38] event, some additional process is necessary to explain these garnet-rich anorthosites that are lower in ^{18}O than normal anorthosite. These samples are from near the contacts of the anorthosite and have been interpreted as resulting from metasomatic interaction with metasedimentary wall rock[4,16]. It is reasonable to suggest that these anorthosite samples have also interacted with meteoric water.

Shallow intrusion of anorthosite

The involvement of large amounts of meteoric water in the skarn formation at Willsboro would require a depth of anorthosite emplacement much less than the 23 km inferred for granulite facies metamorphism. This is because meteoric waters circulate at hydrostatic pressures (P_H) and cannot penetrate to depths of high grade metamorphism, where porosity is extremely low and fluids are at lithostatic pressures ($\sim 3P_H$). The maximum depths to which groundwater circulates are estimated[39,40] at 7–10 km. Many documented examples of ^{18}O exchange with meteoric waters occur at the margins of such shallowly emplaced plutons[41], and we propose that the Adirondack massif likewise intruded at shallow depths of < 10 km.

Shallow anorthosite intrusion is supported by the presence of contact aureoles at two anorthosite massifs from outside of the Grenville Province. At Nain coexisting orthopyroxene+olivine+quartz limits pressure[3,13] to 3.2±0.2 kbar, and at Laramie coexisting pigeonite+hedenbergite+fayalite limits pressure[42] to 1.5–2.0 kbar. These bodies lie to the north-west of the Grenville Front and do not show Grenville metamorphic overprints. It is thus likely that North American anorthosites intruded at all levels in the crust before the Grenville orogeny and that subsequently those nearest the continental margin were buried at the time of metamorphism. Such rapid burial is supported in the Adirondacks by whole-rock Rb/Sr ages of 1,263 ± 25 Myr for surface eruption of ash-flow tuffs that were subsequently metamorphosed (1,120 Myr) at 20 km depth to leuco-gneiss[21]. The common inference may thus be incorrect and the close association of anorthosite with granulite facies metamorphism seems to have no relevance to actual emplacement depths.

We believe that these Adirondack results are best explained by the following events. Anorthositic magma intruded to shallow depths at ~1,200 Myr. Metasomatism and skarn formation took place during solidification and cooling in the roof-zone with the involvment of large amounts of low-δ^{18}O meteoric water. The anorthosite and skarn were subsequently buried to 23 km and metamorphosed at ~1,100 at low f_{CO_2}.

This study was partly supported by NSF grant EAR81-2124 to J.W.V. We thank Hugh P. Taylor Jr for stimulating and challenging discussions, Yngvar Isachsen and Clark Johnson for reviewing this manuscript, and Lauren Choate and Ron Bauer for providing access to the Willsboro Mine.

Evidence for the direct involvement of DNA replication origin in synthesis of late SV40 RNA

R. Contreras, D. Gheysen, J. Knowland*, A. van de Voorde & W. Fiers

Laboratory of Molecular Biology, University of Ghent, Ledeganckstraat 35, B-9000 Ghent, Belgium

Analysis of the late simian virus 40 (SV40) transcription initiation patterns of viable and non-viable mutants and a DNA replication-negative mutant in permissive monkey cells and/or in Xenopus laevis *oocytes suggests a direct role for the origin of DNA replication in the activation of late transcription.*

THE SV40 genome contains two transcription units. The early unit is functional in permissive cells throughout the infection cycle and in SV40-transformed cells. The minimal promoter elements and more remote regulatory functions have been characterized in detail[1–4]. The late transcription unit, however, is actively transcribed only in permissive cells during the late phase of the infection cycle. Late mRNA is not synthesized in significant quantities in transformed cells, in lytically infected cells in the presence of inhibitors of DNA synthesis[5,6], or in cells infected at the non-permissive temperature with temperature-sensitive (ts) A mutants[6,7]. Furthermore, microinjection experiments with form I and replicative intermediate DNA into chemically blocked permissive cells or non-permissive cells, also suggested a role of DNA replication in late mRNA synthesis[8,9]. However, other data obtained from studies with transcription complexes[10,11], early mRNA[12], or mRNA from infected non-permissive cells[13], led to the rejection of the idea of a special role for DNA replication in the activation of the late SV40 promoter. These studies suggest that the large amount of late mRNA is caused by a marked increase in the gene copy number. The much smaller amount of early RNA observed at late times after infection may be explained by the autoregulatory function of large T antigen[14,15].

We attempted to resolve this controversy and to give a better definition in molecular terms of the requirements for synthesis of late SV40 mRNA. We therefore analysed the RNA produced by several deletion mutants in the putative late promoter region[16] (D. G. *et al.*, in preparation) and a DNA replication-negative mutant in infected CV1 cells and/or in *X. laevis* oocytes. Extensive deletions in the late initiation region were found to have a very limited effect on downstream initiation points, but a deletion of four base pairs (bp) that had been shown to prevent DNA replication[17] caused a marked inhibition of late RNA synthesis even at some downstream initiation points over 300 nucleotides away.

5′-Termini of wild-type and deletion mutant late mRNAs in CV1 cells

The 5′-termini of late lytic SV40 RNAs are strikingly heterogeneous[18–20]. The positions of these 5′-termini have been mapped by reverse transcription[18] and by direct analysis[19,21].

Fig. 1 Mapping of 5′ termini of SV40 late mRNA with S_1 nuclease and exonuclease VII. The upper part of the figure shows a 12% polyacrylamide–8 M urea gel of wild-type (wt) SV40 late mRNA 5′-termini. (Migration in all the figures is from left to right.) 1 μg of poly $(A)^+$ RNA isolated from SV40-infected CV1 cells 48 h after infection as described elsewhere[19], was hybridized to a single-stranded (SS), 5′-end-labelled *Hpa*II–*Mbo*II DNA probe, and digested with exonuclease VII at increasing concentrations of NaCl (*a*, 50 mM; *b*, 200 mM; *c*, 300 mM) or with S_1 nuclease (*d*, *e*) as described elsewhere[22,45] (*d* and *e* are identical experiments carried out separately). The 5′-labelled restriction fragments in this and all following experiments were strand-separated on a 5% polyacrylamide gel as described[46], and an aliquot of the isolated single strand was co-precipitated with each RNA preparation. After hybridization in 15 μl buffer (40 mM PIPES *p*H 6.4, 400 mM NaCl, 1 mM EDTA) for a minimum of 4 h, the hybrids were digested with S_1 nuclease or exonuclease VII. Lanes *f* (T+C) and *g* (A+G) show a Maxam–Gilbert[46] DNA sequence ladder. Lane *h* is a control digest of the probe. Lanes *i*–*k* are S_1 nuclease digests in conditions identical to those of *d* and *e* with strands separated from the SV40 *Hind* F RI fragment. As this fragment is localized in the body of the VP1 gene, the late coding strand is entirely protected against S_1 nuclease digestion (lane *i*); the other strand is not protected (lane *j*). Lane *k* shows the late coding strand digested in the absence of RNA and lane *l* is a chain length marker. This experiment (lanes *i*–*l*) was carried out on a 20×40 cm polyacrylamide sequencing gel, while lanes *a*–*h* were fractionated on a 30×90 cm gel. The lower part of the figure shows the nucleotide sequence of the region where the late SV40 mRNAs initiate. The initiation points as deduced from a comparison of lanes *a*–*d* with lanes *f* and *g* (and considering data in the literature; see text) are indicated. The identification of the exact 5′ ends of the four longest bands (wavy lines) is less accurate than for the others; they were assigned from a longer run (results not shown). Some characteristic restriction sites and the 72-bp repeats are also shown. The flag indicates the major SV40 wt initiation of late mRNA at position L325. The positions of the deletion mutants are indicated at the bottom; the deletions are identified by the nucleotide numbers (the numbering system is as described previously[47,48]). The deletion mutants were constructed as follows: pBR325 was deleted for the tetracycline gene by partial *Hae*II digestion, which produced the plasmid pBGF1 (D. G. *et al.*, in preparation). Wild-type SV40 and d1 894 DNA were digested with *Eco*RI and ligated in the unique *Eco*RI site of the chloramphenicol resistance gene. After opening at the *Sph*I site in the cloned SV40 DNA, treatment with nuclease *Bal*31, followed by re-ligation, produced the series of deletions which were characterized by nucleotide sequence analysis.

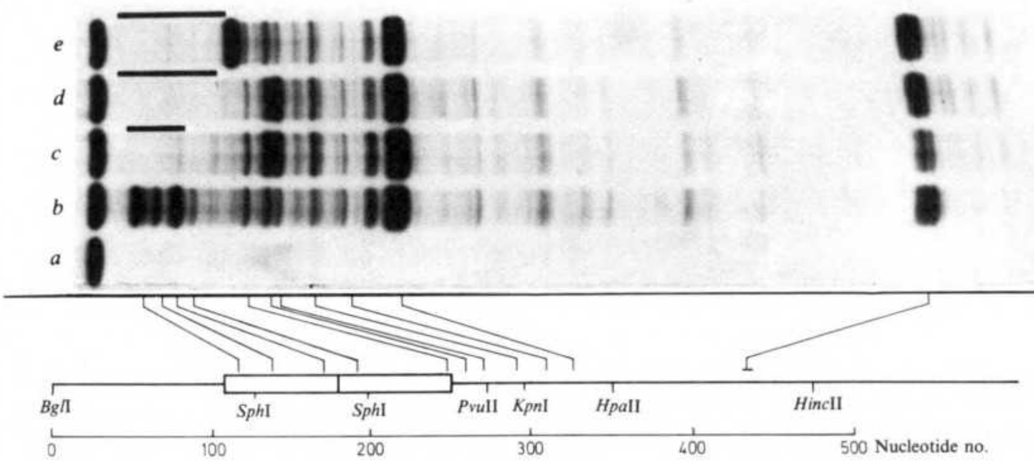

Fig. 2 Exonuclease VII mapping of the 5′-ends of wt- and viable mutant-induced late poly(A)$^+$ mRNA extracted from CV1 cells. Cytoplasmic poly(A)$^+$ mRNA of wt and mutant viruses extracted at 48 h post-infection was hybridized against the single-stranded [5′-^{32}P]-labelled *Bgl*I–*Hin*dII (position 472) fragment and the RNA–DNA hybrid digested with exonuclease VII as described in Fig. 1 legend. *a*, 1 μg poly(A)$^+$ mRNA from uninfected CV1 cells; *b*, 1 μg poly(A)$^+$ mRNA of wt-infected CV1 cells; *c*, 0.5 μg poly(A)$^+$ mRNA from dl 894-infected cells; *d*, 1.0 μg poly(A)$^+$ mRNA from dl 1845-infected cells; *e*, 1.0 μg poly(A)$^+$ mRNA from dl 1846-infected cells. The size and position of the deletion is shown on the polyacrylamide–urea gel by a solid line (see also diagram in Fig. 1). The lower part of the figure is a schematic representation of the wt initiation points and major restriction enzyme sites.

Previously we have shown that the physical 5′ cap structures correspond to genuine initiation points for transcription[16]. For the present analysis of the late mRNAs, we used the S_1 nuclease and/or exonuclease VII mapping technique with single-stranded probes [5′-^{32}P]-labelled at the *Hpa*II (Fig. 1) or *Hin*dII sites (Fig. 2). An S_1 nuclease and an exonuclease VII 5′-end analysis of wild-type mRNA are shown in Fig. 1. As in a high resolution gel, three to five bands are formed per 5′-end after an S_1 digestion, the pattern obtained is rather complex and is not very well suited for mapping at the exact nucleotide level especially in regions where several 5′-ends occur close together (see lanes *d* and *e* of Fig. 1). The pattern produced by exonuclease VII mapping is similar to the S_1 nuclease pattern but is more discrete. Comparison of the S_1 pattern and the direct 5′-end analysis data[19,21] with other data in the literature[22], shows that the major band of the S_1 nuclease-digested DNA is two nucleotides longer than its RNA counterpart. This phenomenon is even more pronounced with exonuclease VII where in most cases the DNA is four to five nucleotides longer than the RNA to which it was hybridized (possibly the enzyme is inhibited by the positive charge on the cap structure). The patterns of the initiation points which can be deduced from the gel analyses reported here, are very similar to those obtained from reverse transcription mapping[18,20]. Note also that some of the late 5′ initiations start in the 72-bp repeats (Fig. 1).

To test the hypothesis that the remarkable heterogeneity of initiation points is caused by tandemly repeated promoter elements[16], a series of deletion mutants was constructed by nuclease *Bal*31 digestion of *Sph*I-opened SV40 DNA cloned in plasmid pBGF (D.G. *et al.*, in preparation; see also Fig. 1). Analysis of the late mRNA obtained from CV1 cells infected with the largest viable mutants, dl 1845 and dl 1846, and with the natural deletion mutant, dl 894, is shown in Fig. 2. The analysis involved exonuclease VII digestion with a DNA probe labelled at the *Hin*dII site at position 472 (similar results have also been obtained with an *Hpa*II probe labelled at position 348). Four major conclusions arose from these experiments: (1) The analyses showed that the initiation patterns downstream from the deleted sequences were almost unchanged when compared with the wild-type 5′-termini, suggesting that

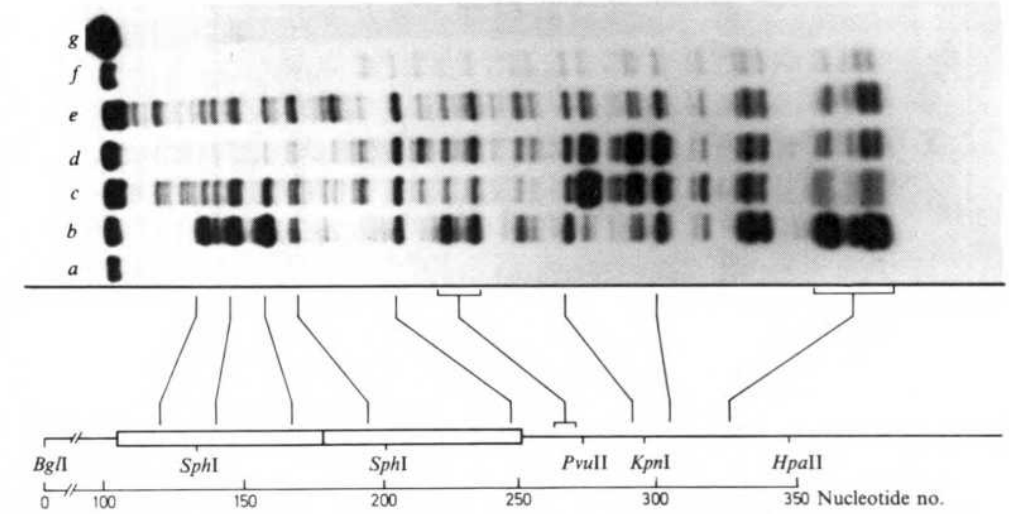

Fig. 3 Mapping of the 5′ ends of SV40-specific RNA synthesized in *X. laevis* oocyte nuclei injected with wt templates. Stage VI oocytes were injected with 10 ng sucrose gradient-purified DNA aiming for the nucleus [23,49] and incubated at 22 °C for 6 h. The nucleus and cytoplasm were separated after heating the oocyte at 75 °C for 3 min, followed by making an incision and manual removal of the nucleus. The nuclear RNA was isolated by hot phenol extraction and the preparation was further digested with proteinase K-treated DNase I[50] (twice for 15 min at 37 °C with 1 μg per nucleus), phenolized with hot phenol and co-precipitated with the isolated [5′-^{32}P]-labelled single-stranded probe. Hybridization and exonuclease VII digestion were as described in Fig. 1 legend. *a*, RNA from uninjected oocytes; *b*, reference pattern of poly(A)$^+$ mRNA from CV1-infected cells (same as lane *b* in Fig. 2); *c*–*e*, RNA from oocytes injected with: *c*, viral wt DNA; *d*, pSCLO$_4$ DNA; *e*, pSMboC DNA; *f*, not relevant to this experiment; *g*, undigested single-stranded probe. Each gel analysis was carried out with three oocyte RNA equivalents. The wt templates pSCLO$_4$ and pSMboC plasmids were constructed as follows: pSCLO$_4$ contains the SV40 *Hin*dII + *Hin*dIII fragments C and L (568 nucleotides) and was made by addition of a *Bam* linker to the *Hpa*I site at position L501 and cloning between the *Hin*dIII and *Bam*HI sites of pBR322. pSMboC contains the SV40 *Mbo*II fragment C (710 nucleotides) which was blunt-ended, *Bam* linkers were added and the fragment was cloned in the *Bam*HI site of pBR322. The SV40 formation in both pSCLO$_4$ and pSMboC spans the region of DNA replication and transcription initiation.

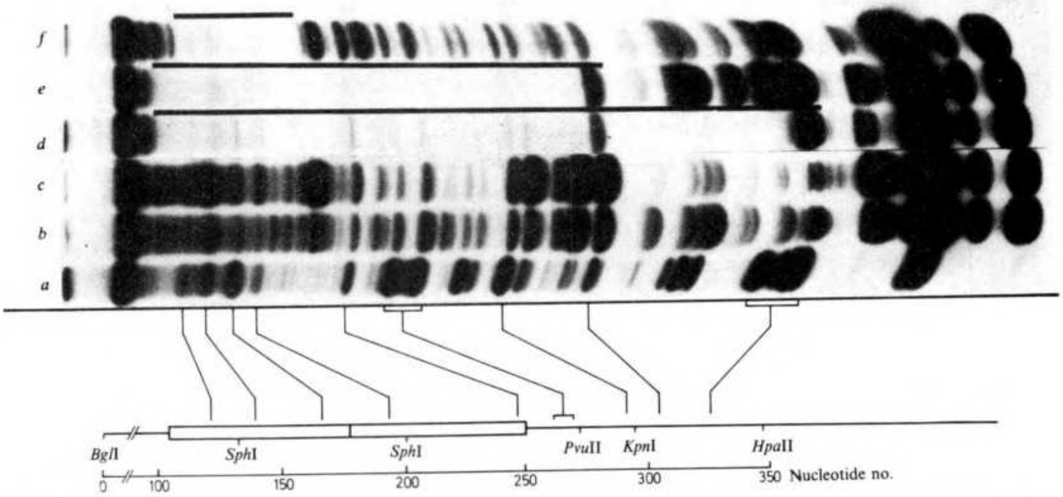

Fig. 4 5′-End analysis of oocyte nuclear RNA synthesized on SV40 wt and deletion mutant templates. The experimental procedure was as described in Fig. 3 legend. *a*, CV1 wt poly(A)$^+$ mRNA reference pattern (same as for Fig. 2*b*); *b*, injection with wt viral DNA, 4 h incubation; *c*, injection with wt viral DNA, 22 h incubation; *d*, injection with mutant pS1849 DNA; *e*, injection with mutant pS1850 DNA; *f*, injection with mutant dl 1846 DNA. The position of the deletions is shown by a heavy horizontal line above the corresponding lanes (see also the map of the mutants at the bottom of Fig. 1). The darker band in lanes *d* and *e* near the *Kpn*I site is a background band, as no initiation sites can be present at this position.

the deletions in the regions immediately upstream have little function in the positioning and synthesis level of the remaining RNA species. (2) As these viable deletions also delete major parts of the 72-bp 'enhancer' sequences, which are required for early gene expression[2], it seems that the most crucial elements of the 'enhancer' sequences are localized at the right part of the repeat and/or that other regulatory mechanisms (for example, T-antigen autorepression) back-up for a decreased enhancer function. (3) The dl 1846 pattern, the largest viable deletion in this region, shows a new strong band located at the end of the deletion, which could represent an artificial new initiation point formed by the combination of nucleotides around the deletion; alternatively, it could be derived from RNAs initiated in foreign DNA inserted at the position of the deletion. Indeed, it was found (D.G. *et al.*, in preparation), that the viral DNA collected after CV1 infection, especially that from the mutant dl 1846, showed some heterogeneity in the *Hin*d C fragment (the mutant dl 1845 was found to be more stable in this respect). To avoid this complication, late SV40 transcription was also analysed in *X. laevis* oocytes (see below). (4) There is also a predominant initiation point around position 433. This site probably corrresponds to the initiation sites mapped by Piatak *et al.*[20] at positions 428–481. Again, the position of this initiation point was not shifted by extensive upstream deletions.

During the construction of the deletion mutants, several non-viable mutants having more extensive deletions in the presumed promoter region were also isolated (for example, pS1849 and pS1850). The transcriptional behaviour of these and the other mutants was examined in *X. laevis* oocytes.

Initiation of wild-type and mutant late SV40 transcripts in nuclei of *X. laevis* oocytes

Xenopus oocytes have been shown to synthesize late[23,24] and early[25] SV40-encoded products. Faithful promoter-specific initiation, however, has not yet been demonstrated. Figure 3 shows the 5′-end analysis of SV40-specific RNA synthesized in *X. laevis* oocytes injected with various wild-type templates (Fig. 3*c–e*) compared with *bona fide* late mRNA from CV1 cells (Fig. 3*b*). It is evident that the wild-type viral RNA initiation pattern in oocytes (Fig. 3*c*) closely resembles the pattern found in CV1 cells (Fig. 3*b*). There are some small differences, mainly quantitative, in the relative strength of transcription initiation, rather than qualitative differences in the pattern of transcription. At later times (22 h), these differences increase but the basic pattern remains the same (Fig. 4*c*). The results indicate that oocyte nuclei provide a reliable and faithful system for the study of SV40-directed transcription at least at short times after injection (6–7 h). Injection with the SV40 fragments *Hin*d C+L (position E67–L501; for numbering see Fig. 1 legend) or *Mbo*II C (position E236–L474) containing the expression control signals cloned in a pBR322 derivative, again produced the typical late transcription pattern (Fig. 3*d* and *e*, respectively). Therefore, it may be concluded that the fidelity of the transcription of the SV40 sequences is not appreciably affected by neighbouring plasmid sequences. In addition, it is clear from the results obtained with these plasmids that information for large T antigen is neither needed for efficient late transcription in oocytes nor involved in positioning of the late mRNA start sites. This situation resembles the *in vitro* transcription initiation pattern of early SV40 RNA[15] which is similar to an *in vivo* late-early pattern, although it was found that late time initiation patterns of '*in vivo*' early mRNA do require the presence of a functional T antigen[26]. Injection of the non-viable mutant DNA, pS1850 and pS1849 (see Figs 1, 4), which lack almost the entire late mRNA initiation region, showed that here again the deleted sequences apparently have no effect on the downstream initiation points. Therefore, the results obtained with deletion mutants in CV1 cells described here and by others[19,20], and those obtained with extensive deletion mutants in injected oocytes, indicate that unlike the normal system of a classical promoter-driven transcription, the control elements for SV40 late transcription are not localized in the regions immediately upstream (or downstream) from the mRNA initiation site. As discussed above, various data in the literature suggest that DNA replication is linked to the activation of late transcription. To test the possibility of a direct involvement of the SV40 DNA replication region in late transcription, we injected the DNA replication-negative mutant 8-4[17,27] into *X. laevis* oocytes.

Transcription of a DNA replication-negative mutant in *Xenopus* oocytes

The 5′-end of the late SV40-specific RNA synthesized in *X. laevis* oocytes injected with the plasmid pSCLO$_4$ (containing the SV40 control region from E67 to L501) and with the DNA replication-negative mutant 8-4 DNA, is shown in Fig. 5 (lanes *c* and *d*, respectively). Clearly the amount of late SV40 RNA isolated from the nucleus of mutant 8-4-injected oocytes is greatly reduced, although the remaining mRNAs are still faithfully initiated. The possibility of some artefact such as faulty nuclear injection with the mutant DNA is excluded by two different controls. First, in the experiments shown, wild-type and mutant DNAs were mixed with an equal amount of DNA from the plasmid p(325)-gHFIF-4, which contains the gene for human fibroblast interferon[28], and the incubation medium of the injected oocytes was assayed for interferon. The results show even better interferon synthesis by the oocytes injected

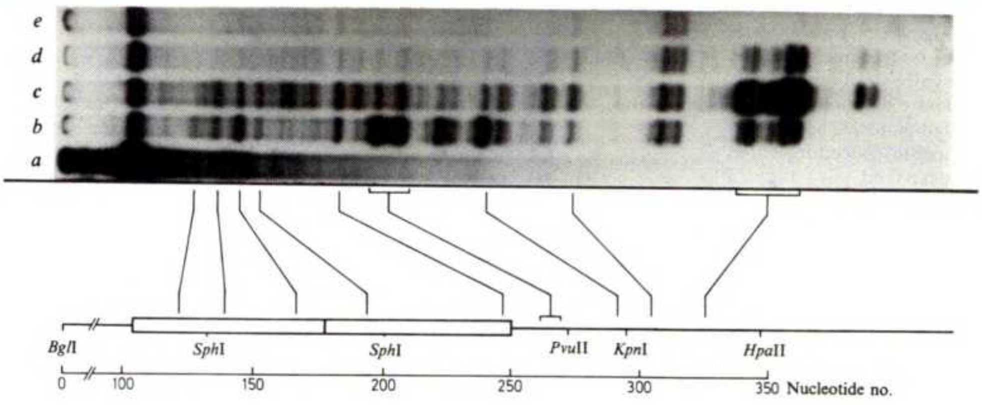

Fig. 5 5′-End analysis of SV40-specific late RNA synthesized in *X. laevis* oocyte nuclei injected with a plasmid containing an SV40 DNA replication-negative mutant. *a*, Undigested single-stranded probe; *b*, poly(A)$^+$ mRNA of wt-infected CV1 cells, reference pattern; *c*, injection with the plasmid pSCLO$_4$ containing a functional wt SV40 DNA replication region (same as used in Fig. 3*d*) plus p(325)-gHFIF-4 DNA as an internal control; *d*, injection with the DNA replication-negative mutant 8-4 (see below) plus p(325)-gHFIF-4 DNA as an internal control; *e*, nuclear RNA from oocytes injected with plasmid p(325)-gHFIF-4, which encodes human fibroblast interferon[28] (internal control for lanes *c* and *d*). The mutant 8-4 was constructed by Gluzman *et al.*[17] by directed mutagenesis of pMK16/SV40 DNA at the *Bgl*I site. The deletion of four nucleotides at the *Bgl*I site does not influence the synthesis of T antigen (and hence the major type of early mRNA synthesis), but prevents DNA replication and production of V antigen and infectious virus[17].

with mutant than by those injected with wild-type DNA. The validity of the experiment was further corroborated by data obtained from the analyses of the early SV40 RNAs synthesized in the same oocyte nuclei (see Fig. 6), which showed that the amount of early RNA from the DNA replication-negative mutant is even higher than the amount of RNA from the wild-type-injected oocytes (the higher early transcription may be coincidental or may be due to the absence of competition for transcription factors by an inactive late region). Densitometer tracings of the gels and visual interpretation indicate that there is a reduction of at least 10-fold in late SV40 RNA synthesis by the DNA-replication-negative mutant compared with transcription from the wild-type template. The possibility of gene copy number amplification (despite the non-permissivity of this system[29]) of the wild-type pSCLO$_4$ DNA was analysed by quantitation of the DNA by dot hybridization and by analysing the methylation pattern of the injected DNA. Although by dot hybridization we could not exclude a slight increase (1.3–1.9-fold) in the amount of nuclear plasmid DNA 7 h after injection, the methylation pattern of the DNA as analysed by a Southern blot of *Mbo*I and *Sau*3A digests was unchanged during the incubation, indicating the absence of even a single round of DNA replication (data not shown). In addition to the quantitative aspect of late transcription by the origin-defective mutant, there is also a difference in the initiation pattern of early transcription. It was observed that the initiation positions of early RNA which appear only at late times after infection[26,30] (after the onset of DNA replication) are used considerably less by the origin-defective mutant than by the wild-type DNA (Fig. 6*b*, *d*). Instead, the more rightward initiation points around nucleotide E40 are more pronounced. We propose that in addition to the classical polymerase II promoter for early transcription, there are heterogeneous early transcripts which are formed as a result of the activation of the DNA replication origin.

Discussion

RNA polymerase II promoters have been well characterized in different (*in vitro* and *in vivo*) systems by the construction of deletion mutants in critical regions. In this manner the function of the TATA box was elucidated[31–33], evidence for the function of a −70 signal (the CAAT box) was obtained from studies *in vivo* (including oocytes)[34–36], and a more upstream 'enhancing' function was found[2,37].

The late transcription unit of SV40 is unlike most cellular or viral transcription systems because it is only actively expressed

Fig. 6 5′-End analysis of SV40-specific early RNA synthesized in *X. laevis* nuclei. *a*, Poly-(A)$^+$ mRNA from wt-infected CV1 cells, reference pattern (48 h after infection); *b*, *c*, injection with plasmid pSCLO$_4$ containing a wt DNA replication region (same RNA as used in Fig. 5*c* for analysis of late SV40-specific RNA); *d*, injection containing the plasmid containing the SV40 DNA replication-negative mutant 8-4 (same RNA as used in Fig. 5*d* for analysis of late SV40-specific RNA); *e*, injection with pS1846 DNA (same RNA as used in Fig. 4*f*); *f*, the probe incubated in the presence of poly(A)$^+$ mRNA from uninfected CV1 cells. The dark full-size band near the top of the gel is due to contamination of the [5′-^{32}P]*Hin*dIII-labelled single-stranded probe with some complementary strand and renaturation. At the bottom, note the nucleotide sequence (from 5′ to 3′) of the strand having the same polarity as the early SV40 mRNA (unlike the diagrams below Fig. 1–5 which dealt with late transcription). The early transcription is from left to right. The initiation points were identified relative to a chemical degradation pattern[46] run on another gel. The RNA initiation points do not correspond exactly with those given by Ghosh and Lebowitz[26], but the differences may be due to the different methods used and these precise assignments do not affect our main conclusions. The leftmost initiation point is mapped less accurately (wavy line). Also indicated on the diagram is one of the 21-bp repeats, the 4-nucleotide deletion at the *Bgl*1 site in the mutant 8-4, and the start codon for synthesis of small t- and large T-antigen synthesis. (T, t init.).

in permissive cells, and because of its high degree of transcriptional start site heterogeneity. Neither our own results for CV1 cells described here, nor the results of others with SV40 (ref. 38 and W. Schaffner, personal communication) or with polyoma virus[39], have indicated a function of the aforementioned classical promoter elements for late viral transcription. Therefore, an analysis of larger (and hence non-viable) deletions in the region upstream of the major transcription initiations was required. We therefore explored the possibility of studying the late SV40 transcription system in nuclei of *Xenopus* oocytes and found that it was faithful. As in the CV1 system, however, we were unable to find any evidence of classical polymerase II promoter elements by analysis of a series of appropriate deletion mutants. Instead, we found a clear coincidence between the DNA replication function and an essential function required for late RNA synthesis located within four nucleotides at the *Bgl*I site. This unexpected result can be explained by assuming either that the region of DNA replication is directly required for late mRNA synthesis, or that the overlapping of functions is purely incidental. The latter explanation would imply the presence of a remote control element, as yet unidentified, that would be involved in transcriptional initiation at sites some of which are over 300 nucleotides downstream. We therefore consider it more likely that the mutation 8-4 at the *Bgl*I site[17] largely abolishes late transcription due to an impaired DNA replication function.

The 'special' structure present in SV40 DNA, which has an active origin of DNA replication and which functions as a novel type of polymerase II promoter, may be either a 'DNA replication eye', a D-loop structure, a region where special DNA replication proteins bind, or a special conformation of the origin DNA formed in the nuclear environment. This 'special' structure is presumed not to be formed or to be formed to a considerably lesser extent by the *Bgl*I deletion mutant, 8-4.

Hay and De Pamphilis[40] recently proposed that SV40 DNA replication starts with the synthesis of DNA having the same polarity as early mRNA, whereby a single-stranded region is exposed on the retrograde template which is the same strand as is transcribed for late RNA synthesis. As it was generally found that class II RNA polymerases prefer denatured DNA as template[41], this single-stranded region on the retrograde arm may allow the formation of a stable complex with the RNA polymerase which then begins to travel along the template and initiates RNA synthesis at many but non-random positions, giving rise to late SV40 mRNA transcripts.

It may be argued that *X. laevis* nuclei do not constitute a permissive system for SV40 DNA replication but as mentioned above, the special structure formed by the origin of DNA replication and implicated in late SV40 transcription does not necessarily even involve incipient DNA strand synthesis. It may be formed either by properties intrinsic to the DNA sequence itself or by interaction with nuclear components whose properties are conserved even between CV1 cells and *X. laevis* oocytes. In permissive monkey cells, T antigen may be responsible for the progression of the special structure to an active DNA replication complex. In non-permissive cells, such as mouse or rat cells, T antigen which binds to the replication origin region[14] may be responsible for shut-off of all late transcription. Of course, additional factors may be involved in distinguishing a permissive system from a non-permissive system (for example, factors needed for expression of the V antigens). Note, however, that Subramani *et al.*[42] have observed expression in non-permissive cells of a dihydrofolate reductase gene cloned in the late region of SV40.

Ghosh and Lebowitz[26] have shown that there is an increase in 5'-terminal heterogeneity of early SV40 mRNA at late times in infection. Similar observations had been reported for polyoma virus early mRNA[30]. If the heterogeneity of the late RNA initiations were coupled to the formation of a special DNA structure in the origin region, as we propose, then the increase in heterogeneity of early start points could be produced by a similar mechanism—that is, direct activation of a second type of transcription system by the DNA replication region.

Thus, we believe we have demonstrated a novel type of gene regulation. RNA polymerase II can either initiate transcription on classical promoters or it can initiate by a mechanism driven by a DNA replication origin. Considering that many genes are regulated in function of the cell cycle, it certainly seems meaningful to couple the expression of several genes to DNA replication. Indeed, the phenomenon of regulation of late SV40 gene expression by DNA replication may also have a role in the expression of some cellular genes, such as the regulation of histone synthesis as observed in yeast[43], Chinese hamster ovary cells[40] and hamster fibroblast cells[44].

R.C. is a Research Associate of the Belgian Nationaal Fonds voor Wetenschappelijk Onderzoek. We thank Dr Y. Gluzman for his gift of SV40 mutant 8-4, J. Van der Heyden for technical assistance and Susan Kaplan and Wim Drijvers for help with the manuscript. This research was supported by grants from the Belgian Fonds voor Geneeskundig Wetenschappelijk Onderzoek (no. 3.0063.81), the 'Gekoncerteerde Akties' of the Belgian Ministry of Sciences and from the Cancer Fund of the ASLK. J.K. thanks the EMBO for a short-term fellowship.

Are there black holes in quasars?

Marek Artur Abramowicz* & Luciano Nobili†

Department of Astrophysics, Oxford University, South Parks Road,
Oxford OX1 3RQ, UK

There are two main theoretical models for the central engine of quasars and other active galactic nuclei: the black hole model and the spinar model. Observations of the time scales of flux variations can rule out the black hole model and are therefore extremely important. The widely accepted argument of Elliot and Shapiro[1] states that the maximal luminosity of the nucleus is given by the Eddington limit, $L_{Edd} = 10^{38}$ $(M/M_\odot)$ erg s^{-1}, and the minimal time scale for periodicity is given by t_{min} = (gravitational radius)/(velocity of light) = 10^{-5} $(M/M_\odot)$ s. Therefore, the observed time scale of variations t, and the luminosity L must obey $\log t > \log L - 43$. Variations on a time scale shorter than that would rule out the black hole model. We point out here that this statement is wrong in view of recent developments in the accretion disk theory: much shorter periodicities are still consistent with the black hole model.

One of the most important new results of the theory of accretion disks is that the observed flux of geometrically thick disks can be formally consistent with luminosities up to 100 times (but probably not much more) greater than the Eddington luminosity[2-5]. This is not only due to genuine super-Eddington luminosities of the disks, but mainly because the radiation is highly beamed in a long and narrow vortex along the axis of rotation. This high flux in the beam, when multiplied by the surface of the whole celestial sphere, can give formally a luminosity of the order of $100 L_{Edd}$, when the intrinsic luminosity of the nuclei is only a few Eddington luminosities. The possibility that the radiation of quasars and other active galactic nuclei, especially BL objects, is highly beamed was suggested a few years ago by Blandford and Rees[6]. The agreement of this hypothesis with quasar statistics is very good[7]. Figure 1 (taken from ref. 5) shows how highly the radiation is beamed. The observed flux is formally consistent with a luminosity

$$L = \lambda L_{Edd} = 1.26 \times 10^{38} \lambda \left(\frac{M}{M_\odot}\right) \quad \text{erg s}^{-1} \qquad (1)$$

where the dimensionless, model-dependent, parameter λ obeys the condition $\lambda \leqslant 10^2$.

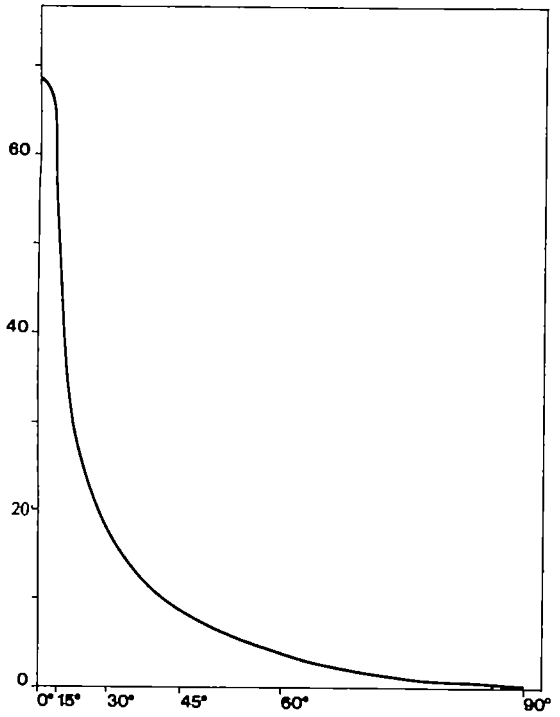

Fig. 1 Beam of radiation emerging from the funnel of a thick accretion disk. The luminosity L formally obtained from the observed flux (by assuming an isotropic radiation field) depends on the angle θ which line of sight makes with the axis of the beam. Luminosities substantially greater than L_{Edd} are possible.

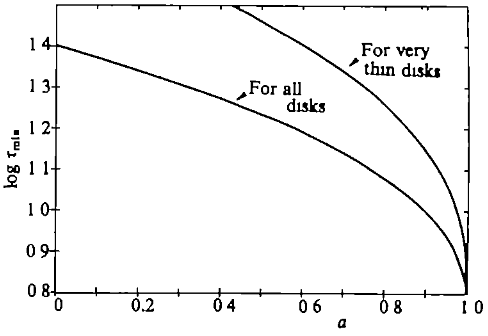

Fig. 2 Log τ_{min} plotted against the Kerr parameter a. Although the condition $\log \tau_{max} > 0.8$ cannot distinguish between thin and thick disks, one must remember that if $\lambda \gg 1$, the thin disks are ruled out.

Another important recent result of the theory of accretion disks is that the innermost edge of the disk does not necessarily coincide with the marginally stable orbit, $r = r_{ms}$, but can be much closer to the hole: as close, in fact, as the marginally bound orbit, $r = r_{mb}$. Frequency of circular orbital motion gives a good estimate of a minimal possible periodicity of flux generated at a given point on the surface of the disk[8]

$$t_{min} = \tau \frac{r_G}{c} = 0.98 \times 10^{-5} \tau \left(\frac{M}{M_\odot}\right) \quad \text{s} \qquad (2)$$

with the dimensionless parameter $\tau \equiv \pi(r_*^{3/3} + a)$ depending on the location of the region which provides the time variation, $r = 1.48 \times 10^5 r_*(M/M_\odot)$ cm, and on the dimensionless Kerr parameter a which characterizes the rotation of the black hole: when $a = 0$ the hole does not rotate, and when $a = 1$ the hole rotates at the maximum possible rate. The locations of the horizon, marginally bound, and marginally stable orbits for the non-rotating black hole are given by $r_* = 2$, $r_* = 4$, and $r_* = 6$ respectively; for the hole rotating at the maximum speed all

Table 1 Estimated values of a_{min} for seven observational points shown in Fig. 3

						a_{min}

three locations are given by $r_* = 1$. Therefore, the parameter τ must obey $\tau > \tau_{\min} = 2\pi$, or $\log \tau_{\min} = 0.8$ for an $a = 1$ hole and $\tau > \tau_{\min} = 8\pi$ or $\log \tau_{\min} = 1.4$ for an $a = 0$ hole.

The function $\tau_{\min}(a) = \pi[(r_*)^{3/2}_{\mathrm{mb}} + a] = \pi\{[2 - a + a(1 - a)^{1/2}]^{3/2} + a\}$ is shown in Fig. 2.

From equations (1) and (2) we deduce the corrected form of the basic Elliot–Shapiro formula

$$\log t_{\min} = \log L - 43.1 + \log(\tau/\lambda) \qquad (3)$$

If the source of radiation is undergoing relativistic motion then, as pointed out by Blandford and Rees[6], the observed time variation can be even shorter. This, however, cannot be applied to periodic variations observed over many periods as these must be connected with disk rotation. Knowing from observation the values of $t_{\min}$ and L one can find from equation (3) the value of $\log(\tau/\lambda)_{\mathrm{obs}}$. Assuming that $\lambda = 10^2$ is an upper limit for luminosity one can find the upper limit for $\log \tau$, equal to $\log \tau_{\max} = \log(\tau/\lambda)_{\mathrm{obs}} + 2$. If $\log \tau_{\max} < 0.8$ then one can say that observations exclude the possibility of the black hole model. In the case when $0.8 < \log \tau_{\max} < 1.4$ non-rotating black holes are ruled out. Observations are still consistent with rotating black holes for which the Kerr parameter a is bigger than the minimal one, $a_{\min}$, given by the solution of the equation

$$a_{\min}: \quad \log \tau_{\max} = \log \tau_{\min}(a) \qquad (4)$$

Figure 3 shows observational points taken from refs 1, 9 and 10 for seven objects which are closest to the original Elliot–Shapiro restriction (heavy line). The observations of OJ287 by Valtaoja *et al.* which suggest the most extremal flux and the most rapid rotation of the black hole are very recent ones and must still be confirmed. The five thin lines give the shortest possible $t_{\min}$ (that is for $\log \tau = 0.8$) in the case when $\lambda = 1$, 3, 10, 30 and $\lambda = 100$. In Table 1 we present estimations of $a_{\min}$ for these seven points. All the observational points are consistent with the black hole model. Figure 3 indicates that thick, but not thin, accretion disks can explain observations. In some cases observations show that the central black hole must rotate. More detailed analysis of the greater body of observational data is now in progress and the results will be published elsewhere.

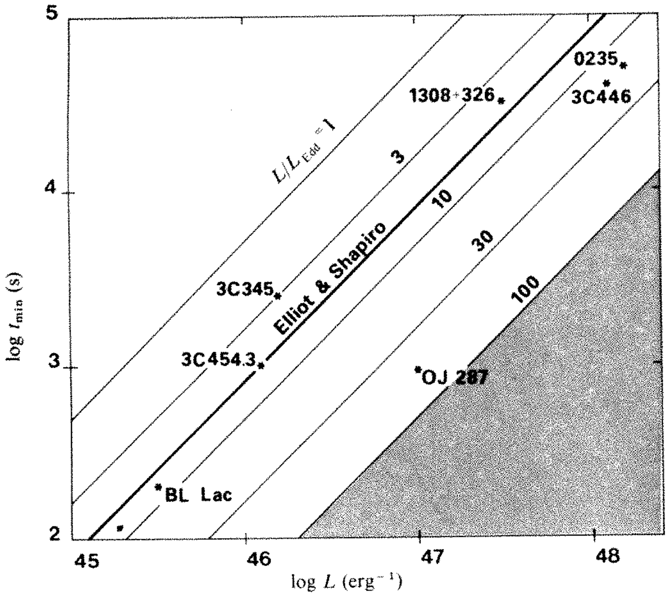

Fig. 3 Seven active galactic nuclei on the log L versus log t plane. The heavy line corresponds to the original Elliot–Shapiro relation ($\lambda = 1 = \tau$). Three thin lines give absolute lower limits for $t_{\min}$ in the cases $\lambda = 1$, 3, 10, 30, 100 ($\log \tau = 0.8$ is assumed on these lines). For almost all the objects $\lambda \gg 1$. This rules out thin accretion disks. Observational points in the dark region would contradict the black hole model.

$H_2CN^+ \cdot nN_2$ clustering formation and the atmosphere of Titan

C. V. Speller, M. Fitaire & A. M. Pointu

Laboratoire de Physique des Gaz et des Plasmas, Bâtiment 212,
Université Paris-Sud, 91405 Orsay Cedex, France

Measurements performed by Voyager 1 have revealed a dense atmosphere around Titan mainly composed of N_2 with some CH_4 and other minor components, including hydrocarbons and organic–nitrogen molecules[1–4]. Based on Voyager and some laboratory data, it is reasonable to assume that other complex organic–nitrogen molecules are formed in Titan's atmosphere[5–7]. Three-body association reactions are probably involved in the synthesis of such compounds[5,7,8]. It has been suggested[5] that the clustering of H_2CN^+ with N_2 or CH_4 could have an important role in these reaction mechanisms. Recently,[8] we observed the $H_2CN^+ \cdot N_2$ cluster ion in a N_2–CH_4 mixture irradiated by α particles. Here we report the results of laboratory measurements of equilibrium constants for the clustering of N_2 with H_2CN^+ leading to $H_2CN^+ \cdot nN_2$ ($n = 1$–6) formation, which should help in understanding the ion–molecule chemistry in the atmosphere of Titan.

The chemical complexity of Titan's atmosphere detected in the course of the Voyager 1 encounter has been accepted to be a result of the coupled chemistry of ion–molecule and neutral reactions[4,5,7,9]. In the lower atmosphere of Titan, where ionization results from cosmic-ray bombardment, lower temperatures and higher neutral densities are suitable conditions for three-body ion–molecule association reactions. The temperature and pressure in the region of maximum cosmic-ray activated chemistry are ~150–160 K and ~20 mbar (ref. 5).

The ion H_2CN^+ probably has a major role in the chemistry of Titan's atmosphere: it can be associated with N_2, CH_4 and C_2H_2 molecules leading possibly to formation of compounds such as CH_3CN, C_2H_3CN ... through three-body ion–molecule reactions, while it is assumed to be partially responsible (with $N(^4S)$ and $N(^2D)$) for HCN formation[10]. Although Voyager 1 did not directly observe any evidence of the presence of the H_2CN^+ ion, electron and ion measurements[11] suggest the presence of an ion with a mass of the order of 28 AMU, which is believed[11] to be H_2CN^+. Recently[12], this ion has been tentatively identified in the Earth's stratosphere: in fact, some of the chemical processes involved in the formation of prebiotic molecules in the atmosphere of Titan are probably similar to those which could have acted in the primitive Earth's atmosphere.

To gain some insight into the ion chemistry on Titan, we carried out a simulation experiment[8] in temperature, pressure and atmosphere composition conditions consistent with the interpretation of the Voyager 1 data. In this, a gas mixture of

0028–0836/82/490507—03$01.00

N_2 and CH_4 (~100:1–5) simulated Titan's atmospheric composition while ionization resulted from α particle (^{241}Am, 5.4 MeV, 40μCi cm^{-2}) bombardment. The irradiated gas bleeds through a leak into an evacuated electrode chamber. There the ions carried by the gas are captured by the electric fields while the gas is pumped away. The ions are focused, accelerated and then subjected to mass analysis and electron multiplier detection. The temperature (10–300 K) is carefully controlled and can be varied by means of a cryostat. The experiments were carried out in the pressure and temperature ranges 20–80 torr and 134–293 K respectively. As in our previous experiment, ^{15}N or CD_4 were used to identify the ions studied.

The ion intensities change with temperature in ways that suggest that they are formed by three-body reversible reactions, and thus

$$H_2CN^+\cdot(n-1)N_2+2N_2 \rightleftarrows H_2CN^+\cdot nN_2+N_2, \qquad n=1\text{–}6 \qquad (1)$$

The experimental results are summarized in Fig. 2 where the van't Hoff plots of the equilibrium constants are shown for the three-body association reactions (1). H_2CN^+ is produced by reactions starting with N^+ or $N_3{}^+$ ions and CH_4 (refs 5, 8, 10) (Fig. 1). The equilibrium constants, K_n are deduced from the observed ion current ratios, $I(H_2CN^+\cdot nN_2)/I(H_2CN^+\cdot(n-1)N_2)$, and from the N_2 pressure by the relation

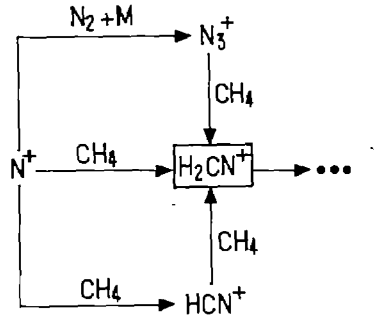

Fig. 1 N^+ ion-molecule reactions with CH_4 and N_2 leading to production of H_2CN^+.

$$K_n = I_n/I_{n-1}P_{N_2} \qquad (2)$$

Corrections were applied for variations in the mass spectrometer sensitivity with respect to the selected mass.

The corrected equilibrium constants are independent of the N_2 pressure, as assumed by relation (2) over the pressure range studied (20–80 torr). Also, within the experimental accuracy, no significant effects were observed on adding different proportions of CH_4 (~1–5%) nor when different voltages were applied in the electrode chamber. This is the experimental evidence of thermodynamic equilibrium.

Thermodynamic properties (Table 1) for the association reactions (1) were derived from the least-squares-fitted linear curves of Fig. 2 using the relation

$$K = \exp(\Delta S^\circ/R - \Delta H^\circ/RT)$$

where R is the perfect gas constant and it is assumed that variation in entropy, ΔS°, is small in the range of studied temperatures.

The data contained in Fig. 2 and Table 1 allow the relative concentrations of the ion clusters to be determined over a wide range of temperatures and pressures. An example of such equilibrium distribution is given in Fig. 3, for the N_2 pressure of 40 torr. This plot, which shows a characteristic behaviour of the reversible reaction (1), was obtained by the following procedure: a set of equilibrium constants was calculated by substituting the desired constant temperature T in the straight-line relationships (Table 1) $\log K_n = [A\times10^3)/T]-B$. The concentration of H_2CN^+ was then set equal to unity. The relative concentrations of the species $H_2CN^+\cdot nN_2$ were obtained using the equation $\log[H_2CN^+\cdot nN_2] = \log K_1 + \log K_2 + \ldots + \log K_n + n \log P_{N_2}$. By setting the sum of the concentrations as 100, the relative concentrations are obtained in per cent of the total.

Table 1 Thermodynamic values for the reactions $H_2CN^+\cdot(n-1)N_2+2N_2 \rightleftarrows H_2CN^+\cdot nN_2+N_2$

n	$-\Delta H^\circ$ (kcal mol^{-1})	$-\Delta S^\circ$ (cal mol^{-1} K^{-1})	$-\Delta G^\circ_{300}$ (kcal mol^{-1})	A†	B†
1	7.6*	35.4	−3.0	1.66	7.73
2	5.1	33.1	−4.8	1.12	7.24
3	3.2	26.3	−4.7	0.71	5.75

5	~3.2	~28.4	~−5.3	~0.7	~6.2

* From ref. 8.

† Constants for the equation $\log K_n = (A/T)\times10^3 - B$.

The $\Delta H_n{}^\circ$ values reported in Table 1 show that the $H_2CN^+\cdot nN_2$ cluster ions are very weakly bound and hence, collisional dissociation is expected to occur in the mass analysis system owing to collisions with 'background' gas. However, in a recent study on the $NO^+\cdot nN_2$ and $O_2{}^+\cdot nN_2$ formation, no evidence was found for this effect with respect to the equilibrium constant measurements.

Because N_2 is a weak base and has no dipole moment, the formation of large N_2 clusters is not expected. No results on the clustering of N_2 to H_2CN^+ leading to $H_2CN^+\cdot nN_2$ are available. The existence of these weakly bound cluster ions suggests that chemical bonding are also probably involved in their interactions. Hiraoka *et al.*[13] have shown that this is the case for $N_2H^+(N_2)_n$, $n=1$ to 6, that is the interactions are not

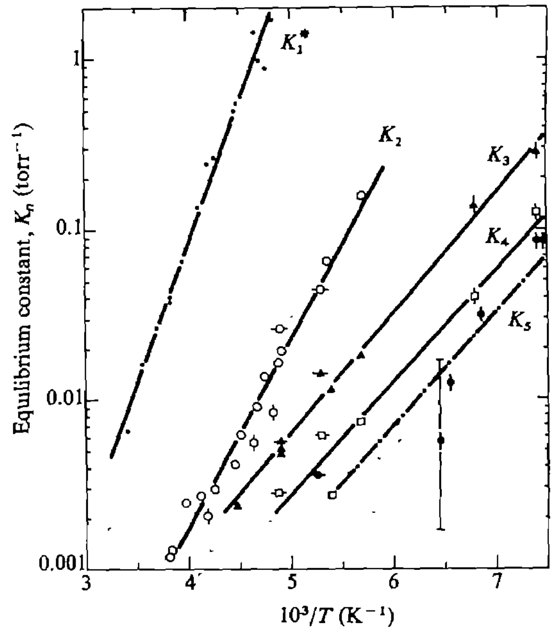

Fig. 2 Van't Hoff plots of equilibrium constants for reactions (1), (*from ref. 8). The dashed line for K_5 should be considered tentative, due to large measurement error (the estimated error for $T=155$ K, $n=5$, is shown). The estimated lower and upper limits for K_6, at $T=134$ K, are respectively 2.3×10^{-2} and 9.3×10^{-2} torr^{-1}. For clarity, K_6 is not drawn. Φ, ▲, ◫, ● 20 torr; ○, ▲, □, 40 torr; ⊖, ▲, ⊟, ●, 80 torr.

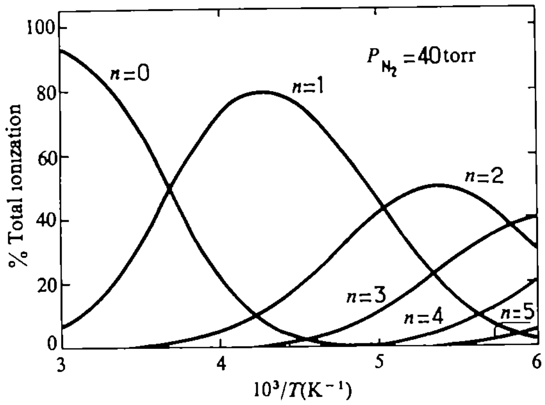

Fig. 3 Equilibrium distribution of ions $H_2CN^+ \cdot n\,N_2$ predicted by experimental data.

dominated by physical bonding (polarizabilities). There are some common features between the present results and those obtained by Hiraoka; for example (1) spacing between the lines of the van't Hoff plots shows a larger gap between the (0, 1) and (1, 2) equilibria; (2) the $\Delta H^{\circ}_{n-1,n}$ values are found to be almost constant between (2, 3,) and (4, 5); (3) these values are found to be nearly the same between (2, 3) and (4, 5) equilibria. The first feature indicates that $H_2CN^+ \cdot H_2$ and $N_2H^+ \cdot N_2$ are much more stable (towards loss of N_2) than the higher n complexes; the second feature shows that the stability decreases in that range are almost entirely due to entropy decreases. Finally, in both cases, $\Delta H^{\circ}_{n-1,n}$ decreases as n increases ending ultimately to the heat of vaporization of liquid N_2 (~1.3 kcal mol^{-1}).

The present results are consistent with the statement made by Capone *et al.*[4] on the possibility of $H_2CN^+ \cdot N_2$ association by three-body ion clustering reactions in the atmosphere of Titan. Furthermore they show that higher order associations are not excluded in this atmosphere.

Nevertheless, the high-altitude detection by Hartle *et al.*[11] of an ion of mass of the order of 28 AMU could also be interpreted as $C_2H_5^+$ (29 AMU) or N_2^+ (28 AMU). These ions are effectively observed in our mass spectra, as well as $C_2H_5^+ \cdot (N_2)_{1-5}$, $CH_5^+ \cdot (N_2)_{1,2}$ and $CH_3^+ \cdot (N_2)_{1,2}$. The lower limits for enthalpy and entropy changes for the three-body association reactions leading to $C_2D_5^+ \cdot (N_2)_{1,2}$ formation have been determined[14] recently in N_2–CD_4 mixtures. Moreover, the presence of small amounts of C_2H_2 in the atmosphere of Titan must have a very important effect on the ionic populations as we observe[15] in this experiment: ions such as $[(C_2H_2)_n(N_2)_m]^+$ and $X^+(C_2H_2)$ (where $X = C_3H_3, C_3H_4, C_3H_5, \ldots$) have been detected with very small admixture of C_2H_2 in N_2 and N_2–CH_4 mixtures respectively.

Enhanced soft X-ray detection efficiencies for imaging microchannel plate detectors

G. W. Fraser, M. A. Barstow, M. J. Whiteley & A. Wells

X-ray Astronomy Group, Department of Physics, University of Leicester, Leicester LE1 7RH, UK

Position-sensitive detectors using microchannel plate (MCP) electron multipliers have been widely used in X-ray astronomy[1–3]. Although MCPs facilitate X-ray imaging with high spatial resolution, as on the Einstein[1] or EXOSAT[3] satellites, their intrinsic soft X-ray detection efficiencies are low. These lie typically in the range 1–10% (ref. 4), much lower than the (near unity) values attainable with competing forms of gas proportional counter. To enhance sensitivity to X-ray energies below a few keV, a material of relatively high photoelectric yield may be deposited on the MCP front surface and channel walls. MgF_2 has commonly fulfilled this role for X-ray astronomy[1–3], resulting in enhanced efficiencies 1.1–1.6 times those of uncoated MCPs[1]. We report here high 0.18–1.5 keV X-ray detection efficiencies for MCPs bearing CsI deposition photocathodes. Efficiency enhancement factors, dependent on X-ray incident angle, of up to 15 times have been stably obtained. The importance of this work for the sensitivity of future X-ray astronomy experiments, such as the Röntgensatellit (ROSAT) Wide Field Camera, is outlined.

A microchannel plate, formed by the drawing and etching of a lead glass matrix, consists of many (~10^6) hollow channels of common diameter 10–50 μm electrically connected in parallel. When a large bias voltage is applied along their length these channels can be made to act as a regular array of miniature photomultipliers. The many applications of MCPs have been reviewed by Wiza[5]. In the MCP's role as focal plane detector for grazing incidence X-ray optics[1,3] its above-mentioned inefficiency, even with the small enhancements provided by MgF_2 coating, has been a major factor in determining overall X-ray telescope sensitivities.

The adoption of MgF_2 as a 'standard' MCP coating for X-ray astronomy has been based on its relative photoelectric stability in a normal laboratory atmosphere[6] and not on its 'optimum' photoelectric yield properties in any absolute sense. A detailed study of X-ray photocathodes was therefore undertaken to identify, without experimental precondition, truly optimum candidate coating materials[7]. A collation of 1–300 Å X-ray photoemission data from many sources within a simple, predictive theoretical framework is given in ref. 7. CsI is found to be potentially a much superior MCP coating material to MgF_2 provided its hygroscopic nature—and hence possible instability in normal atmospheric humidity—can be accommodated by careful detector preparation and handling techniques.

Measurements were made on two position-sensitive X-ray detectors incorporating Mullard microchannel plates. The first of these (detector A) used a pair of MCPs of channel diameter $D = 12.5$ μm in a 'chevron'[5] arrangement. The input MCP (on which the CsI was deposited) had channels with a length-to-diameter ratio $L/D = 120:1$ biased at an angle $\phi = 4°$ to the front surface normal. The rear plate of this chevron was characterized by $L/D = 80:1$, $\phi = 13°$. The second detector (detector B) employed two 25-μm channel diameter MCPs, both of $L/D = 80:1$, with bias angles $\phi = 0°$ (input MCP) and $\phi = 13°$ (rear MCP).

The final stage in MCP manufacture is a reduction of the lead oxide glass content in a hydrogen atmosphere. New MCPs therefore copiously outgas water vapour and must be subjected to a prolonged vacuum bake before receiving a hygroscopic

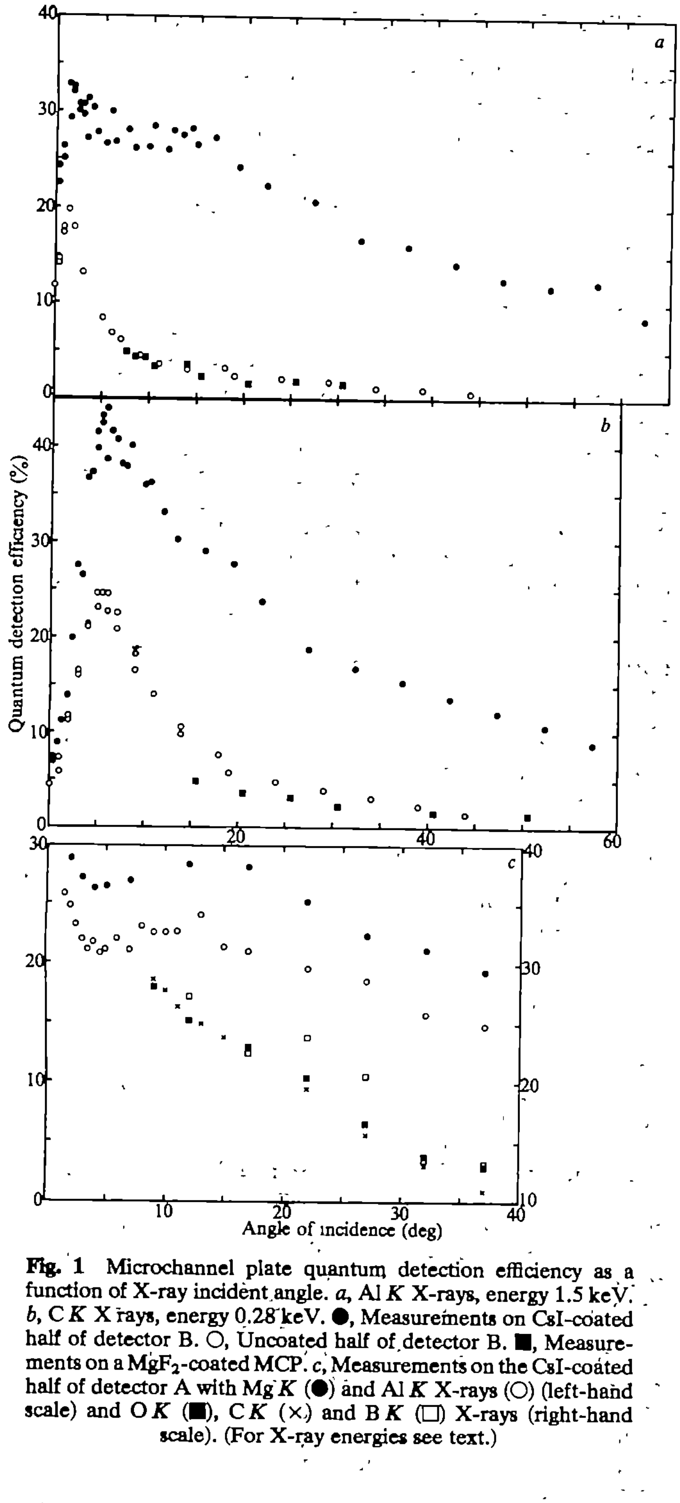

Fig. 1 Microchannel plate quantum detection efficiency as a function of X-ray incident angle. *a*, Al *K* X-rays, energy 1.5 keV. *b*, C *K* X rays, energy 0.28 keV. ●, Measurements on CsI-coated half of detector B. ○, Uncoated half of detector B. ■, Measurements on a MgF_2-coated MCP. *c*, Measurements on the CsI-coated half of detector A with Mg *K* (●) and Al *K* X-rays (○) (left-hand scale) and O *K* (■), C *K* (×) and B *K* (□) X-rays (right-hand scale). (For X-ray energies see text.)

coating. All our MCPs were vacuum-baked for 48 h at a temperature of 275 °C. The partial pressure of evolved H_2O was thus reduced by a factor of $\sim 10^3$, giving a final value of $\sim 10^{-10}$ torr (at room temperature) comparable with the partial pressures of secondary products—CO, N_2 and CO_2—revealed by mass spectral analysis.

CsI coatings were vacuum-evaporated onto one-half of each input MCP to a thickness of 6,000 Å on the MCP front surface. A nominal coating angle (between the molybdnum evaporation vessel and the normal to the centre of the MCP) of 15° was used for both detectors. The MCPs, preheated to 100 °C before CsI deposition, were rotated during the evaporation to ensure coating uniformity on the channel walls. The coating angle–front surface thickness combination used here produced a coating extending $\sim 3.7\,D$ down the channels with a characteristic thickness of 400 Å, about twice the escape length for X-ray-induced secondary electrons in CsI (ref. 7). The coated MCPs were then assembled into their respective detector bodies. All manipulations and transfers of the MCPs after bake-out took place in a local atmosphere of dry N_2 with the coated plates protected additionally by removable detector caps whenever possible. Thus, on entry into the vacuum chamber used for efficiency measurements, the CsI coatings had been exposed to air for only a few tens of seconds.

A comprehensive study of detector gain and noise count was made for each detector at operating pressures between 1 and 2×10^{-5} torr. Satisfactory peak gains and narrow pulse height distributions were obtained for both detectors. A peak gain $G = 3\times10^7$ and FWHM $\Delta G/G = 45\%$ were easily achievable with detector A. Noise count rates of the order of 0.5 $cm^{-2}\,s^{-1}$ (3–5 s^{-1} over total detector areas) were consistently obtained.

X-ray quantum detection efficiencies were measured for a range of X-ray energies and incident angles (the angle between the X-ray beam and the input MCP channel axis). The experimental technique was essentially that of Bjorkholm *et al.*[8]. The intensity of the incident X-ray beam, produced by a filtered, collimated fluorescence source, was measured using a pill-box type Ar–CH_4 (90:10 mixture) gas proportional counter[6] of known window absorption. Figure 1*a* displays detection efficiency versus incident angle for both CsI-coated and bare glass halves of detector B illuminated by Al *K* X rays of energy 1.5 keV. Use of a CsI deposition photocathode has dramatically increased the MCP efficiency at all angles. The prompt nature of the photoemission process (on time scales of 10^{-14} s) and the long dead time of an individual microchannel ($\sim 10^{-2}$ s)[5] dictate that the absorption of an X ray can give rise to at most one output pulse: the enhancement shown in Fig. 1*a* is not due to multiple pulses generated by a single photon. Figure 1*a* also shows measurements made in this laboratory on an MgF_2-coated MCP (M. Lewis, personal communication). The coating angles and thicknesses of the CsI and MgF_2 photocathodes were identical, although the pre-coating histories and quantum efficiencies of their MCP substrates differed. Figure 1*b* is the analogous figure for C *K* X rays, of energy 0.28 keV. All the efficiency–angle curves can be simply interpreted in terms[4] of (1) the increase in photoelectric yield with decreasing grazing angle to the channel walls until (2) the onset of X-ray reflection, (3) the fraction of X rays incident on the coated channel walls, (4) the geometric transparency of the MCP, (5) the divergence of the test beam (±0.5° FWHM).

Figure 1*c* shows efficiencies measured on the CsI-coated half of detector A for Al *K*, Mg *K* (1.25 keV), O *K* (0.525 keV), C *K* and B *K* (0.18 keV) X rays. Some spectral impurity of the O *K* line, arising from carbon contamination of the source anode, was possible with the present source–filter arrangement. Small-angle efficiencies have been omitted for clarity. Measured peak efficiencies in the order of decreasing X-ray energy were: 34.1, 35.6, 41.9, 48.1 and 38.3%. Detector A and B efficiencies are comparable, given the small differences between detectors due to bias voltage and channel geometry.

No measurements of the uniformity of the detection efficiency across the MCP surface were possible within the present vacuum system. A careful study of the photocathode deposition geometry has, however, been made to ensure that variations in the CsI coating profile were minimized within and between channels.

Repeat measurements on detector A were done to establish the ability of the CsI coating to withstand the vacuum breaking inevitable in the development of a flight detector for X-ray astronomy. No significant changes in gain, noise count or efficiency were noted during 11 cycles between vacuum and a dry N_2 environment, involving an accumulated input to the CsI of 5×10^5 photons mm^{-2} over a period of 18 days under continuously pumped vacuum. Detector B, by contrast, was subjected to several deliberate exposures to laboratory air. Relative humidity on exposure varied between 42 and 53% with ambient temperatures of 22–25 °C. No degradation in CsI efficiency was observed even after an accumulated exposure time of 8 h. Work continues to establish the long term stability of the response of CsI-coated MCPs under various methods of storage. We note here that planar CsI XUV photocathodes have been found to be stable after 9 months of storage in dry N_2 (ref. 9).

These preliminary measurements indicate that CsI deposition photocathodes can provide a simple, stable and reproducible means of producing high efficiency microchannel plate X-ray detectors both for X-ray astronomy and other imaging applications[5]. We stress that the efficiencies reported here do not represent the limits attainable using a deposition photocathode technique. A thicker CsI layer, deposited at smaller coating angle, should appreciably increase peak efficiencies. Further, in the work discussed above, there is no contribution from the inter-channel area (37% of the MCP front surface) to the detection efficiency because of its large negative potential (~ -3.5 kV). As the input MCP is preceded by an earthed carbon-coated plastic film, photoelectrons released from the front surface are directed away from the channel entrances[4]. The use of a high transparency grid to establish an appropriate electron collecting field at the MCP input may be expected to increase detection efficiencies at all angles of incidence.

Calculations based on the work described in refs 4 and 7 and supported by the present data, indicate that an MCP efficiency of 45% should be attainable for an X-ray energy of 0.1 keV and an incident angle of 30°. Such a combination is directly relevant to the Wide Field Camera (WFC), an XUV telescope now being developed by a consortium of UK research groups for flight on the German national ROSAT[10] in 1987. The WFC is intended to carry out the first XUV (0.04–0.2 keV) sky survey. Use of a CsI-coated MCP is expected to increase the WFC sensitivity by a factor ~4 times relative to the MgF_2-coated detector of the design study (R. Willingale, personal communication).

Calculations also indicate an efficiency of at least 20% for 6-keV X rays incident at 4° to the channel axes, about six times the corresponding efficiency of an uncoated MCP. This energy-angle combination is of interest for focal plane instrumentation for AXAF[11], NASA's principal mission in X-ray astronomy planned for the next decade.

We thank Mr H. Chapman for technical assistance and Professor K. A. Pounds for his interest and encouragement. This work was supported by the SERC.

Seasonal effects of temperature and salinity on the partial pressure of CO_2 in seawater

R. F. Weiss, R. A. Jahnke & C. D. Keeling

Scripps Institution of Oceanography, University of California,
San Diego, La Jolla, California 92093, USA

The exchange of CO_2 between the atmosphere and the sea is of major importance to our understanding of the climatic consequences of anthropogenic CO_2. Because the solubility of CO_2 and the dissociation of carbonic acid in seawater are modulated by temperature and salinity, the detection of long-term changes in the oceanic carbonate system, first requires that the comparatively large short-term variations in the partial pressure of CO_2 should be characterized. We present here the first direct observations of seasonal variations in the partial pressure of CO_2 in the subtropical gyres of the North and South Pacific Ocean. These variations compare well with the variations predicted from observed changes in temperature and salinity using empirical equations which do not require the determination of alkalinity or total inorganic carbon, and the agreement is improved by the inclusion of air–sea exchange in the model calculations. Thus we predict that specific alkalinity within the two gyres remains extremely constant, which is confirmed by carbonate equilibrium calculations based on our measurements of total inorganic carbon.

The measurements were carried out as part of the NORPAX Equatorial Experiment during a series of month-long oceanographic expedition legs extending between Papeete, Tahiti and Honolulu, Hawaii. Continuous shipboard measurements of CO_2 partial pressures in surface waters were carried out between August 1979 and June 1980 aboard RV *Wecoma* on the northbound expedition Legs 7, 9, 13 and 15. The analyses were made using automated dual-catalyst flame ionization gas chromatography[1] to determine the mole fraction of CO_2 in a dried aliquot of a gas phase which was equilibrated continuously with seawater pumped from a depth of ~3 m. The results were corrected for slight warming in the pumping and equilibration system using the empirical temperature dependence given below (equation (1)). Measurements of atmospheric CO_2 mole fractions were also made by the shipboard chromatographic system. Standard deviation of replicate chromatographic CO_2 measurements is ~0.04%, and the estimated systematic uncertainty of these measurements, including uncertainties associated

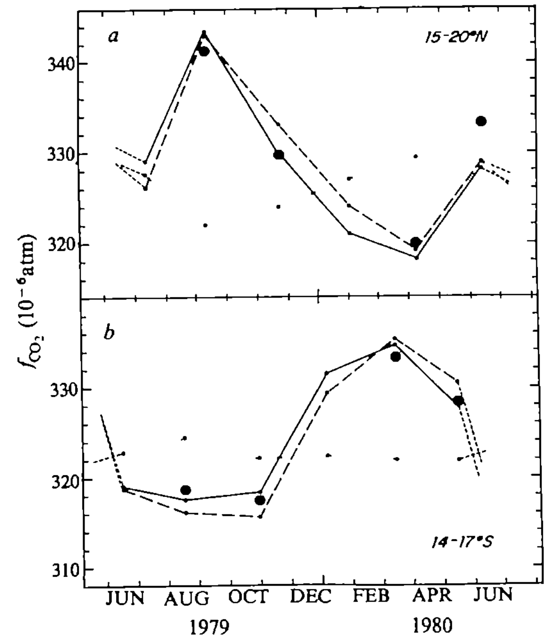

Fig. 1 Seasonal variations in the equilibrium fugacity of CO_2 in surface ocean water of the tropical limbs of the North Pacific (*a*) and the South Pacific (*b*) subtropical gyres. The regional mean measured seawater fugacities are plotted as solid circles, and the fugacities of atmospheric CO_2 at the water-saturated air–sea interface are connected by dotted lines. Surface ocean water fugacities predicted from temperature and salinity without air–sea exchange are shown as dashed lines, and with air–sea exchange are shown as solid lines (see text).

† Fugacities at the water-saturated air–sea interface.

with the calibration of compressed air standards by nondispersive IR analysis and manometric techniques[2], is ~0.05%. An additional estimated uncertainty of 0.5% is associated with possible systematic effects in the seawater equilibration process.

Measurements of atmospheric CO_2 were also made by shorebased nondispersive IR analysis[2] using flask samples collected in triplicate on all the NORPAX expedition legs. The standard deviation of replicate flask measurements is ~0.06%, with an additional systematic uncertainty of ~0.04%.

Seawater samples for shorebased determination of total inorganic carbon (ΣCO_2) were collected at hydrographic stations on northbound odd-numbered expedition legs using Niskin bottles at a depth of 10 m. The samples were collected in duplicate and were preserved with $HgCl_2$. The ΣCO_2 measurements were made by acidifying a weighed sample and trapping the evolved CO_2 with liquid nitrogen in a vacuum system. The CO_2 was separated from H_2O with a dry ice trap and was then determined manometrically with the same constant volume manometer used to determine the mole fraction of CO_2 in air[2]. The standard deviation of replicate samples is 0.7 μM kg^{-1}, and the accuracy, as judged from artificial samples, is ~1.0 μM kg^{-1}.

The measured concentrations of CO_2 in the equilibrated gas and in the atmosphere were converted to fugacities for the purpose of evaluating real-gas equilibrium relationships, using the virial equation of state[3] and assuming a water-saturated interface at the measured barometric pressure. The solubility of CO_2 in seawater as a function of fugacity was taken from the equations in ref. 3. Calculations of carbonate system equilibria were carried out using the dissociation constants in seawater of carbonic acid, boric acid and water, as measured on the hydrogen ion concentration scale by Hansson[4] and fitted to the equations of Millero[5]. These values were chosen in preference to the measurements on the NBS buffer scale[6–8], principally because the Hansson values for boric acid are in better agreement with the work of Millero[9] and with the recent measurements of A. Dickson (personal communication) than are the Lyman values[7]. Note, however, that the results presented below are not strongly dependent on the choice of dissociation constants[5].

The temperature dependence of the fugacity of CO_2 (f_{CO_2}) in a gas phase in thermodynamic equilibrium with seawater at constant total titration alkalinity (A_T) and constant ΣCO_2 was determined empirically from calculated equilibria. Values of f_{CO_2} were calculated over the ranges of 0–36 °C in temperature (t), 30–38‰ in salinity (S), 64–68 μequiv. kg^{-1} ‰$^{-1}$ in specific alkalinity (A_T/S), and 1.05–1.20 μequiv. μM^{-1} in the $A_T/\Sigma CO_2$ ratio. The resulting values of f_{CO_2} bracket the atmospheric range at all temperatures and salinities and include extrema from 80 to 2,000 μatmospheres (atm). For each combination of ΣCO_2, A_T and S, $\ln(f_{CO_2})$ was fitted by least squares to a power series in t. These expressions were then differentiated to obtain values of $\partial \ln(f_{CO_2})/\partial t$, which were again fitted to the equation

$$\frac{\partial \ln(f_{CO_2})}{\partial t} = 0.03107 - 2.785 \times 10^{-4}\, t - 1.839 \times 10^{-3} \ln(f_{CO_2}) \quad (1)$$

which represents the temperature dependence of the calculated fugacities with a standard deviation of 0.05% °C^{-1}. The precision of this fit greatly exceeds those of previous empirical representations[10].

The salinity dependence of f_{CO_2} at constant specific alkalinity and constant specific total inorganic carbon ($\Sigma CO_2/S$) was determined in an analogous fashion to the temperature dependence, using values of f_{CO_2} calculated over the same ranges of t, S, A_T, and $A_T/\Sigma CO_2$. For each combination of t, A_T/S and $\Sigma CO_2/S$, $\ln(f_{CO_2})$ was fitted to a power series in S, differentiated to obtain values of $\partial \ln(f_{CO_2})/\partial S$, and fitted to the equation

$$\frac{\partial \ln(f_{CO_2})}{\partial S} = 0.08620 - 1.272 \times 10^{-3}\, S \quad (2)$$

which represents the salinity dependence of the calculated fugacities with a standard deviation of 0.06% per ‰ salinity.

An important characteristic of equations (1) and (2) is their independence from A_T and ΣCO_2, which makes it possible to evaluate the effects of temperature and salinity variations on f_{CO_2} in nature and in experimental applications without the need to determine other parameters of the dissolved carbonate system. Both equations are easily integrated in modelling applications, without significant loss in accuracy compared with equilibrium calculations for waters with well-characterized carbonate systems.

The results of the NORPAX f_{CO_2} measurements in the North and South Pacific subtropical gyres are summarized in Table 1. The mean values listed are confined to the tropical limbs of the gyres north of 15° N and south of 14° S, where the continuous chromatographic measurements do not show the increase in f_{CO_2} due to upwelling in the equatorial region[11]. To facilitate comparisons between the chromatographic measurements and the hydrographic observations spaced at 1° latitude intervals[12], the tabulated values include only the chromatographic measurements at the individual station locations. In addition to the data for expedition Legs 7, 9, 13 and 15, on which the chromatographic measurements were made, Table 1 includes hydrographic and atmospheric CO_2 flask data for adjoining Legs 5 and 11.

The seasonal variations of surface water f_{CO_2} in both gyres are plotted in Fig. 1. The peak-to-peak amplitude of the variations is about 20 μatm, with both hemispheres showing summer maxima. The predicted variations in f_{CO_2}, calculated from the observed changes in temperature and salinity by integration of equations (1) and (2) with the fugacity boundary condition adjusted to minimize the r.m.s. deviation of the measured fugacities, are plotted for each hemisphere as dashed lines in Fig. 1. The agreement between the measurements and these calculations, which do not allow for air–sea exchange or for seasonal variations in the admixture of waters with other carbonate chemistry, is nonetheless striking, with r.m.s. deviations of 3.0 and 2.3 μatm in the northern and southern gyres respectively. Thus, the observed variations in both hemispheres are due mainly to seasonal variations in surface water temperature and salinity, rather than to removal or addition of CO_2 by physical or biological processes.

We have considered the effect on f_{CO_2} of biological activity, as reflected in the surface water nutrient concentrations[12]. Assuming carbonate chemistry equilibrium, the Redfield, Ketchum and Richards mean planktonic composition[13], and the complete assimilation of available nitrate, the maximum predicted f_{CO_2} variation is 0.3 μatm in the northern gyre and 0.6 μatm in the southern gyre. However, inasmuch as the measured surface water nitrate values in these regions remain at or below the 0.1 $\mu M\,kg^{-1}$ detection limit, we have neglected this small effect in our model calculations.

The solid lines in Fig. 1 show the effect of including air–sea exchange in the calculations. This was done by a simple numerical integration, in which the CO_2 flux was assumed to be proportional to the fugacity difference between the surface water and the measured atmosphere, the mean exchange rate was taken as $22\,M\,m^{-2}\,yr^{-1}$ (refs 14, 15), the mean depth of the mixed layer determined from the hydrographic data was 70 m, the mean values of t, S and atmospheric f_{CO_2} were interpolated linearly between legs, and the mean buffer factor $\partial\ln(f_{CO_2})/\partial\ln(\Sigma CO_2)$ calculated from the chemical constants discussed above was 8.35 in the northern gyre and 8.50 in the southern gyre. As in the case of the conservative calculation, the fugacity boundary condition in each hemisphere was adjusted to minimize the r.m.s. deviation of the measured seawater fugacities. The main effect of adding air–sea exchange to the calculations is a slight advance in the phase of the predicted variations, which further reduces the r.m.s. deviations to 2.6 and 1.1 μatm in the northern and southern gyres respectively.

This excellent agreement between the measured values of f_{CO_2} and the predicted variations for a model which is conservative in CO_2 except for air–sea exchange, requires that the salinity-normalized alkalinity in both gyres be constant to within about 2 $\mu equiv.\ kg^{-1}$. To test this hypothesis, we have calculated A_T from our ΣCO_2 and f_{CO_2} measurements using the chemical constants discussed above. The mean values of A_T normalized to $S = 35‰$ are listed in Table 1. The averages and standard deviations of the normalized values of A_T for the four expedition legs are $2{,}319.3 \pm 2.0\ \mu equiv.\ kg^{-1}$ in the northern gyre and $2{,}319.6 \pm 1.8\ \mu equiv.\ kg^{-1}$ in the southern gyre. The results thus confirm the remarkable seasonal constancy of specific alkalinity in the tropical limbs of the Pacific subtropical gyres, and demonstrate that seasonal variations in their CO_2 fugacities may be calculated directly from changes in temperature and salinity, with a small correction for air–sea exchange.

Note that the seasonally averaged surface water CO_2 fugacities in the tropical limbs of both gyres are significantly greater than the seasonally averaged atmospheric fugacities (Fig. 1), and there is therefore a net flux of CO_2 from the sea to the atmosphere of the order of $0.1\,M\,m^{-2}\,yr^{-1}$. While part of this flux may be due to upwelling across the thermocline, we expect the major source to be thermal pumping of atmospheric CO_2 which dissolves in the cooler high-latitude limbs of the gyres and is subsequently liberated as these surface waters are advected into the tropics and warmed. However, seasonal measurements of CO_2 in higher latitudes are needed to determine the relative importance of these mechanisms.

We thank F. A. Van Woy, P. R. Guenther and A. F. Herron for their contributions to the shipboard and shorebased analytical work; and the officers and crew of the RV *Wecoma*, the NORPAX scientific participants and the staff of the Scripps Physical and Chemical Oceanographic Data Facility for their help and cooperation. This work was supported by the US Department of Energy and the NSF.

A new type of decollement thrusting

One of the fundamental rules of decollement tectonics is that decollement horizons form in mechanically weak layers[1,2]. Here we document two examples of decollement-style thrust faults that detach within thick platformal dolostones in preference to apparently weaker layers of shale, siltstone and limestone underlying the dolostones. The thrusts are the Keystone–Muddy Mountain–Glendale thrust system (the KMG thrust system), , and the underlying Contact–Red Spring–North Buffington–Mormon thrust system (the CRM thrust system), both of southern Nevada. They form part of the Sevier orogenic belt, and extend for roughly 250 km along strike, together showing at least 65 km tectonic overlap (Fig. 1). Although the thrust systems are closely related spatially, the higher KMG system is younger than the underlying CRM thrust system, and the two developed essentially independently[3–7]. Three points are important: first, that both the KMG and the CRM thrust systems are decollement style thrusts; second, that the decollement horizon is primarily restricted to a narrow stratigraphical interval within a bedded sequence of essentially homogeneous dolostones of the Middle Cambrian Bonanza King Formation; the third, that the thrust faults formed at a very shallow crustal level (<5 km).

Detailed field studies in the past 15 yr have yielded a wealth of structural and stratigraphical data for the thrust systems in question[5–12]. To demonstrate a decollement geometry for any foreland thrust, it is sufficient to show that the thrust fault carries the same structural or stratigraphical unit in the hanging wall for a large distance across strike (in the transport direction). If this criterion is met, the thrust fault must have decollement geometry, regardless of later deformations. The two thrust systems are discussed separately—first the CRM thrust system, then the KMG thrust system.

Both the KMG thrust system and the CRM thrust system carry the Banded Mountain Member of the Bonanza King

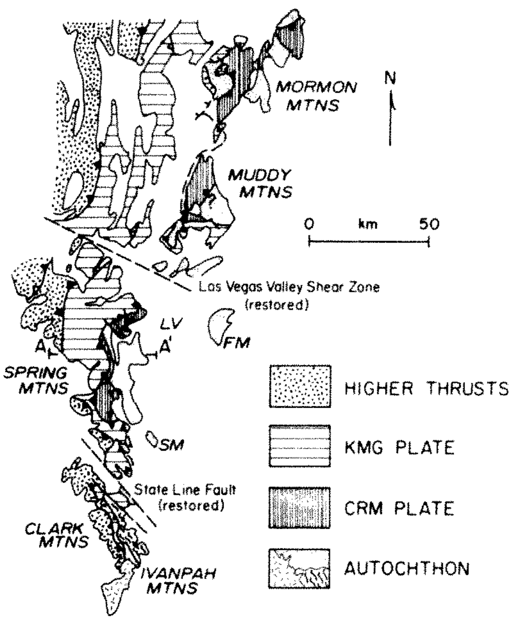

Fig. 1 Simplified tectonic map of the Keystone–Muddy Mountain–Glendale and Contact–Red Spring–North Buffington–Mormon thrust systems. Right-lateral movement on the Tertiary Las Vegas Valley shear zone and Pahrump-State Line fault zone has been removed. Thrust transport direction is roughly east-northeast[9]. LV, Las Vegas; FM, Frenchman Mountain; SM, Sheep Mountain.

Formation in the hanging wall for great distances along and across strike. With a few exceptions, the thrust faults virtually everywhere occur within 75 m of a distinctive marker horizon at the base of the Banded Mountain Member[10,11,13]. The Middle and Upper Cambrian Bonanza King Formation (for original definition, see ref. 14) is the basal unit of the thick Palaeozoic miogeoclinal platform carbonate sequence of the southern Great Basin. Two members are commonly identified: the upper Banded Mountain Member and the lower Papoose Lake Member[9,13,15]. The Banded Mountain Member generally consists of well-bedded dolostone with rare limestone in the region of Fig. 1; the Papoose Lake Member generally consists of mottled dolostone and limestone[13]. The Banded Mountain Member averages ~500 m in thickness where a complete section is exposed; the Papoose Lake Member varies between 175 and 450 m thick, where exposed (Fig. 2).

The Banded Mountain Member forms the hanging wall of the Mormon thrust fault for a distance of at least 40 km in the transport direction[7]. The Mormon thrust fault is probably correlative with the North Buffington thrust in the central Muddy Mountains, and the Red Spring and Contact thrusts in the central Spring Mountains[6,7]. All of these correlative thrusts carry the Banded Mountain Member of the Bonanza King Formation in the hanging wall[6,12]. The CRM thrust system carries the same unit in the hanging wall for at least 40 km across strike and at least 150 km along strike; it therefore has a decollement geometry.

Thrust faults in the KMG thrust system carry the Banded Mountain Member of the Bonanza King Formation in the hanging wall for 15 km across strike in the northern Clark Mountains[5,8], for 8–10 km across strike in the central Spring Mountains[10,16], and for at least 25 km across strike in the Muddy Mountains[6]. The KMG thrust system carries the Banded Mountain Member in the hanging wall for nearly 200 km along strike, from the southern Mormon Mountains in the north[7], through the Muddy Mountains[6] and Spring Mountains[5,9] to the Clark and Ivanpah Mountains of southeastern California[8]. Therefore, the KMG thrust system also has decollement geometry, by the criterion above.

The phrase 'in the hanging wall' is used to denote that part of the upper plate immediately adjacent to the thrust fault itself: 'hanging wall' means the bottom surface of the upper plate of the thrust, and not volume of the upper plate.

Because the Banded Mountain Member forms the hanging wall for virtually all of the exposures of both thrust systems, it is clear that this unit contains the decollement horizon for the exposed portions of the thrusts. To demonstrate that a decollement horizon formed within the Bonanza King Formation in preference to the underlying Middle and Lower Cambrian limestones, shales and siltstones, it must be shown that the Papoose Lake Member was present beneath the Banded Mountain Member in the allochthon before formation of the thrust faults.

Complete sections of Cambrian strata are exposed in the autochthon in the Mormon Mountains, at Frenchman Mountain, at Sheep Mountain and in the Ivanpah Mountains (see Fig. 1). All three of these sections contain a thick Papoose Lake Member[7,9,17,18]. The Papoose Lake Member is also present in the higher allochthons west of the KMG thrust system[8,9,19,20]. The Papoose Lake Member and underlying strata are regionally extensive, present everywhere the entire Cambrian section is exposed both east and west of the two thrust systems discussed here. It follows that these beds were originally present beneath the Banded Mountain Member of both the KMG and CRM allochthons, and were left behind beneath the decollement during thrust faulting. This is supported by the occurrence of slivers of the Papoose Lake Member preserved locally above the thrusts[12,18].

It is possible that the decollement in the Banded Mountain Member is not a basal decollement, but rather the roof fault for a duplex structure at depth. There is no structural evidence for such a duplex: if one exists it is nowhere exposed, and an internally consistent set of balanced cross-sections can be drawn without postulating such a structure. In addition, the CRM thrust system, overlying KMG thrust system, and still higher Green Monster–Lee Canyon thrust system all carry the basal beds of the Banded Mountain Member in the hanging wall in virtually every exposure; the Papoose Lake Member is present only as slivers, and lower units are not present at all. The simplest explanation is to postulate a master decollement near the base of the Banded Mountain Member.

We infer that the CRM and the KMG thrust systems formed at shallow levels on the basis of the general absence of ductile deformation within the thrust sheets and the presence of fore-thrust debris and stream-channel conglomerates in the footwall of both thrust systems. The absence of pervasive ductile defor-

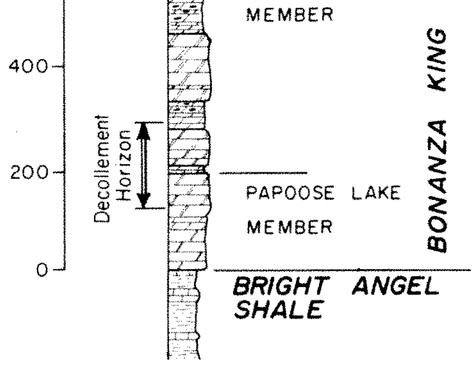

Fig. 2 Generalized stratigraphical column of the Bonanza–King Formation in the area of Fig. 1. Decollement horizon of the Keystone–Muddy Mountain–Glendale and Contact–Red Spring–North Buffington–Mormon thrust systems lies at base of the Banded Mountain Member.

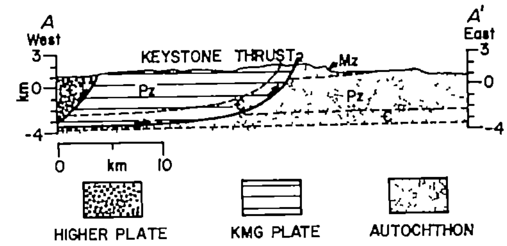

Fig. 3 Cross-section of the Keystone thrust system in the central Spring Mountains (A–A' in Fig. 1), showing decollement nature of the fault and simple ramp geometry. No vertical exaggeration.

mation merely implies that the thrusts did not form in metamorphic conditions. The presence of forethrust debris beneath the thrust faults implies that both thrust systems were 'erosional thrusts'; thrust systems whose fault plane lay at or near the surface of the Earth during thrusting, and whose upper surface was a topographic surface during thrust advance[21–23,30]. A typical cross-section through the central Spring Mountains (Fig. 3) shows that the Keystone thrust fault forms a single ramp from the decollement horizon in the Banded Mountain Member of the lower plate to the ancient erosional surface. The autochthonous section is roughly 4.5 km thick at the Keystone ramp; therefore the thrust fault at the base of the ramp must have been no more than 5–5.5 km below the surface at the time of formation, allowing for post-Keystone erosion. A similar argument holds for the CRM thrust system.

One important aspect of the Banded Mountain Member decollement surface is its very large area. Palinspastic restoration of the displacements on the two thrust systems provides an estimate of the initial size of the decollement surface. The length along strike is at least 200 km, from exposures of the KMG thrust system. Adding values of tectonic overlap for the KMG and CRM thrust systems will give a minimum value for the across strike extent of the decollement surface. Minimum overlap on the CRM system is 40 km (ref. 7); minimum overlap on the KMG system is 25 km (ref. 6). The decollement formed in the Banded Mountain Member must then be at least 65 km wide; the total area of the decollement must be at least 13,000 km^2.

The principal mechanism of deformation near the thrust faults appears to be cataclasis[24]. Moderate to intense brecciation is common in the upper plate up to several tens of metres away from the fault[7,8,10–12,18,25]. Evidence for extensive ductile deformation within the thrust sheets is present only in the Clark Mountains at the southernmost end of the Keystone thrust, where late syn-tectonic plutonism provides a source for heat and fluids[8,18]. Evidence for ductile deformation near the thrust fault disappears a short distance away from the plutons.

Of paramount importance in the problem of formation of this decollement surface is that there are no lithological reasons for postulating any special mechanical properties for the rocks of the Banded Mountain Member in the decollement zone: there are no shaley layers, no gypsiferous layers, nothing but monotonous fine-grained laminated dolostone locally including secondary, recrystallized coarse-grained dolomite (Fig. 2). This has been established by detailed stratigraphical and petrological studies in both allochthonous and autochthonous sections[5,16]. The formation of the decollement horizon appears to be controlled by factors other than lithological contrasts within the decollement zone.

The key mechanical problem is not the transport of these thrust systems, although that problem is complex, and despite recent purely theoretical models[23,26] is still poorly understood. The main mechanical problem is: why did the decollement form within the dolostones, ignoring shale only a few hundred metres below? Our present view is that when subjected to horizontal compression the highly competent dolostones acted as a stress guide, concentrating horizontal stress within the dolostones unit with respect to the weaker materials below[27]. Preliminary modelling studies by one of us (J.H.W.) indicate that this variation in horizontal stress may have a key role in the localization of the decollement horizon.

The observation that the thrusts formed at shallow crustal levels is very important in light of the low strength of shale, siltstone and limestone in brittle conditions[28]. Our finding that the decollement formed within the strong dolostones in preference to the apparently weaker underlying layers demonstrates that a low-strength layer at the decollement horizon is neither a necessary nor a sufficient condition for the formation of a decollement thrust in the orogenic foreland. Existing theories of foreland thrusting appear inadequate to explain the formation of these decollement zones[2,29]. We suggest that the Keystone–Muddy Mountain–Glendale thrust system and the Contact–Red Spring–North Buffington Mormon thrust system represent type examples of a class of 'strong' decollement' foreland thrusts.

The La–Ce geochronometer: a new dating method

T. Tanaka

Geological Survey of Japan, Higashi 1-1-3, Yatabe, Ibaraki, 305 Japan

A. Masuda

Laboratory for REE Microanalysis, Department of Chemistry, University of Tokyo, Hongo, Tokyo, 113 Japan

The isotope ^{138}La(0.089% of natural lanthanum) decays by β^- and electron capture to ^{138}Ce and ^{138}Ba with a long half-life. We present here the first age determination using La–Ce dating. An internal La–Ce isochron of a gabbro from the upper zone of the Bushveld, South Africa, yields an age of 2,390 ± 480 (2σ) Myr based on the partial decay constant 2.58×10^{-12} yr^{-1}. This age agrees with the Sm–Nd isochron age (2,050 ± 90(2σ) Myr) which was obtained from an aliquot of the same sample solution: within the uncertainties of ^{138}La half life and isotopic measurement.

Radioactivity of ^{138}La has been predicted, because of Mattauch's rule concerning the stability of isobaric atomic nuclei

* Weighted mean of the data from refs 4–11.

† Weighted mean of the data from refs 4–10 which were multiplied by 1/1.17 (see text) and raw data of ref. 11.

($^{138}_{56}$Ba–$^{138}_{57}$La–$^{138}_{58}$Ce) with contiguous atomic numbers and the half-life has been measured[1–11,25]. ^{138}La decays by β^- emission to an excited level of ^{138}Ce which emits 789 keV γ ray and by electron capture to an excited level of ^{138}Ba which emits a 1,436 keV γ ray. The published values for the half lives of these two decay processes and weighted average values are summarized in Table 1. These partial half lives as well as the total half life scatter rather widely, while the branching ratios of the two decays are in reasonable agreement. Reported values of half lives with no information on volatile impurities were uniformly reduced here by a factor of 0.855 (=1/1.17) assuming that the oxide measured contained 17% volatiles due to absorption of H_2O and CO_2. The weighted average values are also listed in Table 1.

An upper zone gabbro of the Bushveld complex was sampled at Magnet Height, is composed of about 50% pyroxenes, 40% plagioclase and minor amounts of biotite, hornblende and magnetite. The gabbro was crushed and pyroxenes and plagioclase were separated from both 60–80 and 80–140 mesh fractions by isodynamic separator.

About 0.5–1 g for each sample (two pyroxenes, two plagioclases and a bulk rock) was decomposed by HF and $HClO_4$. The samples were then dissolved in HCl and separated into two aliquots, and composite REE spike was added to one of them. Ce and Nd were chemically separated for the measurement of isotopic abundance ratios involved three ion-exchange columns, and, Nd was finally eluted by 0.25 M α-hydroxyisobutyric acid (α-HIBA), and Ce by 0.3 M α-HIBA, respectively. Overall blanks were 0.4 ng for Nd and 3 ng for Ce. The moderately high blanks were due to the large amounts of reagents used for large samples. However, even for the most Ce-poor pyroxene, the sample/blank ratio was more than 800 for both elements, and hence no correction for blanks on isotopic ratio was made. Blank values for abundance determination by isotope dilution were 10 times smaller than those for isotopic composition. Tiny CeO^+ peaks with natural isotopic ratios were detected from the outgassed filament system, and the beam intensity of mass 158 ($^{142}Ce^{16}O$) was ~5×10^{-16} A in the same operating condition as normal running with a sample. This background intensity was less than 1/10,000 of the sample beam intensity, and the effect was included in the blank value mentioned above.

Cerium isotopes were measured as CeO^+ on Re triple filaments. The peaks of masses 152 ($^{136}Ce^{16}O$), 154 ($^{138}Ce^{16}O$) and 158 ($^{142}Ce^{16}O$) were measured. The biggest peak of mass 156 ($^{140}Ce^{16}O$) was ignored in order to get good measurements for the tiny peaks of masses 152 and 154. Masses 153, 155, 157 and 162 were usually monitored. Although the small 155 ($^{139}La^{16}O$) and 157 ($^{141}Pr^{16}O$) peaks were observed in most cases, the 154/155 and 158/157 intensity ratios were greater than 50 and 1,000, respectively. Very small BaO^+ and BaF^+ peaks were detected only at an early low temperature stage and soon disappeared with growth of the CeO^+ beam. NdO^+ was observed in a few cases and corrected where necessary. The beam intensity of mass 158 ($^{142}Ce^{16}O$) was 0.5 to 1.0×10^{-11} A. Generally 100 scans of the peaks were accumulated for each run. Each run took 3–4 h and 2–4 runs were measured for every sample. $^{136}Ce/^{142}Ce = 0.01720$ was used for normalization. The observed fractionation factor between ^{136}Ce and ^{142}Ce was used to estimate the $^{140}Ce/^{142}Ce$ ratio, followed by an evaluation of $^{140}Ce^{18}O^+$ effect on $^{142}Ce^{16}O^+$. $^{140}Ce/^{142}Ce$ was taken to be 7.992 at $^{136}Ce/^{142}Ce = 0.01720$, that is, with no mutual fractionation. However, the mass fractionation correction for $^{140}Ce^{18}O$ was very small, and almost constant. The Johnson Matthey Ce reagent, JMC 304, was measured with a rather wide range of ion current ($0.3\sim2\times10^{-11}$ A) and isotope fractionation [($^{136}Ce/^{142}Ce$) fractionation = $1.0001\sim0.996$]. No systematic variation was found. The mean $^{138}Ce/^{142}Ce$ value for 15 runs on the reagent was 0.0228559±0.0000011 (2σ).

Neodymium was measured as NdO^+ by a Re single filament. Small PrO^+ and SmO^+ peaks were sometimes observed and $^{147}Sm^{16}O$ was monitored for Sm correction if needed. All the measured isotopic ratios were normalized against $^{146}Nd/^{144}Nd = 0.7219$. La Jolla Nd Standard reagent (provided

* $^{138}La/^{142}Ce = (La/Ce)_{weight}\times0.00811$. The factor was based on ^{138}La abundance (0.00089), ^{140}Ce abundance (0.1107) and atomic weights 138.91 and 140.12 for La and Ce, respectively[25,26]. The factor 0.6049 was used for $^{147}Sm/^{144}Nd$ (ref. 27).

† Errors are $2\sigma_m$.

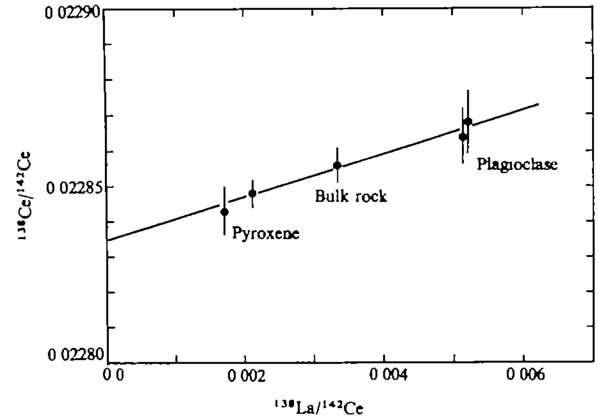

Fig. 1 La–Ce mineral isochron plot for an upper zone gabbro of the Bushveld complex, South Africa. The isochron yields an age of 2,390±480 (2σ) Myr with an initial ^{138}Ce/^{142}Ce ratio of 0.022835±0.000004 (2σ) (λ^{138}_{β} La = 2.58×10^{-12} yr^{-1}).

by G. W. Lugmair) was used as a reference standard. Our ^{143}Nd/^{144}Nd ratio was 0.51183±0.00003 (2σ). All seven Nd isotopes for samples were measured to check the reliability of ^{143}Nd/^{144}Nd measurement. Most ^{142}Nd/^{144}Nd and ^{145}Nd/^{144}Nd ratios agreed with those of the standard reagent within $\pm1\varepsilon$, and ^{148}Nd/^{144}Nd and ^{150}Nd/^{144}Nd ratios agreed with the standard within $\pm2\varepsilon$. A Micromass 30–54R was used for Ce and Nd measurement.

Results are shown on Table 2 and in Figs 1 and 2. The isochron lines were fitted using the York method[12]. Uncertainties (2σ) for ^{138}La/^{142}Ce and ^{147}Sm/^{144}Nd were estimated at 1% and 0.5% respectively. Assuming a partial half life of 2.95×10^{11} yr ($\lambda_\beta = 2.35\times10^{-12}$ yr^{-1}) for ^{138}La (Table 1), the La–Ce isochron yields an age of 2,630±530 Myr (2σ). Similarly, using the modified partial half life of 2.69×10^{11} yr ($\lambda_\beta = 2.58\times10^{-12}$ yr^{-1}) in Table 1 yields an age of 2,390±480 Myr. The former age, 2,630±530 Myr, seems slightly older than the Sm–Nd age (2,050±90 Myr (2σ) with an initial ^{143}Nd/^{144}Nd ratio of 0.50964±0.00010(2σ)); the latter age, 2,390±480 Myr obtained with the modified decay constant is in better agreement with the Sm–Nd age. This suggests that the absorbed H_2O and CO_2 correction in the decay constant measurement as discussed above, was pertinent and that the modified decay constant in Table 1 is more appropriate.

The Bushveld mafic phase has been studied by several investigators. Ages cited here were recalculated on the basis of the new decay constants[13]. Separated biotite from a gabbro of Rustenburg Plats gave a Rb–Sr age of 2,007±49 Myr (2σ) (ref 14). Hamilton[15] determined the Rb–Sr whole rock ages systematically from lower zone to upper zone. These ages are in reasonable agreement through the layer of the mafic rock phase, ranging from 1,901±16(2σ) to 2,126±61(2σ) Myr. A biotite–plagioclase–whole rock internal isochron age, 2,148±14 Myr, is in agreement with the whole-rock isochron ages. Hamilton averaged three selected isochron ages, that is 2,091±94 Myr from the Upper Zone, 2,095±14 Myr from the Merensky Reef and 2,035±18 Myr from the Transition Zone, and presented an age of 2,050±23 Myr as the most reliable for the Bushveld mafic phase. La–Ce and Sm–Nd ages agree with published Rb–Sr ages, although the experimental uncertainty of La–Ce age is considerable.

The ^{143}Nd/^{144}Nd ratio of chondritic uniform reservoir (CHUR) at 2,050 Myr ago was calculated to be 0.51002 by using ^{143}Nd/^{144}Nd ratio (0.50682) of the achondrite Angra dos Reis[16], Sm/Nd ratio (0.321 in weight)[17] of Leedey chondrite and the decay constant (6.54×10^{-12} yr^{-1}) of ^{147}Sm. The initial ^{143}Nd/^{144}Nd ratio, 0.50964±0.00010 (2σ), of the Bushveld upper zone gabbro is slightly lower than the value of the CHUR at 2,050 Myr ago. This fact suggests that the gabbro was derived from a slightly light REE (also probably large ionic lithophiles (LIL)) enriched source compared with CHUR. This is consistent with the Sr data. Two initial ^{87}Sr/^{86}Sr ratios for the upper zone gabbro were obtained as 0.70769±0.00006 (2σ) and 0.70735±0.00008 (2σ) (ref.15). These ratios suggest that the gabbro was derived from LIL enriched source as deduced from the ^{143}Nd/^{144}Nd ratio. Coherent variation of La–Ce and Sm–Nd as a rare earth group suggests that the initial ^{138}Ce/^{142}Ce ratio ($R^{\rm Ce}_{\rm gabbro}$ (2,390 Myr)), 0.022835±0.000004 (2σ), must be higher than the ^{138}Ce/^{142}Ce of CHUR ($R^{\rm Ce}_{\rm CHUR}$ (2,390 Myr)) at that time.

Our results confirm that the La–Ce isotopic system is a promising new geochronometer. Moreover, the La–Ce system, coupled with the Sm–Nd system, will become a unique tool for isotope geochemistry, because both pairs belong to a rare earth group, and this is expected to throw a new light on those studies. In the following section, we will show the variation of ^{138}Ce/^{142}Ce for some terrestrial materials and meteorites.

As discussed above, the gabbro is considered to be derived from a slightly more radiogenic source on ^{138}Ce than CHUR; $R^{\rm Ce}_{\rm gabbro}$ (2,390 Myr) > $R^{\rm Ce}_{\rm CHUR}$ (2,390 Myr).However, it is reasonable to assume that Ce in the source of the gabbro was less radiogenic than the continental crust. Then, $R^{\rm Ce}_{\rm CHUR}$ (4,550 Myr) should be lower than the value obtained by tracing back the $R^{\rm Ce}_{\rm gabbro}$ (2,390 Myr) to T = 4,550 Myr by retrograde decay correction with assuming chondritic La/Ce ratio (0.387 by weight), while it should be higher than the value obtained by tracing back the $R^{\rm Ce}_{\rm gabbro}$ (2,390 Myr) to T = 4,550 Myr by retrograde decay correction assuming the crustal La/Ce ratio (the value of North American Shale, 0.457 was used)[18]. Then, $R^{\rm Ce}_{\rm CHUR}$ (4, 550 Myr) is calculated to be higher than 0.022814 and lower than 0.022817 by using λ^{138}_{β} La = 2.58×10^{-12} yr^{-1}. The La/Ce of the source region of the gabbro is expected to be closer to chondritic than crustal in chemical composition and in the La/Ce ratio. Then we choose rather arbitrarily 0.022816 as a $R^{\rm Ce}_{\rm CHUR}$ (4,550 Myr) between 0.022814 and 0.022817.

The ε notation is used as it is generally on Sr and Nd. ^{138}Ce/^{142}Ce ratios are given as fractionated deviations in parts per 10^4 ($\varepsilon_{\rm Ce}$) from the value in the CHUR and are given by $\varepsilon_{\rm Ce}(T) \equiv [R_{\rm S}(T)/R_{\rm CHUR}(T)-1]\times10^4$ where $R^{\rm Ce}_{\rm S}(T)$ is the ^{138}Ce/^{142}Ce of a sample (s), T is the age under consideration and λ^{138}_{β} La = 2.58×10^{-12} yr^{-1}. $R^{\rm Ce}_{\rm CHUR}$ (0) = 0.022853 is obtained as a value for ^{138}Ce/^{142}Ce in CHUR today (Fig. 3).

Several elements of REE in Isua gneisses were determined[19]. The lanthanum that was not analysed was estimated by extrapolation of Ce–Nd line on chondrite-normalized REE pattern.

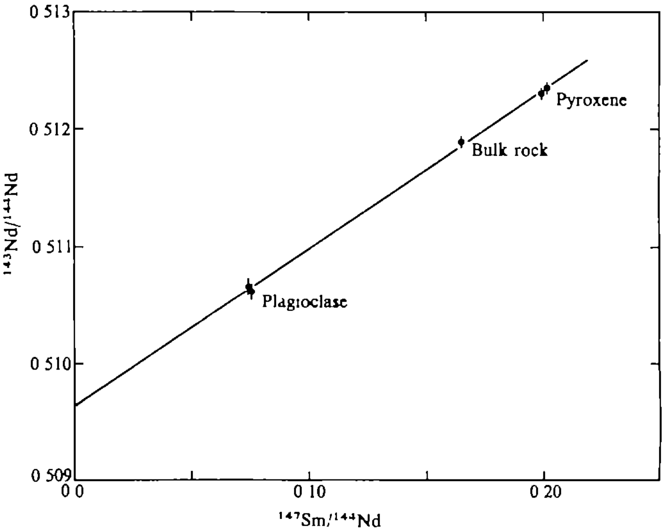

Fig. 2 Sm–Nd mineral isochron plot obtained from an aliquot of the same sample solution as that for La–Ce analysis. The isochron yields an age of 2,050±90 (2σ) Myr with an initial ^{143}Nd/^{144}Nd ratio of 0.50964±0.00010 (2σ) (λ^{147}_{α} Sm = 6.54×10^{-12} yr^{-1}).

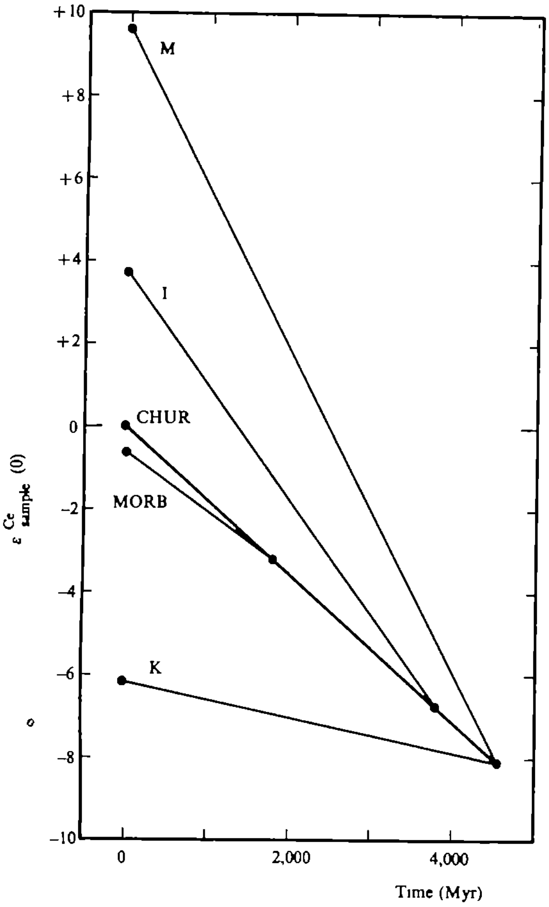

Fig. 3 Calculated ^{138}Ce/^{142}Ce growth curve; Melrose-b howardite (M), Isua gneiss (I), chondritic uniform reservoir (CHUR), mid-oceanic ridge basalt (MORB) and Khohar chondrite (K). Ordinate indicates $\varepsilon_{Ce}(0)$ scale, that is relative to CHUR at present, 0.022853.

$(La/Ce)_{weight} = 0.526$ was obtained for Isua granodiorite gneiss 155766. If we assume that the gneiss was formed from CHUR at 3,770 Myr ago[20], $\varepsilon_{Ce}(0)$ of the gneiss is obtained to be +5.3 (Fig. 3). As discussed from Sm–Nd isotopic systematics by Masuda and Dohmoto[21], if mid-oceanic ridge basalts (MORB) with $(La/Ce)_{weight} = 0.318$ is assumed to be formed at 1,800 Myr ago, $\varepsilon_{Ce}(0)$ of MORB is calculated to be −1.3 (Fig.3). There should be a negative correlation between ε_{Ce} and ε_{Nd}.

For some meteorites with positive or negative Ce anomalies, such as Khohar (L3) and Melrose-b(howardite), larger variations of ^{138}Ce are expected. Khohar$(La/Ce_{weight} = 0.0911)$[22] and Melrose-b$(La/Ce_{weight} = 0.846)$[23] are considered to have $\varepsilon_{Ce}(0)$ of −12.3 and +19.3, respectively, under the assumption that those La/Ce variations were formed at 4,550 Myr ago (Fig. 3). A hibonite inclusion in Allende (HAL) has a La/Ce weight ratio higher than 103 (ref. 24). It will have $\varepsilon_{Ce}(0)$ of more than 4,301.

We conclude that La–Ce isotopic system is a promising geochronometer and also will be a unique tool for isotope geochemistry. It is now essential to establish a reliable new value for the decay constant of ^{138}La.

We thank Professor Kanenori Suwa for samples, Shigeru Nagasawa for use of unpublished data and Toshinari Shimokawa for helpful information.

ESR dating of planktonic foraminifera

Takaharu Sato

Faculty of Engineering Science, Osaka University, Toyonaka, Osaka, Japan

Isotopic and palaeontological studies on Quaternary deep-sea sediment have provided relative but well-established time scales with ages mostly calibrated from the magnetic-polarity time scale. Absolute dating techniques such as U-series or K/Ar-dating have also been successful; however, difficulties exist such as elemental concentrations near the detection limit, or a lack of the necessary minerals. I report here on electron spin resonance (ESR) dating of marine cores, which utilizes the damage caused by natural radiation in planktonic foraminifera. An ESR signal grows linearly with the γ irradiation dose. It is found that the total radiation doses in the foraminifera increase with depth in two cores studied. The results demonstrate the viability of ESR dating for planktonic foraminifera up to 1 Myr in age.

The results presented here are for planktonic foraminifera of diameter 250–503 μm from deep-sea cores KH 73-4-7 and KN 73-4-8 (from the Melanesia Basin of the western equatorial Pacific Ocean, at 2° 41′ N, 164° 50′ E, water depth 4,160 m and 1° 33′ S, 167° 39′ E, water depth 4,000 m, respectively). ESR spectra of 150 mg samples were measured with an JES-ME2X ESR-spectrometer at room temperature. Core sediments were dated in units about 8 cm long. Artificial irradiation from a ^{60}Co source (dose rate of 10^4 rad h^{-1}) was performed at the Radiation Institute of Science and Industrial Research, Osaka University.

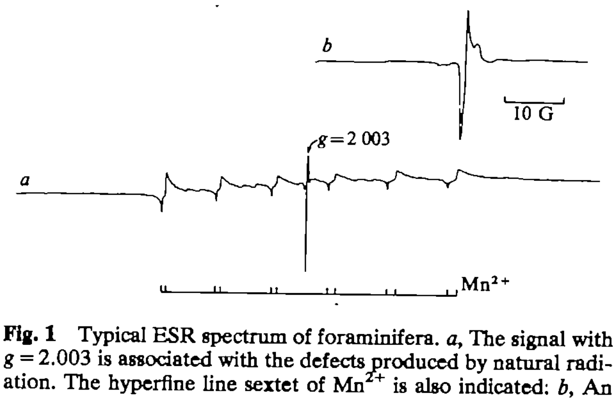

Fig. 1 Typical ESR spectrum of foraminifera. *a*, The signal with $g = 2.003$ is associated with the defects produced by natural radiation. The hyperfine line sextet of Mn^{2+} is also indicated: *b*, An expanded spectrum of the signal associated with the defects.

The mean annual doses are estimated from the TDs shown in Fig. 3 and the reported ages for the levels. The ESR ages are estimated from the TDs shown in Fig. 3 and the mean annual dose at the Brunhes–Matuyama boundary; a constant annual dose assumed is arbitrarily set equal to the mean annual dose at the boundary for each core.

* Results on palaeomagnetic field intensity, which will be reported elsewhere.

† S. Nishida, personal communication.

Figure 1 shows a typical ESR derivative line of the foraminifera, with a predominant signal associated with the radicals created by natural radiation and the hyperfine line sextet of Mn^{2+}.

The relative intensity of the radical signal is enhanced by exposure to ^{60}Co γ rays (Fig. 2). The total dose (TD) was determined by the additive dose method, in which the signal intensity of the samples is compared with that of identical samples which have also received a laboratory radiation dose. This method is used in thermoluminescence dating[1,2] and ESR dating[3], where the TD is frequently termed the AD (archaeological dose). To minimize errors caused by changes in instrument sensitivity and differences in sample weight, the signal intensity of the irradiated samples was measured relative to the ratio of the intensity of Mn^{2+} signals in the irradiated samples to the unirradiated ones, the Mn^{2+} signals were used as an internal standard. As the concentration of Mn^{2+} is high, the change in the signal intensity of Mn^{2+} by irradiation in this dose range is negligible. Growth of the signal intensity is almost linear up to ~250 krad. Maximum irradiation doses here are below 200 krad for samples which were expected to show high TD.

Figure 3 shows TDs obtained from the results shown in Fig. 2 as a function of core depth. The TDs seem to show an exponential increase towards a saturation level for each core. However, palaeomagnetic and biostratigraphical studies demonstrate that the mean sedimentation rate of the past 0.47 Myr is less for each core than in earlier times (Table 1): the Brunhes–Matuyama boundary, the Jaramillo event and the Olduvai event were observed for each core[4–6]. A microbiostratigraphical investigation of the cores studied by Takayanagi *et al.*[7] showed a level of the last appearance of *Pseudoemiliania lacunosa*, which presumably occurred within isotope Stage 12 (~0.474 Myr)[8]. The small TDs at the uppermost portion are associated with the low sedimentation rate. Therefore the TDs should be considered to increase linearly with depth until the Jaramillo event as shown in Fig. 3. Note that the TDs estimated from the linear increase for the remarkable levels are almost proportional to the reported ages in the levels in both cores, especially in KH 73-4-7. The mean annual dose is almost constant for each core as shown in Table 1.

The K-, U- and Th- contents within a deep-sea core[9,10] seem to fluctuate rapidly with depth. The monotonic increase in the TD with depth may be interpreted as being the influence of variation in the contents smoothed out by penetration of the γ rays over 30 cm.

There are three possible causes of the extremely small TDs observed near the surface. First, changes can occur in the sedimentation rate due to dissolution of calcium carbonate, and deposition of really young sediment, or second, in the annual dose near the surface of the sea bottom. Wintle and Huntley[11] pointed out that the sediment within 30 cm below the sediment–water interface does not receive the full γ dose; therefore, it is possible that after a period of deposition at a constant rate, deposition may have ceased since ~0.2 Myr. Third, changes can occur in the annual dose due to the exponential decrease of the ^{230}Th excess. In this case, the mean annual dose should also decrease but more gradually. The almost constant mean annual doses shown in Table 1 indicate little influence of the ^{230}Th excess. A microbiostratigraphical study of the uppermost 1 m of the core (S. Nishida, personal communication) shows evidence of dissolution of calcium carbonate. Species which have thin and fine structures in a coccosphere were not observed and the species assemblage was simplified in both cores. A level of the first appearance of *Emiliania huxleyi*, which presumably occurred within isotope Stage 8 (~0.275 Myr)[8], was observed by Nishida between 15 and 22 cm for KH 73-4-7. However, this portion may correspond to the beginning of the acme zone of the species, as the coccosphere is rather sensitive to dissolution. On the other hand, in KH 73-4-8 the level where the species first appeared was indicated between 71 and 80 cm, however, the species was not observed in portions of this core shallower than 31 cm. The disappearance of the species is probably due to dissolution and the fact that part of the acme zone could not be collected. We assume therefore that the small

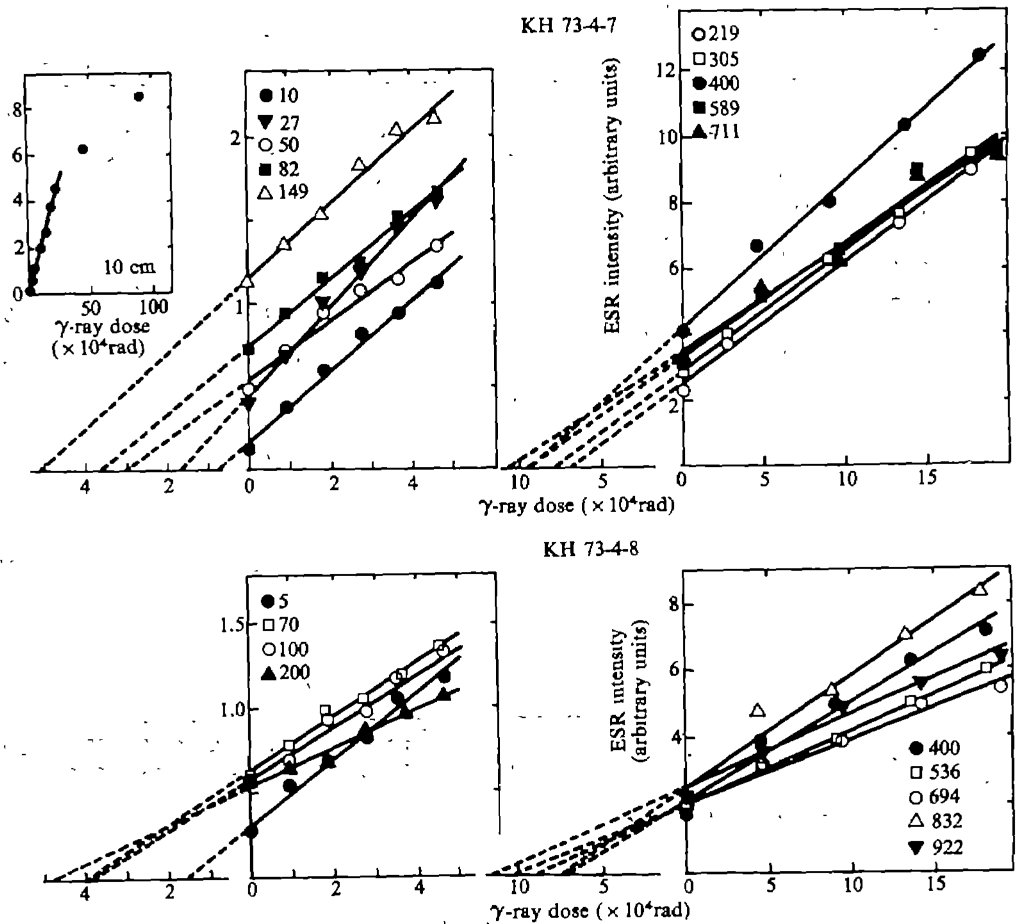

Fig. 2 Growth of the ESR signal of foraminifera from two cores with artificial γ irradiation. The numbers indicate the depths of each core.

TDs at the shallower depth are due to dissolution of calcium carbonate.

Samples taken from portions deeper than those corresponding to the Jaramillo event in both cores did not show any further linear increase of TDs with either depth or age, although the accuracy of TDs decreases. Wintle[12] reported that the mean lifetime of the 275°C TL peak of calcite was 390 Myr at 5°C, and that the anomalous fading, the effect of which could not be detected by mean lifetime estimation, had been observed for a sample of labradorite feldspar. As the tendency towards saturation was observed downward from the portion of similar ages in two cores with different depositional environments, it may be caused by the anomalous fading in calcite.

The ESR ages, determined on the basis of the ages of the Brunhes–Matuyama boundary, assuming a constant annual dose for each core, are compared in Table 1. Detailed palaeomagnetic investigation of these cores, in which variations in the palaeomagnetic field intensity were deduced from the ratio of natural remanent magnetization to the saturation isothermal remanent magnetization, showed correspondence between the curves of the ratio. The ESR ages of two distinctly corresponding depths are compared in Table 1. The results of the palaeomagnetic investigation will be described in detail elsewhere.

The disagreement between the reported ages and the ESR ages in KH 73-4-7 can be explained by dissolution to the order of 10% in the portion shallower than 2 m. On the other hand, the complicated changes in the sedimentation rate may be associated with the disagreement in KH 73-4-8. These changes lead to errors in the TDs estimated from linear increase. The TDs can be said to be almost proportional to the ages for a core with a constant sedimentation rate.

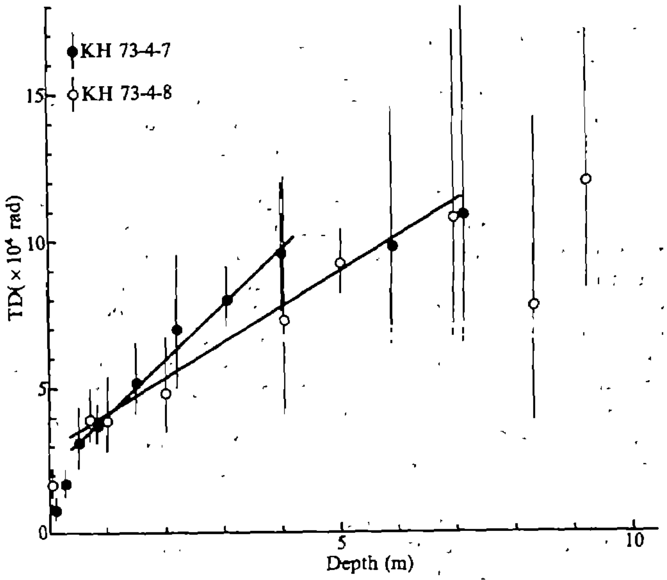

Fig. 3 Total dose (TD) plotted against depth for two cores. The bars represent the 90% confidence level in the TD measurement only.

I conclude that ESR is useful for dating planktonic foraminifera up to 1-Myr old but to obtain detailed changes in the sedimentation rates, some problems must be resolved. More accurate estimation of TD and evaluation of variations in the annual dose versus depth on the basis of the contents of radioactive elements and isotopes are necessary.

I thank Professor S. Nishida for valuable information on micropaleontology, Professor M. Ikeya and Dr I. Koizumi for helpful suggestions, Professor K. Kobayashi for supplying the samples and S. Koshida and T. Ikeda for technical assistance. I also thank the Japan Society for the Promotion of Science for a postdoctoral fellowship.

Female mating preference is genetic

M. E. N. Majerus, P. O'Donald & J. Weir

Department of Genetics, University of Cambridge, Downing Street, Cambridge CB2 3EH, UK

The objection is often raised against sociobiological theory that different behavioural strategies have never been shown to be genetically determined. Yet if they are to evolve at all, the differences must be in part hereditary. Nobody would dispute that many aspects of behaviour—the song of *Drosophila* or birds, or the tendency to migrate, for example—would show genetic variation. But sociobiologists assert that different strategies of behaviour— the alternative courses of action that an animal might take—are also inherited and can thus be selected: strategies for example, such as whether to be a 'hawk' or a 'dove' in conflicts, or whether to choose one type of male because he may be a better mate than others. No doubt there are many aspects of behaviour that vary genetically and thus produce variations in the chances of success in conflicts or in finding mates. But does an animal prefer to follow one course of action rather than other alternative courses, and is its preference hereditary? This is the crucial question for sociobiology. As dogmatically as some sociobiologists have answered 'Yes', so have some population geneticists answered 'No'. Lewontin[1] called Dawkins' *The Selfish Gene*[2] a caricature of Darwinism for assuming that all behaviour may be inherited and natural selection can therefore do anything. These extreme views persist for lack of experimental evidence. We show here that female mating preference can be substantially increased in successive generations by artificial selection. It must therefore have a genetic component.

In *The Descent of Man*, Darwin[3] invoked female preference as one of the two selective mechanisms for the evolution of male characteristics of sexual display. The existence of female preference was a premise of Darwin's theory. Fisher[4] explained its existence as the outcome of an evolutionary process in which both preference and preferred character evolve together. O'Donald[5,6] and Lande[7] analysed models of female preferences that support Fisher's theory. Models of preferential mating have been fitted to observations on the relative frequencies of matings of different genotypes[6], but experiments on the sexual selection of preference have never been carried out over a number of generations.

Preferential mating may be involved in the maintenance of the colour polymorphism of the two-spot ladybird, *Adalia bipunctata*[8,9]. Majerus *et al.*[10] carried out a series of mating choice experiments on melanic (*quadrimaculata*) and non-melanic (*typica*) ladybirds collected at Keele in Staffordshire. *Quadrimaculata* is inherited as a unifactorial dominant to *typica*[11]. The results give a good fit to a model of mixed sexual selection and assortative mating for dominant and recessive traits[12]. The maximum likelihood estimates generated by the model show a strong and very significant non-assorting preference, γ, for *quadrimaculata* males. The assorting preference, c, for these males was appreciable, but not formally significant. Maximum likelihood estimates of assorting and non-assorting preferences for *typica* were very close to zero[10]. Observations of courting pairs indicated that female choice determined the frequencies of the different matings. No male competition for mates has been seen to occur[10].

Following these results, it was obviously imperative to test whether selection will increase the level of female preference in successive generations, and also to confirm experimentally that female choice determines the frequencies of the matings of the different male phenotypes. A sample of ladybirds from the Keele stock was allowed to mate in a population cage. The sample consisted of the following phenotypes: 112♂♂+112♀♀ *typica*, 48♂♂+48♀♀ *quadrimaculata*. This 7:3 ratio of *typica*:*quadrimaculata* was chosen because it gives good estimates of the mating preference at the level at which it occurs in the Keele stock. Our experimental regime has been described elsewhere[10]. We recorded the phenotypes of individuals *in copuli* by continuously observing the cage during a fixed period of 16 h of light per day. We removed the mating pairs of ladybirds. As soon as pairs had separated, we replaced the males in the cage. We placed those females that had mated with *quadrimaculata* males in a new population cage to lay the eggs for the next generation of the selected line. Females which mated with *typica* males were discarded. We repeated this procedure for three subsequent generations, restoring the 7:3 phenotypic ratios at the start of each generation. We also set up a control line, maintained in the same way as the selected line, except that all mating females, regardless of the phenotypes of their mates, laid the eggs of the next generation. The results from both the selected and control lines are given in Table 1. If the deviation from random mating shows an overall preference towards *quadrimaculata* males, then matings take place at the frequencies $\gamma+v(1-\gamma)$ for *quadrimaculata* males, and $(1-v)(1-\gamma)$ for *typica* males, where v is the overall frequency of *quadrimaculata* in the cage and γ the proportion of females expressing a preference for them. Even if the preference is expressed in some partial or frequency-dependent manner, the constancy of v in all experiments ensures that γ will be a constant fraction of the total proportion of females with a preference; hence, γ will always measure the relative magnitude of the preference[6,13]. If n_Q and n_T are the observed numbers of the matings with each phenotype of male, the level of preference is estimated by

$$\hat{\gamma}=\frac{n_Q(1-v)-n_T v}{n(1-v)}$$

where $n=n_Q+n_T$. This maximum likelihood estimate has been derived from a model with no preference for *typica*. Table 1 shows the estimates of preference against the data from which they were obtained. In generation 3, we also set up direct tests of female choice in mating chambers, using progeny from the previous generation and equal phenotypic ratios. In these experiments, each mating pair is immediately replaced by fresh individuals with the same phenotypes as those that had mated. We tested female choice by similar experiments on the original unselected stock. Table 2 shows the results of these mating test experiments.

To differentiate conclusively between male competition and female choice, we set up three further population cage experiments. A sample consisting of males from the progeny of the fourth generation of the selected line and females from the unselected Keele stock were allowed to mate in a population cage. In a second cage, females from the fourth generation of the selected line were allowed to mate with males from the unselected Keele stock. In a third cage, as a control, males and females both taken from the unselected Keele stock were allowed to mate. In all three experiments, 7:3 ratios of *typica*:*quadrimaculata* phenotypes were maintained in the samples. Table 3 gives the frequencies of matings, estimates of preference and statistical analysis.

3	112	48	10	18	10	18	0.2857±0.0955
4	112	48	11	22	13	28	0.2085±0.0825

Analysis of χ^2

Component of variation	Values of χ^2	d.fs	Values of P
Between selected and unselected groups	12.5103	1	0.000405
Within selected populations	1.6837	2	0.431
Within unselected populations	1.3000	4	0.861

N_T and N_Q refer to the total number of *typica* (T) and *quadrimaculata* (Q) ladybirds of a given generation that were placed in a population cage for mating. They consisted of equal numbers of males and females. The male phenotype is shown first in the type of mating: Q×T is a mating of Q♂×T♀; T×Q is a mating of T♂×Q♀. The males were replaced in the cage after they had mated. The preferred males often mated more than once during the 5 or 6 days of observation of a cage. Females were not replaced after mating. If observations had been continued until all females had mated, an exact 7:3 ratio of T:Q females would necessarily have been found to have mated. However, after 6 days, 90% of Q and 60% of T females had mated. Comparing numbers of mated and unmated females among Q and T females in the selected line, we obtain $\chi_3^2 = 1.4962$, showing no change in mating propensities of Q and T females with increasing preference over generations. The Q and T females show similar levels of preference, but the T females are slower to mate. 'd.fs' in the analysis of χ^2 means the numbers of degrees of freedom.

Table 1 shows that the proportion of females preferring *quadrimaculata* males increased significantly in the selected line but not in the control line. Although obviously decisive, these results present a problem of statistical analysis. A linear increase in preference is not to be expected because the selection differential declines as more females exercise the preference: sexual selection by female choice is necessarily frequency-dependent[6,14]. We should expect that the rate of increase of preference would fall rapidly in successive generations; how rapidly would depend on the genetics of preference which is unknown. A simple linear regression of the increase of γ would be an inappropriate model to fit to the data. The data of both selected and unselected lines form a 2×8 table of numbers of matings of *quadrimaculata* and *typica* males. Generations 2, 3 and 4 of the selected line represent generations after females have been selected for increased preference. These generations can be tested against the unselected generations. Of course, this test ignores the increase within the selected line. It represents a conservative test which should not overestimate the true level of significance.

The data also show that the response of the selected line differs significantly from that of the control line. This is the crucial test. In the absence of an appropriate regression model, a conservative test of the difference in the responses can be constructed by comparing the differences between the first and fourth generations in the selected and control lines. We expect to find a response over the four generations in the selected line but not in the control line. Thus, we ask: do the selected and control lines differ in their responses? The data form a 2^3 table as follows:

	Selected line Q♂♂	T♂♂	Control line Q♂♂	T♂♂
Generation 1	52	70	28	29
Generation 4	39	17	33	41

The difference in Q:T ratio between selected and control lines differs significantly between generations. For this three-factor interaction (phenotypes × lines × generations): $\chi_1^2 = 6.2678$, $P = 0.0123$. Because we have omitted the data of generations 2 and 3, this is a very conservative test which must underestimate the true level of significance in the total data. The difference between selected and control lines in generation 4 is tested by $\chi_1^2 = 8.0939$ (or 7.1120 with Yates' correction), $P = 0.00444$ (or 0.00766 for χ^2 with Yates' correction). The preference has been raised very significantly in the selected line but not in the control line. As shown in Table 2, the difference between selected and control lines in generation 3 is nearly significant in spite of the very small numbers of matings observed for this generation in the selected and control lines. By Fisher's combination of probabilities test applied to the results of generation 3 and 4, we obtain $\chi_4^2 = 14.9761$, $P = 0.00475$, giving the overall significance of the difference between the lines.

Table 2 Numbers of matings of ladybirds in mating choice experiments and estimates of female preference

Q×Q	Nos of matings between different phenotypes Q×T	T×Q	T×T	Estimate of preference for Q $\hat{\gamma} \pm \sqrt{\mathrm{var}(\hat{\gamma})}$
Mating tests on original unselected stock				
72	67	41	46	0.2301±0.0522
Mating tests on generation 3 of selected line				
15	15	6	4	0.5±0.1369

Overall estimates of preference for generation 3

Preference in selected line in generation 3 estimated from data of mating tests and population cage experiments:	$\hat{\gamma} = 0.4721 \pm 0.0846$
Preference in control line in generation 3:	$\hat{\gamma} = 0.2857 \pm 0.0955$
Test of significance of difference in estimates for control and selected lines:	$\chi_1^2 = 3.2120$; $P = 0.0731$

In these mating test experiments, five males and five females of each phenotype are placed in a mating chamber and kept under continuous observation. When a mating takes place, the mating pair are removed and fresh individuals of the same phenotypes are replaced. Both male and female phenotypes are replaced. A strict 5:5 ratio of Q:T males and females is thus maintained in the mating chamber.

Table 3 Mating tests between the selected line and original Keele stock

Nos of matings and estimates of preferences

Stocks and sexes used in matings	Q×Q	Nos of matings between different phenotypes Q×T	T×Q	T×T	Estimates of preference for Q $\hat{\gamma} \pm \sqrt{\mathrm{var}(\hat{\gamma})}$
Selected ♂♂ × Keele ♀♀	11	28	17	34	0.1905 ± 0.0746
Selected ♀♀ × Keele ♂♂	16	28	6	15	0.5385 ± 0.0829
Keele ♂♂ × Keele ♀♀	18	35	21	42	0.2241 ± 0.0661

Analysis of χ^2

Component of variation	Value of χ^2	d.fs	Value of P
Selected males compared with Keele males	0.1126	1	0.737
Selected females compared with Keele females	10.4844	1	0.00120

The selected males and females used in these tests were taken from the progeny of the fourth generation of the selected line. No further selection had been imposed after the fourth generation. The level of preference among the progeny of the fourth generation should be the same as that in the fourth generation. The selected males and females were tested in matings with progeny taken from the corresponding generation of the original Keele stock. Population cages were set up with 7:3 ratios of T:Q. They were kept under continuous observation; mating pairs were counted giving the numbers shown in the table.

The response to selection that we have demonstrated has taken place in the females' mating preference for *quadrimaculata* males. As shown in Table 3, when selected females are mated with males from the original stock, the level of preference is characteristic of the selected line; when selected males are mated with females from the original stock, the level of preference is characteristic of the original stock. Female mating preference has thus been shown to have a large genetic component in its determination. We believe that these experiments provide the first formal proof that a female mating strategy is genetically determined.

This proof is fundamental for theories of the evolution of female preference[4–7]. It shows that female choice of mate can evolve: mate choice will be selected if, as in our experiment, females making the choice contribute a relatively greater proportion of offspring to future generations. In a natural population, they will do so if the males they choose to mate with possess a selective advantage. As the female preference contributes some of this selective advantage, it partly selects itself. This gives rise to what Fisher[4] called the 'runaway process of sexual selection'. Initially, while preference genes are rare—they may perhaps have arisen by mutation—this process will be extremely slow, requiring many thousands of generations to get started[5]. Realistically, male competition or natural selection must provide the initial advantage. The preference will then be selected in the course of the selection of the preferred male character. The dynamics of this selection is very complex and depends crucially on the genetics of the preference[5]. Initially, as a gene for the preferred character spreads through a population, a preference gene may be expected to show a three- to fivefold increase in frequency. As the preference becomes more common, it adds to the preferred males' advantage; but the preference gene itself shows progressively smaller increases in frequency as it becomes more common. The process eventually stops when the male character has developed to the point at which it has become so disadvantageous in natural selection that this disadvantage balances the sexual selection.

This work was supported by a research grant from the SERC to P. O'D.

Phenomenal coherence of moving visual patterns

Edward H. Adelson* & J. Anthony Movshon

Department of Psychology, New York University, New York, New York 10003, USA

When a moving grating is viewed through an aperture, only motion orthogonal to its bars is visible, as motion parallel to the bars causes no change in the stimulus. Because there is a family of physical motions of various directions and speeds that appear identical, the motion of the grating is ambiguous. In contrast, when two crossed moving gratings are superimposed, the resulting plaid pattern usually moves unambiguously and predictably. In certain cases, however, two gratings do not combine into a single coherent percept, but appear to slide across one another. We have studied the conditions under which coherence does and does not occur, and we report here that it depends on the relative contrasts, spatial frequencies and directions of motion of the gratings. These effects may reveal the previously unstudied properties of a higher order stage of motion analysis.

Figure 1*a* illustrates the problem of ambiguity[1,2]. The grating moves behind a circular aperture. Any of the physical motions indicated by the arrows will appear the same when viewed through the aperture. The situation can be depicted graphically in 'velocity space', a space in which each vector represents a velocity: the length of a vector corresponds to speed, and its angle corresponds to direction. As shown in Fig. 1*a*, the motion of a single grating is consistent with a family of motions that lies along a line in velocity space; this line is parallel to the grating's bars and orthogonal to the vector representing its 'primary' motion. If two moving gratings are superimposed, the resulting 'plaid' pattern moves with a speed and direction which can be exactly predicted from the velocity space construction: the two loci of possible motions intersect at a single point, corresponding to the motion of the coherent pattern (Fig. 1*b*). This solution to the 'aperture problem' is similar to that proposed (in a rather different context) by Fennema and Thompson[3]. It has advantages over that advanced by Marr and Ullman[4], which can only infer a range of possible directions from the limited information provided by a pair of gratings.

The velocity space combination rule is also different from a vector sum or vector average. In Fig. 1*c*, two gratings move downward and rightward with different speeds and directions.

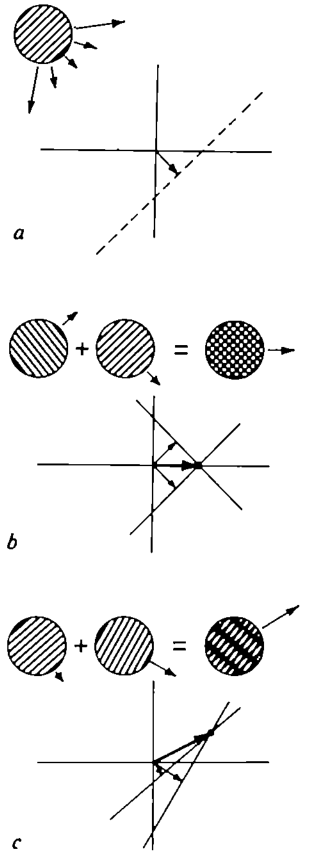

Fig. 1 The velocity-space representation of some moving patterns. In each panel, a vector represents a motion in a direction given by the vector's angle at a speed given by the vector's length. *a*, A single grating moves behind an aperture. The broken line indicates the locus of velocities compatible with the motion of the grating. *b*, A plaid composed of two orthogonal gratings moving at the same speed. The lines give the possible motions of each grating alone. Their intersection is the only shared motion, and corresponds to what is seen. *c*, A plaid composed of two oblique gratings, one moving slowly and the other more rapidly. Both gratings move down and to the right, but the pattern moves up and to the right.

A vector sum or average would predict a pattern motion that was also downward and rightward, but the velocity space solution is a motion upward and rightward, the motion that observers report when the gratings are seen to cohere[5]. Of course, nothing requires that coherent motion be seen, and instead of a single rigidly moving plaid, the two gratings are sometimes seen sliding 'incoherently' over each other. We have studied the stimulus conditions under which coherence occurs, in order to characterize the mechanisms that underly the coherent percept and resolve the ambiguity of one-dimensional motion.

Observers viewed a circular cathode ray tube display subtending 5°; the luminance of the display was constant on average, but was modulated by signals from a PDP11 computer to produce a superimposed pair of sinusoidal gratings that could each be varied in orientation, direction and speed of motion, contrast and spatial frequency. Observers were strictly instructed not to make judgements unless their eyes were steadily fixated on a small black circle in the centre of the display. Subjects under this kind of instruction are capable of stable and reliable fixation[6]. After each 1.5-s exposure, the observer indicated whether the pattern appeared 'coherent' or 'incoherent'.

Contrast strongly affects coherence, even when both gratings are easily visible. Figure 2*a* shows a psychometric function for detection and a similar function for coherence, when the contrast of one of the gratings in a plaid was varied (the other grating's contrast was fixed at 0.3). The gratings were of the same spatial frequency, and moved at an angle of 135° to one another. Open symbols show the probability of detecting the low-contrast grating in the presence of its high-contrast mate. Filled symbols show the probability of a coherent percept. Both detection and coherence become more likely as contrast increases, but reliable coherence only occurs at contrasts where both gratings are clearly visible.

In further experiments, we used this contrast dependence to measure the relative tendency of different pairs of gratings to cohere. We fixed the contrast of one grating at 0.3, and used a staircase procedure to vary the contrast of the other grating until the observer saw coherent motion on half the trials. The gratings' speed, orientation and spatial frequency all affected the strength of coherence. Coherence decreased as the speed of the component gratings increased, as the angle between their 'primary' directions increased, and as the difference between their spatial frequencies increased.

Figure 2*b* shows the effect of relative spatial frequency on coherence. Filled symbols illustrate a case in which the spatial frequency of the high-contrast grating was fixed at 1.2 cycles deg^{-1}, while the spatial frequency and contrast of the second grating were varied; open symbols illustrate a case where the spatial frequency of the first grating was fixed at 2.2 cycles deg^{-1}. As the frequencies of the two gratings were made different, the tendency to cohere was reduced, and the contrast needed for coherence was increased. This spatial frequency dependence suggests that coherent motion, like many other visual properties, is analysed by mechanisms that are selective for spatial frequency.

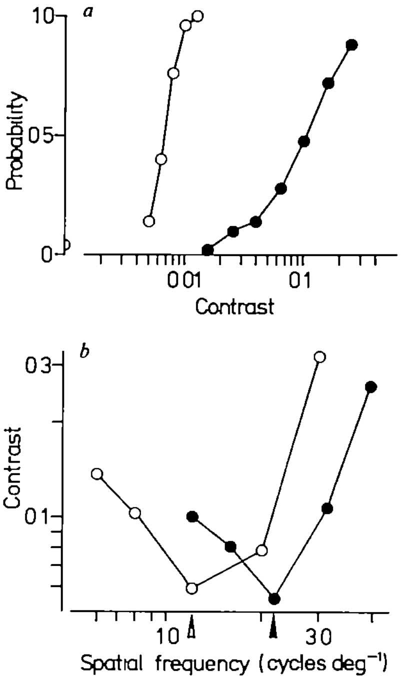

Fig. 2 Two parameters influencing perceptual coherence. *a*, The influence of contrast on the detectability and coherence of two crossed sinusoidal gratings. One grating was fixed in contrast at 0.3. The other was of variable contrast, and moved at an angle of 135° to the first; both had a spatial frequency of 1.6 cycles deg^{-1}, and moved at 3 $\mathrm{deg\,s}^{-1}$. Filled symbols show the probability that the observer judged the two gratings to be 'coherent'; open symbols show the probability that the observer detected the presence of the lower contrast grating. The half-circle on the ordinate shows the probability that the observer judged the second grating to be present when its contrast was zero—the 'false-positive rate' for detection; the false-positive rate for coherence judgments was zero. Subject, E.H.A. *b*, The influence of spatial frequency on coherence. The standard grating again had a contrast of 0.3 and moved at 3 $\mathrm{deg\,s}^{-1}$. The test gratings moved at an angle of 135° to the standard, also at 3 $\mathrm{deg\,s}^{-1}$. Open symbols show the results for a range of test spatial frequencies when the standard grating had a spatial frequency of 1.2 cycles deg^{-1} (open arrow). Filled symbols show the results when the standard grating had a spatial frequency of 2.2 cycles deg^{-1} (filled arrow). Subject, P.A.

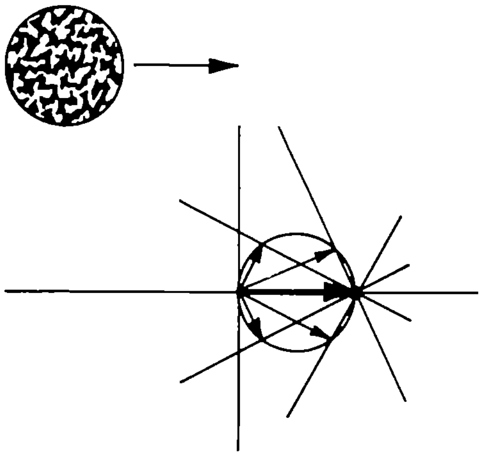

Fig. 3 The velocity-space representation of a random-texture field moving to the right. The field contains components of all orientations, and the primary motion vector for each ends on the circle passing through the origin; the common motion 'implied' is the rightward motion given by the bold arrow. This circular locus of primary motions represents all the motions that can exist in a single rightward-moving pattern. As such, the locus could represent the preferences of a family of primary motion analysers whose outputs are combined to signal coherent two-dimensional motion (see text).

There are two kinds of model that might account for our results. The first relies on the presence in our patterns of localizable blob-like features where the peaks and troughs of the crossed gratings intersect. Some process based on direction-selective elements not selective for orientation might detect and signal the motion of these 'blobs', which is of course identical to the motion of the pattern as a whole. We have evidence to suggest that such a scheme is incorrect. We superimposed one-dimensional dynamic random visual noise (a rapidly changing pattern of random-width lines)[7] on our test patterns. A non-oriented mechanism that responds directly to the motion of blobs should be most affected by noise oriented at right angles to the coherent motion. But a mechanism that combines the outputs of oriented channels should be most affected when those channels are most affected—when the noise is oriented at right angles to the primary motion of one or the other of the component gratings. Our results support the orientation-based model. Coherence is strongly reduced when the noise mask is perpendicular to a component's motion (and thus parallel to the component's orientation), but is almost unaffected when the mask is perpendicular to the coherent motion of the pattern. This suggests that some orientation-selective process must precede the analysis of coherent motion, and our second model incorporates this feature.

There is abundant evidence that visual analysing mechanisms selective for orientation and spatial frequency exist at a relatively early stage in the visual pathway[8–12]. It is clear that such mechanisms are often sensitive to the direction of motion of one-dimensional contours[8,9,13–15], but they also seem unable to signal the true direction of motion of two-dimensional patterns[16–19]. The perceptual coherence of two gratings into a single moving plaid may therefore represent the action of an additional stage of visual processing beyond those usually considered to be involved in analysing motion. At this second stage, the outputs of several 'one-dimensional' motion analysers would be combined. Coherence phenomena may offer an approach to studying the properties of this postulated second-stage motion analyser.

Figure 3 shows how the velocity space construct helps to assign motion to more complex patterns, such as a horizontally moving random-texture field. The texture contains components of many orientations; their motions are represented in velocity space by the arrows in Fig. 3. As the speed of each component is proportional to the cosine of the angle between its direction and horizontal, the vectors all end on a circle that passes through the origin. Note also that the motion 'families' associated with the various components all pass through the common point corresponding to the horizontally directed pattern motion.

A given vector in Fig. 3 could represent the preference of a one-dimensional motion detector, and the circle might represent the 'receptive field' in velocity space of a second-stage motion analyser. If it combined the outputs of one-dimensional analysers corresponding to points on the circle by an operation akin to a logical 'and', the second-stage analyser would respond only to a particular direction of motion of the two-dimensional stimulus. Our results on perceptual coherence might reflect the relative strengths of the different inputs to such a motion analyser. They would suggest that this analyser computes the weighted combination of signals arising from a collection of one-dimensional motion analysers having different velocity preferences but similar spatial frequency preferences.

Prenatal misrouting of the retinogeniculate pathway in Siamese cats

Carla J. Shatz & Michel Kliot

Department of Neurobiology, Stanford University School of Medicine, Stanford, California 94305, USA

In the mammalian visual system, retinal ganglion cells send their axons to several distinct structures in the brain. One of these, the lateral geniculate nucleus (LGN), receives a substantial projection from both eyes in higher mammals such as the cat[1–3]. How does this pattern of input arise during development? One possibility is that retinal ganglion cell axons project from the very beginning to the appropriate side of the brain. Another is that the initial projection may contain many inappropriate connections which are eliminated after the axons reach their target, the LGN. We thought the Siamese cat might provide an opportunity to study these alternatives. Guillery and others[4–7] have shown that in adult Siamese cats, the LGN receives a disproportionately large input from the contralateral eye and a correspondingly diminished input from the ipsilateral eye due to a genetic mutation at the *albino* locus. We report here that this abnormal pattern of input is present from the earliest stages of development of the retinogeniculate projection and arises as a consequence of the misrouting of fibres at the optic chiasm. These findings suggest that during normal development, growing optic fibres can be directed to the appropriate side of the brain.

0028–0836/82/490525—05$01 00

In normal adult cats the retinal ganglion cells within each eye are sharply divided into two halves by virtue of their axonal projections to the LGN[8,9]. Figure 1*a* shows that axons from retinal ganglion cells in the nasal half of each eye cross in the optic chiasm and terminate in layers A, C and C2 of the contralateral LGN. Axons from retinal ganglion cells in the temporal half of each eye do not cross but project instead to the ipsilateral LGN where they terminate in the alternate A1 and C1 layers[1,10].

In contrast, in adult Siamese cats the nasotemporal division is abnormal, (see Fig. 1*b*). In these animals the contralateral projection to the LGN consists of axons from retinal ganglion cells in the nasal retina, as usual, plus an abnormal component from the temporal retina which projects to portions of layers A1 (abA1) and C1. A reduced number of the remaining retinal ganglion cells in the temporal half of the retina send axons to the ipsilateral LGN, where they are confined to several small patches in layers A1 (mnA1 and lnA1) and C1[6,7,11,12].

We wished to determine how the abnormal Siamese pattern of the retinogeniculate projection arises during development. Therefore, we labelled the projection in 26 Siamese and 43 normal newborn and fetal cats of known gestational age by using the axonal transport of intra-ocularly injected horseradish peroxidase (HRP) or ^{3}H-leucine. (Siamese fetuses were obtained from breedings within our own pure-bred Siamese colony.) The cat's gestation period averages 65 days, with the first day of breeding designated as embryonic day 0 (E0) and birth as postnatal day 0 (P0). Prenatal eye injections were performed using the fetal surgery techniques of Rakic[13] modified for the cat[14]. In most cases both eyes were injected with different labels. Animals were allowed to survive for 24 h, then removed by caesarean section and processed for HRP histochemistry[14,15] and/or autoradiography[7]. Complete and even labelling of the retinas in all the animals studied here was verified by examining the retinas (autoradiographically or histochemically) and by inspecting the pattern of the retinal projections to the LGN and superior colliculus. At each age the labelling pattern was considered to reflect accurately the retinogeniculate projection only when similar results were obtained from three or more injections.

By birth the pattern of axonal projection from retina to LGN as revealed autoradiographically or histochemically is adult-like, both in Siamese and normal cats—see top of Fig. 2, which shows a matched series of darkfield photographs of peroxidase- or radioactively-labelled sections through the LGNs of progressively younger normal and Siamese cats. At postnatal day 2, comparison of Fig. 2*a* (normal) and *f* (Siamese) demonstrates the drastically reduced ipsilateral and correspondingly increased contralateral projections that are typical of the retinogeniculate projection in adult Siamese cats. Compare also Fig. 2*f* with Fig. 1*b*—what remains of the ipsilateral projection in Fig. 2*f* is confined to several small labelled patches.

We next made a prenatal study. The left-hand side of Fig. 2 shows the general time course and pattern of development of the retinogeniculate projection in a series of normal cat fetuses. By E32, a clear projection from the retina to the lateral margin of the thalamus is present bilaterally, with that from the contralateral eye being more extensive than that from the ipsilateral eye (Fig. 2*e*). Note that at this age the label is largely restricted to the optic tracts, particularly ipsilaterally. At older ages (E35, E40; Fig. 2*d*, *c*, respectively), the ipsilateral and contralateral projections increase, and occupy progressively more medial territory within the LGN. By E54 (Fig. 2*b*), afferents from the two eyes are in the process of segregating from each other to form the set of sharply defined layers present at birth (Fig. 2*a*). (For fuller accounts of normal development, see refs 14, 16.)

The overall developmental pattern of the retinogeniculate projection in Siamese cats shown on the right-hand side of Fig. 2 differs from that of normal animals in one important respect; at each embryonic age there is a striking reduction in the size of the ipsilateral projection and a relative increase on the contralateral side. This size disparity is most apparent at E51 (Fig. 2*g*) when, as in normal animals, the retinogeniculate afferents from the two eyes are in the process of segregating from each other. In the Siamese fetus, however, the result is the appearance of the characteristic abnormal adult-like pattern (compare Fig. 2*f* and *g*). Earlier, at E46 (not shown), the projection pattern is similar to that seen at E51 in that the projection to the ipsilateral LGN remains significantly smaller in size and extent than that to the contralateral side. At E41, when the contralateral projection to the LGN is already well established, only a small contingent of ipsilateral fibres have invaded the posterior pole (Fig. 2*h*, arrow). Most of the remaining ipsilateral label is confined to the optic tract and brachium of the superior colliculus. Before E41, ipsilateral label is almost entirely restricted to the tract in the Siamese fetuses. This is the case at E36 (Fig. 2*i*), when the LGN is invaded normally by the first ipsilateral retinal fibres (Fig. 2*d*, arrow). Indeed, as early as E32, when the retinogeniculate afferents initially arrive within the vicinity of the LGN anlage, but in normal animals are still confined largely within the optic tract (Fig. 2*e*), the ipsilateral projection is absent from the Siamese fetus (Fig. 2*j*).

These results indicate that the LGN receives a diminished ipsilateral retinal projection throughout fetal development in Siamese cats. It is worth noting here that in the development of retinogeniculate connections in *albino* rats, Lund and coworkers[17] found that the diminished ipsilateral projection emerges only secondarily, largely due to a massive elimination of connections once they had reached the LGN. Such differences between the two species may simply reflect differences in the action of the mutant gene. Alternatively, they may represent significant differences in the mechanisms underlying normal development—mechanisms that in higher mammals, but not in rodents, operate to produce a large and precise ipsilateral projection.

At least two distinctly different events could account for this reduction in the size of the ipsilateral projection within the

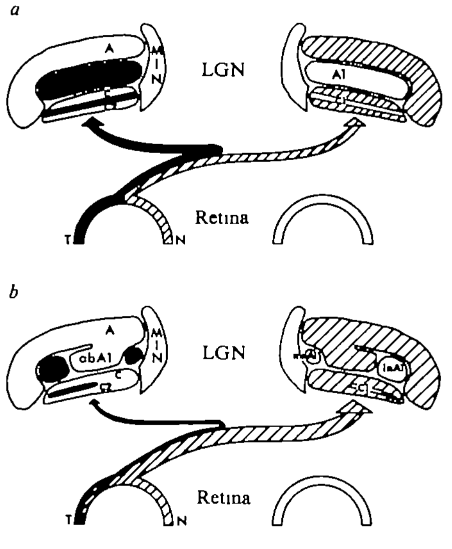

Fig. 1 A diagram of the retinogeniculate projection in normal (*a*) and Siamese (*b*) adult cats. Only connections between the left eye and the LGN are shown here for simplicity. *a*, Normally, axons from retinal ganglion cells in the nasal half of each retina (hatched area labelled N) cross at the chiasm and project to layers A, C and C2 of the contralateral LGN. Those in the temporal half (black area labelled T) project ipsilaterally to the alternate A1 and C1 layers. *b*, In the Siamese cat, the LGN receives an abnormally large projection from the contralateral retina (right LGN: hatched area), consisting of additional fibres from the temporal retina (hatched area) that innervate portions of layers A1 (abA1) and C1. There is a correspondingly reduced projection from the ipsilateral retina (left LGN: black areas) that terminates in several small patches medially (mnA1) and laterally (lnA1) in layer A1, and in layer C1. The projection to the medial interlaminar nucleus (MIN) is similarly affected in Siamese cats but is not shown here.

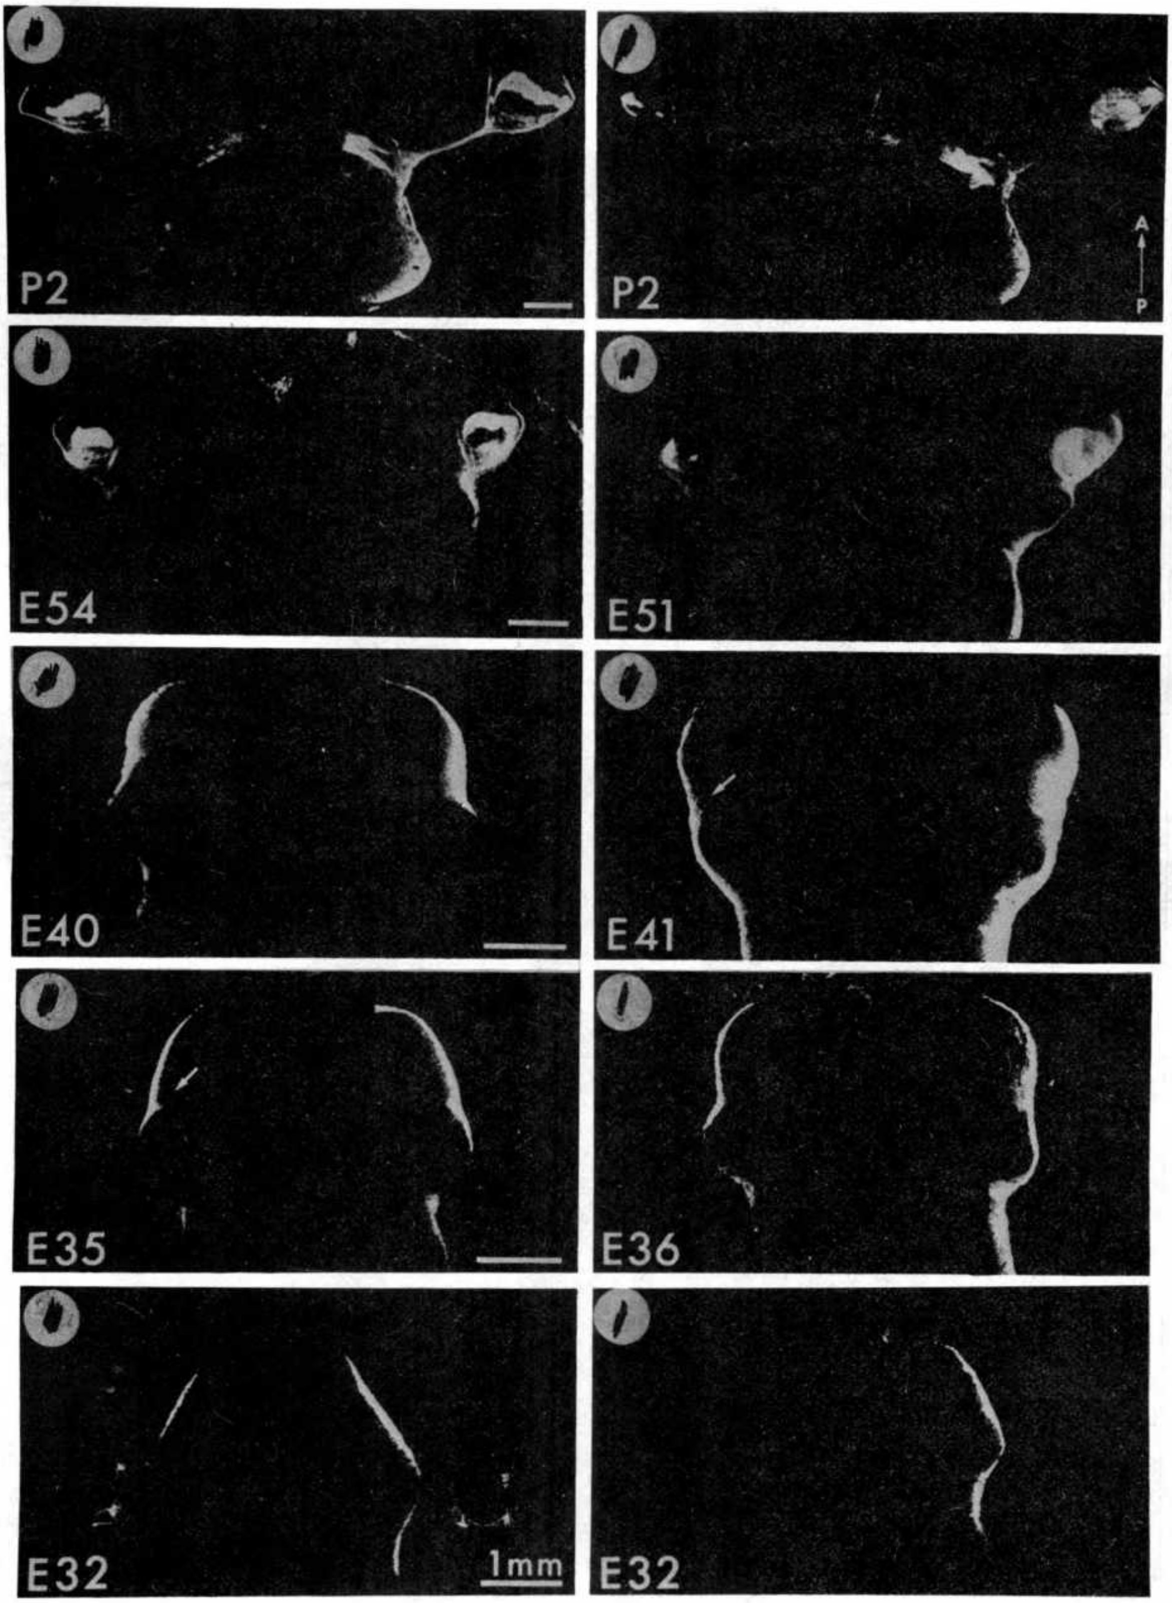

Fig. 2 Two series of darkfield photographs of HRP- or radioactively-labelled retinal afferents in horizontal sections through the lateral geniculate nuclei of normal and Siamese cats to show the progressive development of the retinogeniculate pathway. Postnatal (P) and embryonic (E) ages are indicated, as are the sides contralateral (contra.) and ipsilateral (ipsi.) to the injected eye. Due to the cat's extended gestation period (65 days), reasonable comparisons can be made between normal and Siamese fetuses differing by up to a few days in embryonic age. For each Siamese case, the section shown contained the largest amount of ipsilateral label seen. Label in the top half of each photo is contained within the LGNs and optic tracts. Label in the bottom half lies within the pretectum and superior colliculus. Arrows in *d* and *h* indicate label within the most posterior pole of the LGN. In *f*: A represents anterior, P posterior. The calibration bar (1 mm) for each pair of ages is shown in the left-hand (normal) series. See text for further details.

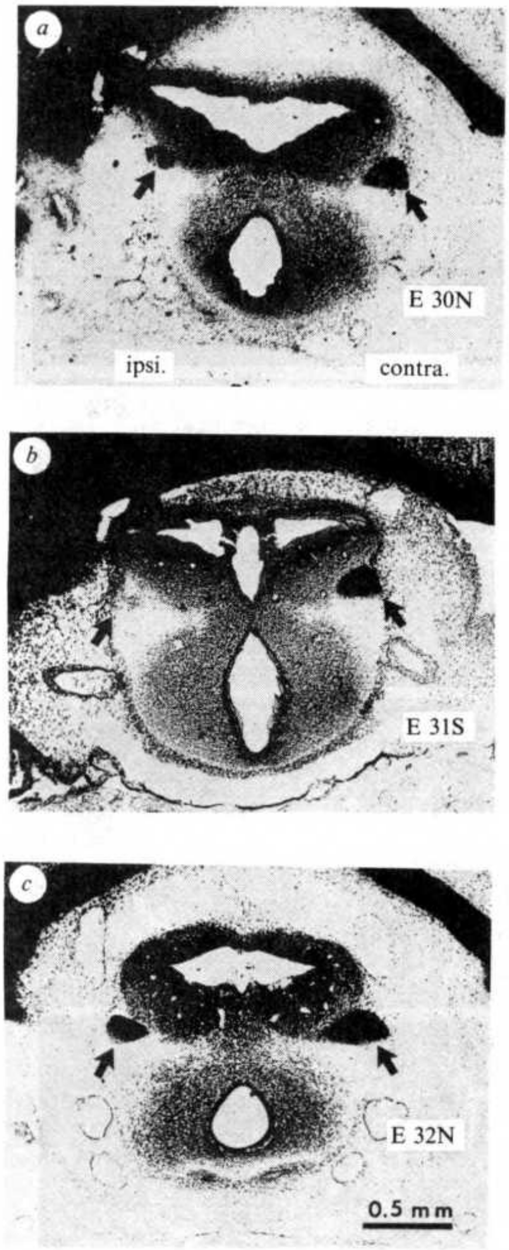

Fig. 3 Brightfield autoradiographs of horizontal sections through the optic tracts immediately adjacent to the chiasm to compare the size of the ipsilateral (ipsi.) and contralateral (contra.) retinofugal projection in three fetuses that received intra-ocular injections of ^{3}H-amino acids. Arrows indicate label (black) in the optic tracts. *a*, Normal E30 fetus; *b*, Siamese E31 fetus; *c*, Normal E32 fetus. The sections were counterstained with cresyl violet. Anterior is up, posterior down. Calibration bar (0.5 mm) is for *a*–*c*.

LGN of Siamese cats. It might arise either as a direct consequence of axonal misrouting at the optic chiasm, as originally proposed by Guillery[3,4], or axons might be routed correctly at the chiasm but subsequently fail to invade the ipsilateral LGN on arrival. We therefore examined the pattern of labelling of ipsilateral and contralateral optic tracts immediately adjacent to the optic chiasm at times when most afferents have not yet grown into the LGN. Figure 3 gives examples of brightfield autoradiographs from fetuses aged between E30 and E32. Substantial label in normal animals is present within the ipsilateral optic tract by E30 (Fig. 3*a*, arrows), roughly 5 days before the time when ipsilateral afferents unambiguously invade the LGN; label has further increased by E32 (Fig. 3*c*). In contrast, at E31 in Siamese fetuses (Fig. 3*b*), the ipsilateral optic tract is only faintly labelled despite extensive label in the contralateral tract. Thus, in Siamese cats the ipsilateral projec-

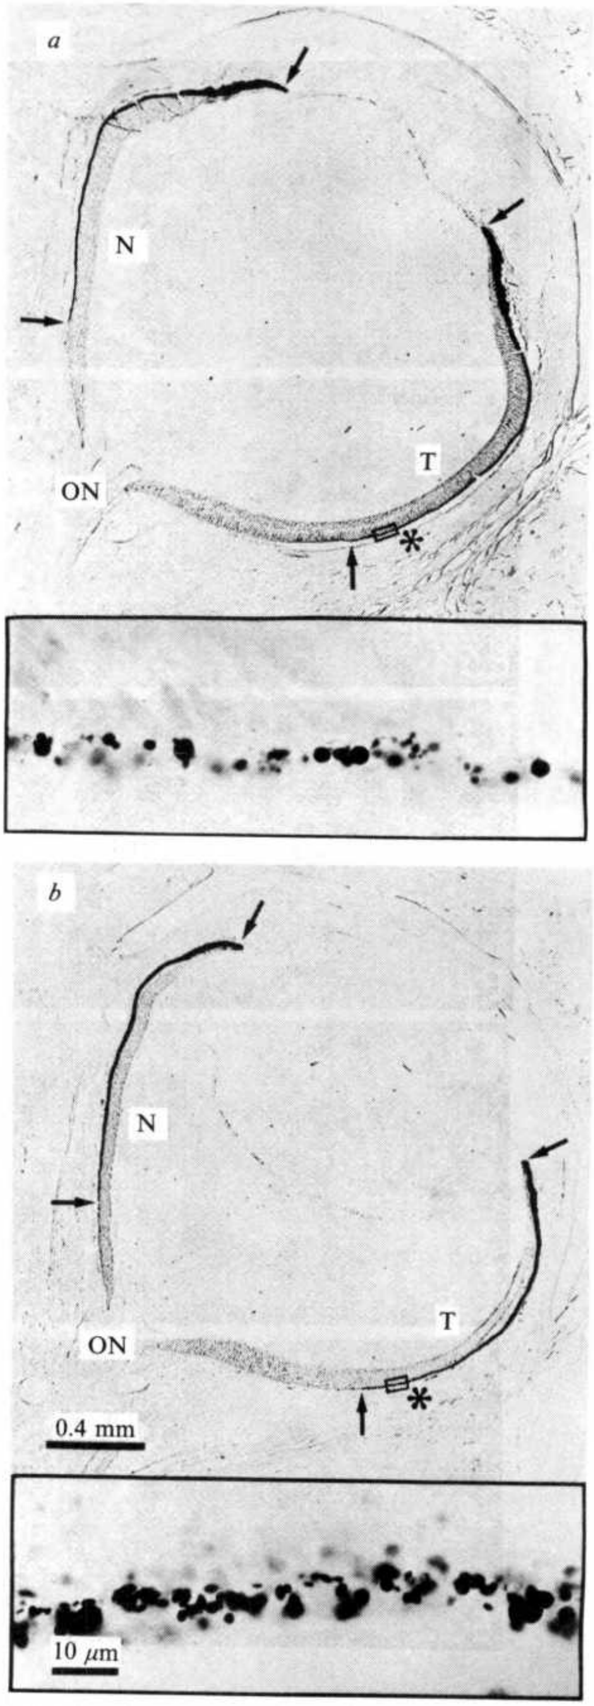

Fig. 4 Brightfield photographs of horizontal sections through the eyes of an E32 Siamese fetus (*a*) and an E32 normal fetus (*b*) to compare the distribution of pigment within the retinal pigment epithelial cells. The sections were counterstained with cresyl violet. Arrows indicate the extent of densely pigmented (black) regions of the epithelium in nasal (N) and temporal (T) retina. ON, optic nerve. Areas enclosed in small rectangles (marked by asterisks) in *a* and *b* are shown at high magnification in the insets beneath to illustrate individual pigment granules that are confined within the pigment epithelial cells. (At these ages, the choroid is unpigmented.)

tion is reduced within the optic tract even before the first retinal afferents reach the vicinity of the developing LGN, thereby supporting the hypothesis that the abnormal projection arises as a consequence of misrouting of growing fibres at the optic chiasm.

It is unknown how the Siamese mutation gives rise to the chiasmatic misrouting of retinal ganglion cell axons seen here. However, it is now well established that an abnormal retinofugal projection is frequently associated with a reduction in adult levels of melanin within the pigment epithelium of the retina. This reduction can be produced by various different mamalian genes, including the Siamese allele[18–20]. In view of this correlation, it has been suggested that melanin itself or another related gene product of the pigment epithelial cell can influence the chiasmatic fate of retinal ganglion cell axons during fetal life[21–23]. We therefore examined the pattern of pigmentation within the retinal pigment epithelium. Surprisingly, we found that the spatial distribution of pigment in our E32 Siamese cats was similar to that in normal cats of the same age (Fig. 4*a*, *b*; compare arrows). However, as can be seen from a comparison of the insets of Fig. 4*a*, *b*, the amount of pigment was somewhat reduced in the Siamese fetus. If pigment does have a role within the retina, then these results suggest that it may do so via an actual reduction in pigment levels. Alternatively, a change in the pigmentation of the developing optic stalk, which in other mammals is known to become transiently pigmented during early embryonic development[21–23], could be the influential factor.

If, as seems likely, optic axons are indeed misdirected at the chiasm in Siamese cats, then it is reasonable to imagine that during normal development, most retinal ganglion cell axons are initially directed to the appropriate side of the brain. It should be emphasized here, however, that our evidence for this conclusion is indirect, as it is based on an examination of the axonal projection pattern. If the present suggestions are substantiated, then the retinogeniculate pathway would represent another example of a system in which directed growth of axons during embryogenesis gives rise to a pattern of connectivity that is retained in the adult. Such directed growth is also found in the development of connections between spinal cord motoneurones and muscles in the chick: motoneurone axons grow directly to the appropriate peripheral muscle masses[24]. In contrast, in the development of the mammalian neocortex, many cerebral cortical neurones initially elaborate axonal connections with both hemispheres and subsequently retract one but retain the other to become either callosal or association projection neurones in the adult[25,26]. Thus, it would seem that the nervous system uses very different strategies in the formation of different sets of connections.

We thank Angela DiBerardino and Mark Siegel for technical assistance, and Drs P. A. Kirkwood, E. I. Knudsen and J. G. Nicholls for their helpful and critical readings of the manuscript. Adult thymectomy does not alter the proportion of T cells of the Ly 123 subclass

Roland Scollay

The Walter and Eliza Hall Institute of Medical Research, Post Office Royal Melbourne Hospital, Victoria 3050, Australia

The murine T cell antigens Ly 1, 2 and 3 have been useful in defining functionally distinct T cell subpopulations[1]. However, the relationship between Ly 123^+ cells and Ly 1^+23^- cells is not clear[2–4]. It has been claimed[5,6] that all cells leaving the thymus are Ly 123^+, the implication being that these must be the precursors of Ly 1^+23^- cells and that maturation involves the loss of Ly 2 post-thymically. Previous work has shown a 50% drop in the proportion of T cells of the Ly 123^+ subclass following adult thymectomy[5]. The interpretation was that the Ly 123^+ cells differentiated into Ly 1^+23^- cells and that no Ly 123^+ migrants from the thymus were replacing them. However, when we directly measured the Ly phenotype of migrant cells within a few hours of their exit from the thymus[7], we found they were mature in phenotype and already contained Ly 1^+23^- cells in the same proportion (~60%)[8] as peripheral T cells. This result suggests that adult thymectomy should not affect the subclass distribution of T cells. We have therefore repeated the adult thymectomy experiments using more precise techniques (flow cytometry and monoclonal antibodies) and the results reported here, in contrast to those of the earlier study[5], did not show any change in the proportion of Ly 123^+ cells after adult thymectomy, even though total T cell numbers were substantially reduced.

In the original studies[5] T cells were considered to consist of Ly 123^+, Ly 1^-23^+ and Ly 1^+23^- subclasses, and after adult thymectomy, a 50% drop in Ly 123^+ cells and an increase in Ly 1^-23^+ and Ly 1^+23^- cells was seen. However, it is now clear that all or most T cells express Ly 1, and the major distinction is between Ly 2^+ (that is, Ly 123 and the so called Ly 23) and Ly 2^- (that is, Ly 1) subclasses[8]. Viewed in this light their data showed a 30% drop in Ly 2^+ cells. For this reason our experiments distinguish T cells primarily on the basis of the presence or absence of Ly 2. With a sensitivity in our assay system of a few per cent, a drop of 30% should be easily detected.

Groups of 4-week-old CBA mice were thymectomized and killed 1, 2 or 4 weeks later. Cells from their mesenteric lymph

Table 1 Proportions of Thy 1^+ and Ly 2^+ cells in spleens and lymph nodes of CBA mice at various times after adult thymectomy

		Thy 1^+ as % of viable nucleated cells			Ly 2^+ as % of Thy 1^+ cells		
		8	14	28	8	14	28
Spleen	Control	27	35	36	43	45	39
	TX	20	28	23	40	44	37
Lymph node	Control	70	77	79	38	34	34
	TX	66	70	74	33	34	39

Mice were thymectomized (TX) at 4 weeks of age and assayed 8, 14 or 28 days later. Controls were untreated, aged matched animals. Percentages are based on a sample of 25,000 cells taken from a pool of three animals.

0028–0836/82/490529—03$01 00

Table 2 Effect of adult thymectomy on T cells in C57BL/6 mice

Organ	Group	No. of animals	% Thy 1^+ (of total cells)	Total Thy 1^+ (% of control)	% Ly 2^+ (of total) T cells)
Spleen	Control	4	34	100	44
	Sham TX	4	29	95	43
	TX (*a*)	3	22	59	44
	TX (*b*)	3	18	60	47
Lymph node	Control	4	73	100	46
	Sham TX	4	62	92	44
	TX (*a*)	3	66	38	49
	TX (*b*)	3	69	49	48

Mice were thymectomized (TX) at 7 weeks of age and assayed 3 weeks later. Controls were untreated age matched animals, while sham TX were age matched animals which were anaesthetized and the chest opened without touching the thymus. Percentages are based on a sample of 50,000 cells taken from a pool of three or four animals. TX (*a*) and TX (*b*) are duplicate groups.

nodes or spleens were stained simultaneously with monoclonal anti-Thy 1 and anti-Ly 2. Age-matched normal control mice were similarly stained. The methods and results obtained on a computer-linked fluorescence-activated cell sorter[9] are shown in Fig. 1. Thy 1^+ and Ly 2^+ cells could be unambiguously identified. The staining pattern was highly reproducible, and despite the apparent complexity of the staining protocol, controls were clear cut. The results of this approach are shown in Table 1. At all the times tested after thymectomy, the proportion of Thy 1^+ cells was reduced (most markedly in spleen as previously noted[10]), but the proportion of Ly 2^+ cells amongst the remaining Thy 1^+ cells was unchanged.

The original observations of Cantor and Boyse[5] were made on slightly older (7 week) C57BL/6 mice, so we repeated the experiment with 7-week-old C57BL/6 and CBA mice and, as they did, examined them 3 weeks later. Tables 2 and 3 show the results of these experiments. Three weeks after thymectomy, there was a slight drop in the proportion of T cells amongst the lymphocyte population as a whole and a substantial drop of around 50% in the absolute T cell numbers. Despite these changes the proportion of Ly 2^+ cells amongst the Thy 1^+ cells remained constant.

Using a similar staining protocol for Ly 1 and Thy 1, we found there was also no change in the small Thy 1^-, Ly 1^+ population 3 weeks after thymectomy (data not shown). This Thy 1^-, Ly 1^+ population makes up a few per cent of the cells in normal spleen or lymph node (ref. 8 and R.S., unpublished results). They would fall in the Thy 1^-, Ig^- group in the experiments shown in Fig. 1, but would probably have been included in the Ly 1^+ group in the experiments of Cantor and Boyse. They do not account for the differences in our results. It is interesting to note that a comparison of the % Thy 1^+ with the total Thy 1^+ (Tables 2, 3) indicates that adult thymectomy must also have caused a substantial drop in non-T (mostly B) cell numbers, indicating that even the adult B cell pool remains to some extent dependent on an intact thymus.

Table 3 Effect of adult thymectomy on T cells in CBA mice

Organ	Group	No. of animals	% Thy 1^+ (of total cells)	Total Thy 1^+ (% of control)	% Ly 2^+ (of total T cells)
Spleen	Control	3	29	100	44
	Sham TX	3	31	73	40
	TX (*a*)	3	25	48	42
	TX (*b*)	3	23	72	41
Lymph node	Control	3	66	100	36
	Sham TX	3	63	117	35
	TX (*a*)	3	68	46	37
	TX (*b*)	3	73	25	35

Mice were thymectomized (TX) at 7 weeks of age and assayed 3 weeks later. Untreated controls and sham TX animals were age matched. Percentages are based on a sample of 50,000 cells taken from a pool of 3 animals. TX (*a*) and TX (*b*) are duplicate groups.

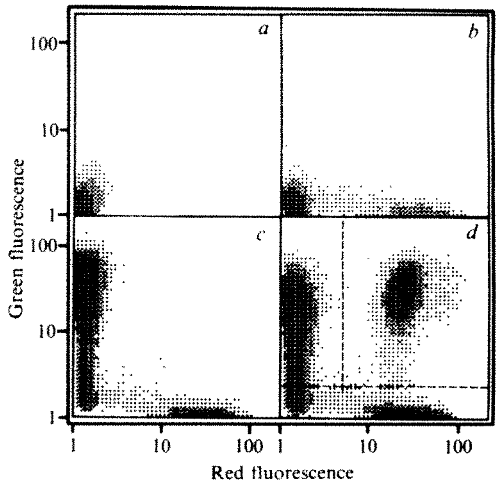

Fig. 1 Typical two-dimensional staining patterns of normal lymph node cells stained simultaneously with anti-Thy 1 and anti-Ly 2 and controls. *a*, Unstained cells; *b*, cells stained with rhodamine-conjugated rabbit anti-mouse immunoglobulin (Rh.RαMIg). B cells can be clearly distinguished from immunoglobulin-negative cells; *c*, cells stained with Rh.RαMIg, followed by rat immunoglobulin to saturate free binding sites on the Rh.RαMIg, followed by fluoresceinated rat monoclonal anti-Thy 1.2 (30-H12, ref. 19). T cells and B cells can be clearly distinguished and a small proportion of double negative cells (null cells) remains; *d*, cells stained with a rat monoclonal anti-Ly 2 (53-6.7, ref. 19) followed by the same staining as *c*. The Rh.RαMIg, which recognizes both mouse immunoglobulin and rat immunoglobulin, now stains both B cells and Lyt 2^+ cells, the latter being distinguished from B cells by the presence of Thy 1. The dotted lines show the levels used to define Thy 1^+ and Ly 2^+ cells and the major subpopulations (Thy 1^+ Ly 2^+; Thy 1^+ Ly 2^-; Thy^-) are easily distinguished. Among the Ly 2^- cells, there is no distinct separation between Thy 1^+ and Thy 1^- (*d*). Thy 1^- cells were arbitrarily chosen as those with levels undistinguishable from the negative controls (*a* and *b*). The data in each box represent 50,000 cells, plotted as a contour diagram. This form of plotting gives little information on peak heights, but clearly shows degrees of separation. The single peak in *a* contains 50,000 cells, while the other peaks vary (for example, the Lyt 2^+, Thy 1^+ peak in *d* contains about 17,000 cells). 3×10^6 cells were stained in each case and suspensions were washed between stages. Cells were analysed by flow cytometry (FACS II Becton-Dickenson) using a logarithmically amplified, two colour, single laser system linked to a PDP-11/34 computer. The computer produced the figures shown above and calculated the proportion of cells in each of the categories defined by the dotted lines in *d*. All the numbers in the tables were obtained from this kind of analysis. The slight increase in apparent red staining with increasing Thy 1 levels on red negative cells (*c* and *d*) is an artefact of the electronic signal separation system which occurs when working with low level signals in logarithmic mode.

In view of the marked discrepancies with the earlier data two technical questions immediately arise. How do the two techniques for measuring Ly phenotypes differ and was thymectomy in our experiments complete? In the flow cytometric analysis described here monoclonal reagents were used, 50,000 cells were analysed per sample, and background staining levels (that is, rhodamine positive, Thy 1^+ cells in preparations stained only with anti-Thy 1 and anti-immunoglobulin antibodies, Fig. 1*c*) were in the range of 1–2%. Thus, the actual numbers of Ly 2^+ cells counted in various samples ranged from about 17,000 in control lymph node to 5,000 in thymectomized spleens. In the sequential ^{51}Cr-release cytotoxic analysis, populations of 20–50% were estimated by subtraction following two sequential killing steps each with a background of up to 12%. Furthermore, as different subpopulations may take up different amounts of ^{51}Cr, the proportion of ^{51}Cr released may not correspond to the proportion of cells killed. Finally there is the complexity of complement-mediated cytotoxicity, as resistance to lysis can result from factors other than density of surface antigen[8]. For these reasons we believe the flow cytometric analysis to be the more reliable method. With regard to completeness of thymectomy, each animal in our experiments was examined macroscopically and histologically and no evidence of residual thymus was found. Furthermore, the total number of T cells was reduced by about 50% following the operation, suggesting that thymectomy was complete.

In conclusion, the data reported here are in agreement with the predictions which come from the direct measurement of the Ly distribution[3,7] and phenotypic maturity[11,12] of thymus migrants in adult mice. They are also in agreement with other recent reassessments of the Cantor and Boyse model. These showed (1) that there is a significant population of Ly 1 cells in the thymus[2] and (2) that T cells in newborn mice (which are presumed to be mostly recent thymus emigrants) are similar in Ly phenotype to peripheral T cells in adults[12,14]. Taken together, these studies support the hypothesis that thymus migrants are mature and that the division between Ly 123$^+$ and Ly 1$^+$23$^-$ cells must occur before emigration from the thymus. In fact, if data showing that Ly 1$^+$ cells appear earlier in ontogeny than Ly 123$^+$ cells are considered[15-17], it is possible to suggest that the division occurs at the earliest stem cell stage[2,3,16].

Finally, although these data support the hypothesis that thymus migrants in adults are phenotypically mature, it is possible that in some circumstances (for example, at specific stages during ontogeny) the thymus does give rise to migrant cells of 'immature' phenotype, a point which is under investigation[3,13,18] but not yet resolved. In addition, it should be made clear that these experiments and our other published data concerning thymus migrants[3,7,11,12] do not necessarily exclude a cortical origin for some or all thymus migrants. Nor do they clarify the relationships of the cortex and medulla. They do however rule out the emigration of immature cells directly from the cortex of adult mice and necessitate a re-analysis of the concept of post-thymic maturation.

I thank Jenni Smith for technical assistance, Drs Alan Harris, Jacques Miller, John Schrader and Ken Shortman and Susan Scollay for helpful discussions, and Jenny Taylor for preparing the manuscript. The work was supported by NIH grant AI-17310-01.

Absence of myosin-like immunoreactivity in stereocilia of cochlear hair cells

D. Drenckhahn*, J. Kellner*, H. G. Mannherz*, U. Gröschel-Stewart†, J. Kendrick-Jones‡ & J. Scholey‡

Movements of the stiff sensory hairs, the stereocilia, which extend outwards from the apical surface of the hair cells in the auditory organ, are thought to have a key role in the process of transduction of sound energy into electrical impulses. Each stereocilium is supported by a paracrystalline axial bundle of actin filaments, which have identical polarities and are extensively cross-linked[1-4]. Recent immunohistochemical observations on whole mounts of the guinea pig organ of Corti indicated myosin-like immunoreactivity in association with hair cell stereocilia[5]. Considering the steric situation, it is, however, difficult to imagine any functional interaction between the bundled actin filaments and the assumed myosin molecules. Here we report that in semi-thin, transverse sections of quick-frozen, freeze-dried and plastic-embedded guinea pig organ of Corti, myosin-like immunostaining was restricted to the apical cytoplasm of hair cells and was not detected along the stereocilia. With respect to the immunohistochemical distribution of actin, myosin and the muscular Z-line protein, α-actinin, the apex of hair cells strongly resembles the intestinal epithelial brush border[6,7].

Specific immunostaining of cochlear hair cells was achieved using antibodies directed against purified non-muscle myosin from calf thymus (Fig. 1*a*, *b*); these antibodies have previously been shown to react with a broad spectrum of non-muscle cells[8-10]. Immunostaining was completely abolished when the antibodies were absorbed with an excess of thymus myosin. The bulk of myosin-specific immunofluorescence was confined to the apex of the hair cells, the so-called cuticular plate (Fig. 2*a*). A narrow, rather faint, fluorescent band extended from the cuticular plate downwards along the lateral cell border of the outer but not the inner hair cells. Antibodies to striated muscle (chicken pectoral) and smooth muscle (human uterus, chicken gizzard)[11] myosin did not react with either the hair cells and their stereocilia or any other cell type of the organ of Corti,

indicating that these cells contain an immunologically distinct type of myosin. This finding is in contrast to the observations of Macartney *et al.*[5], who described staining of cochlear stereocilia with antibody to human uterus myosin. Although we cannot offer a definite explanation for this discrepancy, there are two possibilities to consider. (1) The myosin preparation used by Macartney *et al.*[5,12] contained minor amounts of some other proteins running in SDS-polyacrylamide gel electrophoresis between the heavy and presumed light chains of myosin (Macartney *et al.*[12] discussed the possibility of contamination of their antigen with actin or tropomyosin) and it is possible that the antibody to uterus myosin contained additional immunoglobulins directed against these unknown minor protein components. (2) Macartney *et al.*[5] used whole mounts of the organ of Corti for immunohistochemical staining. This method of tissue handling, however, is sensitive to a particular optical artefact known as 'light piping' of stereocilia that might give the impression of specific immunofluorescence (for detailed discussion, see ref. 13). In the present study we applied immunostaining to 0.5-μm-thick sections of quick-frozen, freeze-dried, plastic-embedded tissue. This method avoids diffusion artefacts and allows examination at high resolution. Considerable light piping will probably not occur in these conditions because the thickness of the sections is within the range of the thickness of an individual stereocilium (0.4–0.8 μm)[2,3].

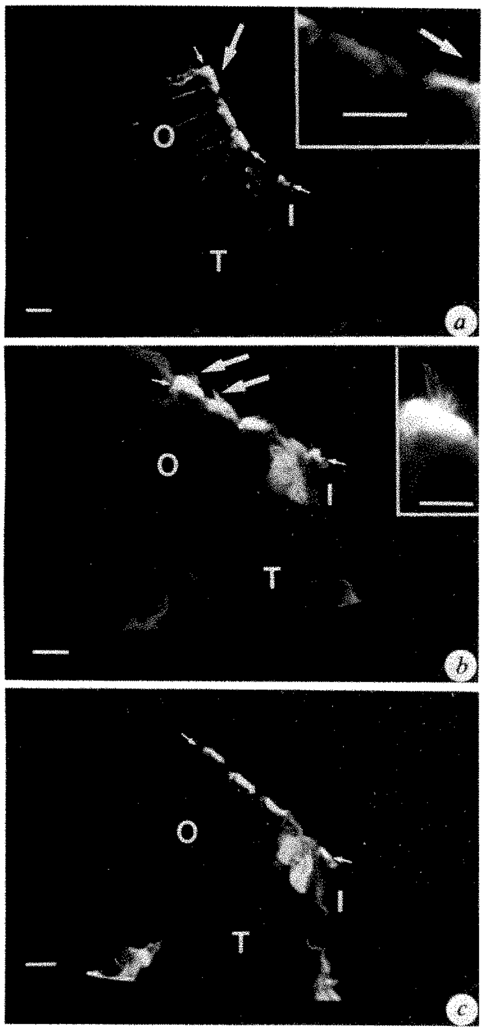

Fig. 2 *a–c*, Semi-thin section (0.5 μm) of guinea pig organ of Corti stained with rabbit antibodies to calf thymus myosin (*a*), chicken gizzard actin (*b*) and chicken skeletal muscle α-actinin[10] (*c*). Large arrows in *a* and *b* indicate stereocilia (shown in the insets at higher magnification), which do not react with anti-myosin antibody (*a*) but react strongly with anti-actin antibody (*b*). The cuticular plate (small arrows) of the inner (I) and outer (O) hair cells display a strong reaction with all antibodies shown. The inner tunnel (T) is bounded by the outer and inner pillar cells which exhibit a strong fluorescence with antibodies to actin (*b*) and α-actinin (*c*). Scale bar, 10 μm. The bony cochlea was removed under ether anaesthesia and was rapidly frozen by placing in melting isopentane cooled with liquid nitrogen. Freeze-drying was performed at 10^{-4} torr starting with a temperature of -100 °C, which was increased stepwise to room temperature over 3 days. Freeze-dried bony cochleae were vacuum-embedded in Epon. Semi-thin sections (cut with glass knives on a Reichert Ultracut microtome) were mounted on glass slides and the resin was removed as described elsewhere[18]. The antibody concentrations used were 0.5 mg ml^{-1} for the primary antibodies and 0.1 mg ml^{-1} for the FITC (fluorescein isothiocyanate)-labelled goat anti-rabbit IgG (Miles). Dilution of antibodies and rinsing steps were done in phosphate-buffered saline, *p*H 7.2 at room temperature.

As expected, antibodies to actin from chicken gizzard reacted strongly with both the cuticular plate and the stereocilia of the hair cells (Fig. 2*b*). There was a strong actin-like staining in the cytoplasm of the outer and inner pillar cells and the apical processes of phalangeal cells (both structures did not react with anti-myosin antibody). Antibodies to α-actinin from chicken pectoral muscle[10] produced very intense staining in the cuticular plate of outer and inner hair cells but not in their stereocilia (Fig. 2*c*). As with anti-actin, anti-α-actinin antibody displayed a high affinity for the apical processes of phalangeal cells and for the outer and inner pillars, indicating that both actin and α-actinin are major constituents of the prominent cytoskeletal apparatus present in these supporting cells. In the pillars this apparatus consists of bundles of microtubules intermingled with microfilaments (actin ?) and electron-dense reticular material (α-actinin ?)[14]. The apex of phalangeal processes is filled with electron-dense reticular material and microfilaments[14].

Thus, the present findings provide evidence that actin, myosin and α-actinin are concentrated within the apex of cochlear hair cells. While actin is present both the stereocilia and the cuticular plate, myosin and α-actinin are obviously absent from the stereocilia and are restricted to the cuticular plate. A similar distribution of these contractile proteins has been demonstrated in the intestinal brush border[6,7,15]. Stereocilia have been shown to react like intestinal microvilli with antibodies to fimbrin (an actin cross-linking protein)[4] but in the present work and in a previously published study[4], they apparently did not react with antibodies to villin[16] (a 95,000-molecular weight (M_r) protein that bundles and severs actin filaments in a Ca^{2+}-dependent manner[17]). This observation indicates differences in the molecular composition of the actin filament bundle present in stereocilia and microvilli. Motile events have so far not been reported in hair cells and their stereocilia. Therefore, it remains to be shown whether myosin and α-actinin serve merely to cross-link and tighten the web of actin filaments within the cuticular plate or whether these proteins constitute a contractile apparatus that might actively modify mechanical properties of the apical portion of cochlear hair cells.

Meta-vinculin—a vinculin-related protein with solubility properties of a membrane protein

Janet D'Angelo Siliciano & Susan W. Craig

Department of Physiological Chemistry, Johns Hopkins School of Medicine, Baltimore, Maryland 21205, USA

The localization of vinculin, an actin-binding protein[1,2] of molecular weight 130,000 (130K) at a variety of cytoskeletal-associated membrane specializations including the zonula adherens of intestinal epithelial cells[3], fascia adherens of intercalated discs[3], focal adhesion plaques in fibroblasts[4,5], and costameres (sarcolemmal domains in periodic register with the I-bands of subjacent myofibrils) in cardiac and skeletal muscle[6], suggests that vinculin could link actin to cell membranes. This hypothesis is supported by immuno-ultrastructural studies which show that vinculin is closely apposed to the plasma membrane at sites where actin-containing microfilaments terminate[3,7]. But since vinculin has the solubility properties of a peripheral membrane protein[4], there would also need to be an integral membrane component to which it bound to link actin filaments to the plasma membrane. Our efforts to identify the presumed membrane binding site for vinculin resulted instead in the detection of a 150K protein which we term meta-vinculin (Greek *meta* among, with; in the sense of closely related to), that is immunologically related to 130K vinculin. Unlike vinculin, meta-vinculin has the solubility properties of an integral membrane protein. Given its location within the cell, it is possible that meta-vinculin is an integral membrane anchor protein for actin filaments.

Unfixed cryostat sections of chicken gizzard were extracted with buffers designed to solubilize either peripheral or integral membrane proteins[8,9] in an attempt to remove vinculin from its location in dense plaques on the smooth muscle plasma membrane (Fig. 1*a*)[3]. The effect of the extractions was assessed by subsequent indirect immunofluorescence staining of the sections with affinity purified anti-vinculin. Because vinculin is isolated by low ionic strength extraction of minced gizzard[4], for example, with 2 mM Tris/1 mM EGTA, *p*H 9.0[10] or 1 mM $KHCO_3$, *p*H 7.5[11], we expected to observe a dramatic decrease in fluorescence when cryostat sections were extracted in these buffers for various times (up to 24 hours) and then fixed and processed for indirect immunofluorescence. However, the low ionic strength buffers extracted barely 20% of the membrane associated vinculin as evidenced both by slightly dimmer staining (Fig. 1*c*, *e*) and by microspectrophotometry (data not shown). Neither was vinculin extracted to any greater extent by the following buffers known to disrupt electrostatic interactions between proteins: 50 mM Na acetate *p*H 5.4 (low *p*H); 0.01 M NaOH *p*H 11.5 (high *p*H); 1.0 M Tris-HCl *p*H 7.4 (high salt); 0.6 M KI (chaotropic agent); 50 mM Tris plus 0.1–0.6 M KCl *p*H 8 (buffers of various ionic strengths); 2 mM Tris plus 5 mM EGTA plus 5 mM EDTA, *p*H 8.0 (chelators). Many integral membrane proteins can be solubilized by non-ionic detergents which primarily disrupt hydrophobic interactions. However, 1% Triton X-100 in 10 mM NaCl, 1.5 mM $MgCl_2$, 10 mM Tris *p*H 7.4 (1% Triton buffer) extracted only about 20% of the vinculin from unfixed cryostat sections (Fig. 1*g*) even though the plasma membranes were disrupted as evidenced by a phase-clear area outlining each smooth muscle cell. Interestingly, the vinculin that remained behind with the detergent-insoluble residue was still organized as in the control sections; the outline of each cell could be clearly discerned by the fluorescence of the anti-vinculin stain. In contrast to all other treatments, we found that over 90% of the vinculin could be extracted by a combination of 1% Triton X-100 and 0.6 M Tris-HCl *p*H 7.4 (Fig. 1*i*). These results suggest that to

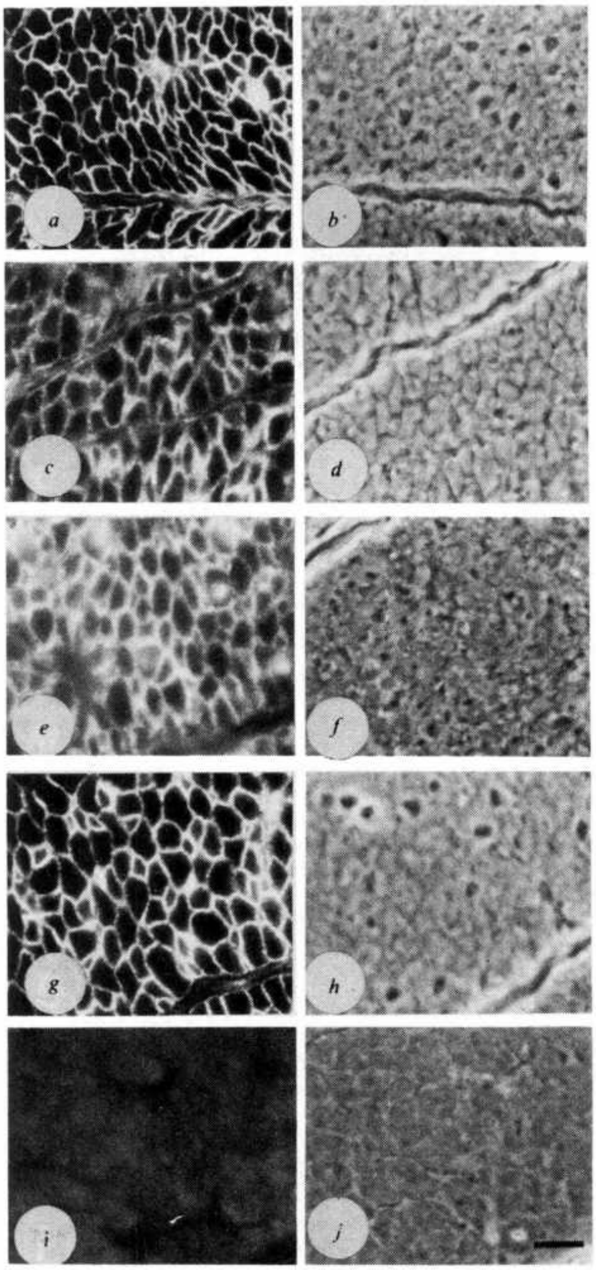

Fig. 1 Conditions for extraction of immunoreactive vinculin from cryostat sections of gizzard. The gizzard from a freshly killed chick was removed, cut quickly into small pieces and dropped into freezing −80 °C isopentane. The frozen tissue was transferred to powdered dry ice and frozen onto a copper chuck with OTC compound. 4 μm sections were cut on a Harris cryostat at −20 °C and mounted immediately on gelatin-coated glass slides. Sections were extracted in the indicated buffer for the following lengths of time: 1% Triton in 10 mM NaCl, 1.5 mM $MgCl_2$, 10 mM Tris *p*H 7.4 or 1% Triton + 0.6 M Tris-HCl *p*H 7.4, 3 min; 1 mM $KHCO_3$ *p*H 7.5 or 2 mm Tris + 1 mM EGTA, *p*H 9.0, 30 min. After extraction, sections were rinsed in Dulbecco's-PBS (D-PBS), fixed for 5 min in 3% paraformaldehyde *p*H 7.3 and then processed for indirect immunofluorescence. After incubation with 120 $\mu g\ ml^{-1}$ affinity purified anti-vinculin for 45 min, sections were washed extensively in D-PBS. Affinity purified fluorescein conjugated goat anti-rabbit Igs (50 $\mu g\ ml^{-1}$) were then added to the sections. After incubation for 30 min, sections were washed in D-PBS and observed using an Ortholux II fluorescence microscope equipped for epifluorescence illumination with Leitz KG1, BG23, K480 filters and H2 cube. Photomicrographs were recorded with a Vario-Orthomat camera on Kodak Tri-X pan black and white film, ASA 1000. *a*,*b*, Unextracted gizzard; *c*,*d*, 1 mM $KHCO_3$ *p*H 7.5 extraction; *e*,*f*, 2 mM Tris/1 mM EGTA *p*H 9.0 extraction; *g*,*h*, 1% Triton *p*H 7.4 extraction; *i*,*j*, 1% Triton + 0.6 M Tris *p*H 7.4. *a*,*c*,*e*,*g*,*i*, Fluorescence micrographs; *b*,*d*,*f*,*h*,*j*, phase micrographs. Fig. 2 Detection of 150K meta-vinculin and comparison of its solubility properties with those of 130K vinculin. A 60-mg fragment of gizzard from a freshly killed chick was homogenized in 1.0 ml of the appropriate extraction buffer which included the following protease inhibitors: (final concentration): leupeptin (10 μg ml^{-1}), antipain (20 μg ml^{-1}), Trasylol (500 units ml^{-1}, benzamidine (100 μg ml^{-1}), chymostatin (10 μg ml^{-1}) and pepstatin (10 μg ml^{-1}). The homogenates were spun at 100,000*g* for 60 min in a SW 50.1 rotor at 4 °C. An equal volume of 2 × Laemmli SDS sample buffer was added to aliquots of supernatants. 500 μl of 2× sample buffer was used to solubilize pellets. Equal volumes of supernatants and pellets were electrophoresed on a 5% Laemmli SDS polyacrylamide mini gel. For immunoblots, the proteins were electrophoresed onto nitrocellulose paper[12]. Vinculin and meta-vinculin were detected by incubating the nitrocellulose paper with affinity-purified anti-vinculin (120 μg ml^{-1}). After extensive washing in Nonidet P-40 (NP-40) buffer (0.05 M Tris, 0.15 M NaCl, 0.05% NP-40, 0.02% NaN_3, 0.1% bovine serum albumin *p*H 8.0), the paper was incubated with ^{125}I-Protein A which was diluted in the NP-40 buffer. The washing was repeated, the paper was dried and then exposed to Kodak XR-5 X-ray film with a Cronex lightening-plus intensifying screen. Immunodetection of proteins in the SDS gel itself was done by the method of Adair *et al.*[18]. *a*, Autoradiogram of immunoblot. 1, 1% Triton + 0.6 M Tris-HCl *p*H 7.4 extraction, supernatant (S) and pellet (P); 2, 1 mM $KHCO_3$ *p*H 7.5 extraction; 3, 2 mM Tris/1 mM EGTA *p*H 9.0 extraction; St, Standards: filamin, 250K; vinculin, 130K; alpha-actinin, 100K; and bovine serum albumin, 68K. *b*, Coomassie blue stained gel. 1, 1% Triton + 0.6 M Tris-HCl *p*H 7.4 extraction, supernatant (S) and pellet (P); 2, 1 mM $KHCO_3$ *p*H 7.5 extraction. *c*, Autoradiograph of anti-vinculin/^{125}I-Protein A overlay of the same gel shown in *b*.

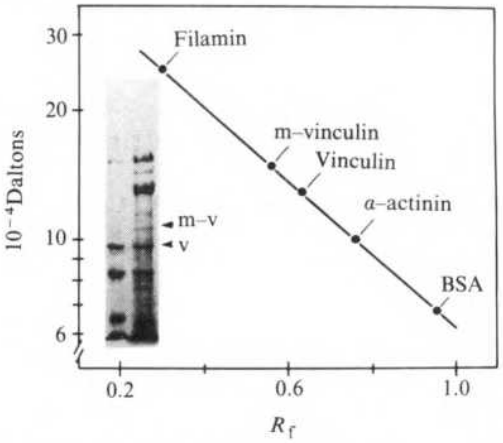

Fig. 3 Estimation of the molecular weight of meta-vinculin by SDS gel electrophoresis. A 100,000*g* supernatant of a 1% Triton + 0.6 M Tris-HCl *p*H 7.4 extract (prepared as described in Fig. 2) was run on a 5% polyacrylamide mini gel. Meta-vinculin and vinculin were localized in the gel by the antibody overlay technique described by Adair *et al.*[18]. Lane 1, standards: Filamin, 250K; vinculin, 130K; α-actinin, 100K; bovine serum albumin, 68K. Lane 2, supernatant of 1% Triton + 0.6 M Tris-HCl *p*H 7.4 extract. Vinculin and meta-vinculin are marked by arrowheads.

solubilize the bulk of the vinculin it is necessary to disrupt two types of linkages—one electrostatic and the other hydrophobic.

Although these data show that vinculin can be extracted efficiently only in the presence of high salt plus detergent, vinculin is conventionally isolated from a low ionic strength extraction of fresh or frozen chicken gizzard[4,10,11]. To assess the basis for this apparent discrepancy we extracted fresh gizzards with various buffers in the presence of protease inhibitors and analysed the 100,000*g* supernatants and pellets by SDS gel electrophoresis followed by an immunoblot[12] developed with affinity purified anti-vinculin. The results (Fig. 2) not only confirm the immunofluorescence observations but also reveal that affinity purified anti-vinculin recognizes two molecules: vinculin and a protein (meta-vinculin) with a slightly higher molecular weight than vinculin. The combination of 1% Triton and 0.6 M Tris-HCl *p*H 7.4 solubilizes most of the vinculin and more than 90% of the meta-vinculin (Fig. 2*a*-1), whereas the low ionic strength buffers (1 mM $KHCO_3$ *p*H 7.5 or 2 mM Tris/1 mM EGTA *p*H 9.0) extract much less of the vinculin and less than 10% of the meta-vinculin (Fig. 2*a*-2 and 2*a*-3). Figure 2*b*, *c* shows that the meta-vinculin detected by an autoradiograph co-aligns with a distinct Coomassie blue stained band (Fig. 2*b*, arrow) which has the appropriate solubility properties of meta-vinculin. In this experiment (Fig. 2*c*), as well as in several but not all other experiments, we also detected a very high molecular weight (>250,000) protein that also reacts with anti-vinculin. Because its presence is variable and unpredictable, the nature of this very high molecular weight cross-reactive material remains unclear. The apparent molecular weight of meta-vinculin was estimated on SDS gels under reducing conditions and is approximately 150,000 (Fig. 3).

To rule out the possibility that detection of the 150K protein was due to the presence of contaminating antibodies, we affinity purified vinculin antibody from immune serum in the following manner[13]: vinculin was electrophoresed on a 5% preparative SDS gel which gave good separation of vinculin from meta-vinculin. The 130K band was excised from the gel, and electrophoresed onto nitrocellulose paper, which was then used to affinity purify anti-130K vinculin. An immunoblot of the 100,000*g* supernatant of a 1% Triton plus 0.6 M Tris extract of fresh gizzard proves that anti-130K vinculin also reacts with 150K meta-vinculin (Fig. 4).

The basis for the antigenic relationship between vinculin and meta-vinculin is unknown. It is possible that 130K vinculin isolated by published procedures is a proteolytic fragment of the 150K meta-vinculin. Alternatively, meta-vinculin and vinculin may be products of two different genes which share some degree of homology, or of a single gene whose transcript is spliced differentially to yield molecules with common and unique functional properties as is the case for secreted and membrane-bound IgM[14].

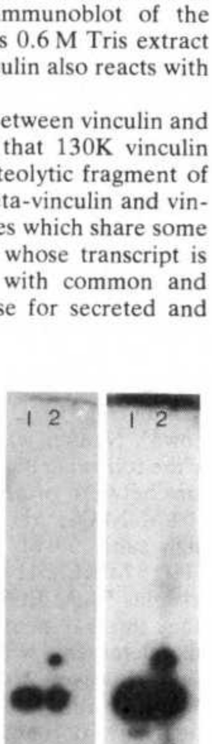

Fig. 4 Anti-vinculin affinity-purified on 130K vinculin also recognizes 150K meta-vinculin. Vinculin (0.5 mg) isolated by low ionic strength extraction of frozen chicken gizzards was electrophoresed on a preparative 5% SDS polyacrylamide gel. After straining the gel for 5 min, the 130K vinculin band was cut out. Vinculin was then electrophoretically transferred to nitrocellulose paper. The paper was incubated with anti-vinculin serum overnight and then washed. Antibody which bound to the 130K protein was eluted with 0.05 M acetic acid, neutralized immediately, and then dialysed overnight against phosphate-buffered saline (PBS) *p*H 7.4. This affinity-purified antibody was then tested for its ability to identify meta-vinculin and vinculin in an immunoblot of the 100,000*g* supernatant of a 1% Triton + 0.6 M Tris-HCl *p*H 7.4 extract of fresh chick gizzard prepared as described in Fig. 2. Lane 1, vinculin standard; lane 2, supernatant of a 1% Triton + 0.6 M Tris-HCl *p*H 7.4 extract. Exposure times were 12 h and 72 h.

Feramisco *et al.*[15] described a 152K protein which is restricted to smooth muscle, and is immunologically related to vinculin, but does not appear to be a proteolytic fragment of vinculin. Possibly this 152K protein is the protein meta-vinculin which we have defined on the basis of solubility properties as well as shared antigenicity with vinculin; however, we do not yet have sufficient information to make a comparison. It will also be of interest to determine if there is a relationship between meta-vinculin and chicken gizzard caldesmon[16], a 150K protein which binds F-actin and is regulated by calcium and calmodulin.

Unlike vinculin, meta-vinculin has the solubility properties of an integral membrane protein. Although it is possible that the low solubility of meta-vinculin in any of the tested solvents other than 1% Triton plus 0.6 M Tris simply reflects tight binding of a peripheral protein to an integral membrane protein, it seems more likely that it reflects differences in the type of bond formed with the plasma membrane. Membrane-associated proteins are divided into peripheral or integral protein classes depending on their solubility properties. Those proteins requiring detergent for solubilization (integral membrane proteins) have been found, with few exceptions, to contain a hydrophobic domain which is buried in the lipid bilayer[17]. Based on these considerations, we speculate that meta-vinculin might be an integral membrane protein and as such, a strong contender for the role of directly linking actin to the plasma membrane.

We thank Dr Solomon Snyder for use of his cryostat, Dr Suzanne Rosenberg for the use of her microspectrophotometer, and Sheila Sanders and José V. Pardo for helpful discussions. This work was supported by AI 13700. J.D.S. is supported by NIH pre-doctoral training grant (GM 07445).

Ca^{2+}-free perfusion of rat heart reveals a $(Na^+ + K^+)$ATPase form highly sensitive to ouabain

P. Mansier & L. G. Lelievre

INSERM Unité 127 Hôpital Laribiosière, Université Paris 7,
41 Bd de la Chapelle, 75010 Paris, France

The sensitivities of the cardiac $(Na^+ + K^+)$ATPases to inhibition by ouabain have been shown to correlate with the pharmacologically active digitalis concentrations in the various source species[1]. The rat heart enzyme is generally considered to be insensitive to ouabain with half-maximal inhibition at $\sim 6 \times 10^{-5}$ M ouabain[2,3] and a K_D for binding[3–7] of $1–6 \times 10^{-5}$ M. However, recent data[5–7] showed that rat cardiac sarcolemma preparations can bind ouabain with high affinity (k_D $1–3 \times 10^{-7}$ M) with no detectable concomitant enzyme inhibition *in vitro* but producing a sustained positive inotropic effect *in vivo*. In the present study, we measured the $(Na^+ + K^+)$ATPase inhibition by ouabain in sarcolemma-enriched fractions obtained from rat hearts relaxed by perfusion with Ca^{2+}-free solutions. In these conditions, two enzyme forms having high and low sensitivities to ouabain were found (half-maximal inhibitions with 1.2×10^{-8} and 6×10^{-5} M, respectively). Their relative proportion is close to 1. Confirming previous data[2–7], the highly sensitive form was not detected in preparations from hearts maintained at a physiological calcium level. This heterogeneous population of functional $(Na^+ + K^+)$ATPases suggests that, in rat heart, the positive inotropic effect of low doses of ouabain *in vivo*[5–9] would act through the inhibition[9] of the enzyme activity highly sensitive to ouabain as detected *in vitro*.

Hearts isolated from male Wistar rats (240–300 g) were depleted of calcium or maintained at a normal calcium concentration (2 mM). In the former case, the heart was completely relaxed by perfusion either with an EDTA-containing relaxing buffer[10] (pCa 8) or with a Ca^{2+}-free Krebs–Ringer bicarbonate buffer (pCa 4.7)[11]. To maintain a physiological Ca^{2+} concentration, the perfusion was either omitted or performed with a Ca^{2+}-containing buffer. Sarcolemmal vesicles were isolated by differential centrifugations. The $(Na^+ + K^+)$ATPase was measured before and after unmasking the total activity with Na–SDS[12] or by reiterative freezings and thawings. As shown in Table 1, the preparation used in the present work is highly enriched in sarcolemmal vesicles with specific activities of $(Na^+ + K^+)$ATPase varying between 40 and 100 μmol of phosphate liberated per mg of protein per h. The sensitivity of $(Na^+ + K^+)$ATPase to ouabain was checked with 10^{-9} to 2×10^{-3} M ouabain (Boehringer) (prepared daily).

Native sarcolemmal vesicles isolated from relaxed hearts exhibited a two-step dose–response curve to ouabain (Fig. 1, curve *a*): 55±7% of the $(Na^+ + K^+)$ATPase activity was inhibited between 10^{-9} and 3×10^{-7} M ouabain, the half-maximal inhibition (IC_{50}) occurring with $1.2 \pm 0.2 \times 10^{-8}$ M ouabain. A plateau associated with 45±7% of the total activity was found between 3×10^{-7} and 10^{-5} M, 50% inhibition of this residual activity was obtained with $6 \pm 2 \times 10^{-5}$ M ouabain. This latter value is consistent with previous data on the insensitivity of rat heart $(Na^+ + K^+)$ATPase to ouabain[1–9,13] but involves only 45% of the enzyme activity.

A similar biphasic curve having the same proportion of the $(Na + K^+)$ATPase forms was obtained with sarcolemma vesicles subfractionated by centrifugation on sucrose[14] (Fig. 1, curve *a*). (Specific activity of $(Na^+ + K^+)$ATPase: 205±18 μmol phosphate h^{-1} mg^{-1}.)

Sarcolemmal vesicles from hearts maintained at a physiological Ca^{2+} level yielded a homogeneous population of $(Na^+ + K^+)$ATPase exhibiting a low sensitivity to ouabain (IC_{50} $4 \pm 2 \times 10^{-5}$ M) (Fig. 1, curve *b*) confirming all previous results[1–9,13]. Nevertheless, the yields in microsomal proteins and 5′-nucleotidase activity (a sarcolemma-bound marker[15]) were lower than those from hearts perfused with Ca^{2+}-free solutions, whereas the specific activity of the $(Na^+ + K^+)$ATPase remained constant (Table 1). These results are consistent with the observations of Zak *et al.*[16] who showed that the initial relaxed state of myofibrils facilitated the isolation of subcellular fractions in higher yield and with less destruction. However, as the specific activity of the $(Na^+ + K^+)$ATPase remained constant, one might suppose a conversion of the high affinity form into the low affinity one exhibiting the same molecular turnover. In considering both the specific activity and the protein yield, the total $(Na^+ + K^+)$ATPase activity in Ca^{2+}-containing hearts represented half that found in completely relaxed hearts. In the former case, the enzyme form highly sensitive to ouabain is lost or exists as a catalytically inactive conformation as suggested by Adams *et al.*[6].

Three more possibilities had to be excluded before concluding that it is the initial low Ca^{2+} level before preparation that reveals a $(Na^+ + K^+)$ATPase activity highly sensitive to ouabain.

First, a variable fraction of the vesicles used in this study may have an inside-out polarity; the curves may reflect differences in accessibility of ouabain to its internalized binding site or

Table 1 Distributions of proteins and enzyme activities in sarcolemmal vesicles

Opened	/	100±9 (60%)	16±2 (96%)	/	95±15 (30%)	1.6±0.1 (5%)

Animals were killed by cervical dislocation, the heart was removed and either perfused with Ca^{2+}-free medium or maintained at a normal Ca^{2+} level (2 mM). Ca^{2+}-free hearts were perfused via coronary arteries for 1 min at room temperature with 5 ml of the ice-cold relaxing buffers[10,11]. Hearts at normal Ca^{2+} levels were either perfused in the same conditions with an ice-cold solution containing 2 mM $CaCl_2$, 25 mM KCl and 39 mM sodium tetraborate/HCl *p*H 6.8, or kept in ice for 5 min. The minced ventricles were homogenized at 4 °C in 30 ml of 20 mM sodium pyrophosphate (PP_i), 0.1 mM phenylmethanesulphonylfluoride, 10 mM Tris-HCl *p*H 7.8, with a Polytron PT 20 (2×0.5 s, setting 5). After stirring for 20 min at 4 °C, the suspension was made up to 120 mM KCl, 30 mM NaCl and 250 mM sucrose by adding concentrated solutions. The 500*g* 5-min supernatant was diluted to 120 ml of this isotonic and isoosmotic solution, adjusted to *p*H 6.8 with 40 mM imidazole–HCl, and centrifuged at 7,500*g* for 15 min and then at 31,000*g* for 30 min. The final pellet was washed in 50 mM PP_i, 135 mM NaCl, 5 mM $MgCl_2$ and 5 mM Tris-HCl *p*H 7.4 to eliminate myofibrils. The sarcolemmal vesicles were resuspended in 100 mM NaCl, 250 mM sucrose and 40 mM imidazole–HCl *p*H 6.8 and analysed for enzyme content. The $(Na^+ + K^+)$ATPase activity was assayed at 37 °C in a medium containing 10 μg sarcolemma protein[27], 4 mM $MgCl_2$, 100 mM NaCl, 10 mM KCl, 40 mM imidazole–HCl *p*H 7.4. The reaction was initiated with the addition of prewarmed ATP (final concentration 4 mM) and carried out over six time points to assess linearity. Aliquots were taken every 30 s and the released orthophosphate was measured[28]. The $(Na^+ + K^+)$ATPase activity was taken as that inhibited by 2×10^{-3} M ouabain. The activities of the $(Na^+ + K^+)$ATPase reported here represented 30–50% of total ATPase activities. 5′-Nucleotidase activity[15] was assayed for 1 h at 37 °C in a medium containing 20–100 μg protein ml^{-1}, 100 mM KCl, 10 mM $MgCl_2$, 5 mM AMP and 50 mM imidazole–HCl *p*H 7.4. This activity was taken as that insensitive to 10 mM potassium sodium tartrate[29] but that inhibited by 1 mM adenosine 5′-diphosphonate. Activities are expressed as μmol orthophosphate per mg of protein per h. Opened vesicles were obtained by pretreatment with Na–SDS[12] or by reiterative freezings and thawings: samples of freshly prepared sarcolemma vesicles (~0.1 mg) were frozen at −40 °C for 24 h, thawed, analysed for their enzyme content and frozen again. This procedure was performed twice. Values in parentheses give recovery of enzyme activity as % of total patent activity of homogenate. Whatever the pretreatment of the heart, the specific activities of $(Na^+ + K^+)$ATPase and 5′-nucleotidase in the ventricle homogenates were 2.1±0.5 and 0.2±0.06 μmol phosphate per h per mg, respectively. Note that in the intermediate fractions obtained along with the purification procedures, no significant $(Na^+ + K^+)$ATPase and 5′-nucleotidase activities could be measured.

variations in the proportion of inverted vesicles in the sarcolemma preparations. This possibility was excluded as a pretreatment of the vesicles, whatever their source, with Na–SDS or by reiterative freezings had no effect on the dose–response curves.

Second, the sensitivities of the $(Na^+ + K^+)$ATPase activity to ouabain seemed not to be due to drastic differences in the rates of drug binding to both native and opened vesicles. In the absence of ATP, either a 10-min or a 30-min equilibration period at 37 °C with varying doses of the drug led to the same inhibitions of the enzyme activity. In the presence of ATP, which favours ouabain binding[17], the amounts of phosphate liberated over the assays were linear with respect to time, suggesting that the reversible enzyme–ouabain equilibrium[2,3] was reached in less than 30 s (the shortest time used) even in the presence of 10 mM KCl.

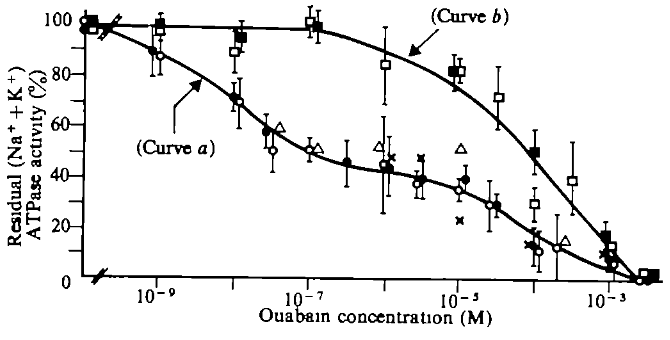

Fig. 1 Dose–response curves of $(Na^+ + K^+)$ATPase activity versus ouabain concentration. Curve *a*, Ca^{2+}-free perfused heart: native (●) and opened (○) sarcolemmal vesicles from ventricle, opened vesicles subfractionated on sucrose[14] (×), and opened vesicles (△) from isolated myocytes[11,28]. Curve *b*, heart maintained at 2 mM Ca^{2+}: native (■) and opened (□) sarcolemmal vesicles. The sensitivity of $(Na^+ + K^+)$ATPase was checked as follows. After incubation of sarcolemmal vesicles for 30 min at 37 °C with various amounts of ouabain in the ATP-free assay medium, ATP was added to initiate the enzymatic reaction. The activity at a given ouabain concentration (x) is: $[(\text{activity})^x - (\text{activity})^{2\times10^{-3}\text{ M}}/(\text{activity})^0 - (\text{activity})^{2\times10^{-3}\text{ M}}]\times100$. Whatever the pretreatment to which the heart was subjected, neither of our data showed net stimulation of the enzyme at any concentration. Each point represents the mean of 4–18 observations with bars denoting s.e.m. computed from percentage inhibition in each experiment. Each experiment was performed at least four times with at least four different sarcolemmal preparations.

Third, the enzyme form highly sensitive to ouabain could be associated with cell membranes from more than one cell type[18]. The experiments with sarcolemma vesicles from isolated myocytes[19] from relaxed hearts[11] ruled out this alternative explanation. The two-step inhibition by ouabain was the same as in sarcolemma preparations from the whole ventricle (Fig. 1, curve *a*). In isolated myocytes, Adams *et al.*[6] reported a high affinity binding site for ^{3}H-ouabain with a K_D of 1.2×10^{-7} M. Our process of isolation may have changed the properties of the enzyme in relation to the effect of the glycoside, that is, an increased sensitivity. However, the disparity with our data may be due to calcium loading as a result of the long-lasting incubation of the myocytes at 37 °C with 0.5 mM Ca^{2+}. This would lead to a situation different from the physiological conditions (intact heart, 2 mM external calcium and 10^{-5}–10^{-7} M internal free Ca^{2+}) and the conditions used here (sarcolemma vesicles, 3×10^{-6} M free Ca^{2+}). Thus, the dose–response curve for the low ouabain concentration reported by Adams *et al.*[6] would represent the sum of both high and low sensitivity enzyme forms in an unknown proportion depending on the internal Ca^{2+} pools and/or the size of the rapidly exchanging calcium stores[20].

These parameters would control the expression of the high sensitivity enzyme form. Such an effect of Ca^{2+} on the effects of ouabain is consistent with the different relationships between ouabain and the systolic (10^{-5} M internal free Ca^{2+}) and diastolic (10^{-7} M internal free Ca^{2+}) tensions in rat heart[7]. Further, the experiments of Carrier *et al.*[21] show that in guinea pig heart preparations, the relative inotropic action of ouabain is much larger when the Ca^{2+} store is small than when it is large. A direct effect of millimolar external Ca^{2+} levels on the expression of the two enzyme forms cannot be excluded but is very unlikely since our observations are consistent with the biphasic inotropic action of ouabain (10^{-8}–10^{-6} M and 10^{-4} M) in isolated rat hearts perfused with 1.4 mM Ca^{2+} (ref. 22).

There is some evidence that two components could be involved in the inotropic effect of ouabain *in vivo*[5–8,22] as if the high- and low-affinity ouabain-binding sites detected in rat heart sarcolemmal vesicles were two $(Na^+ + K^+)$ATPase isozymes[6] being inhibited by the drug in a concentration range between 3×10^{-8} M and 10^{-3} M[7]. Alternatively, a single class of enzyme molecules may express one or two sensitivities to ouabain depending both on the Ca^{2+} concentrations[23,24] and on the interactions with other membrane proteins[24,25].

The present results provide further insight into the therapeutic mechanisms of ouabain[26]: the high sensitivity enzyme form might represent the physiological site responsible for the positive inotropic effect of low concentrations of ouabain *in vivo*.

We thank Drs Carl Apstein, Paul Cassidy, Danièle Charlemagne and Bernard Swynghedauw for stimulating discussions and Mrs F. Marotte and Dr J. L. Samuel for providing us with isolated myocytes. This work was supported by grants from INSERM (CRL 805034) and from Société Française de Cardiologie.

Minute virus of mice inhibits cell transformation by simian virus 40

S. Mousset & J. Rommelaere*

Département de Biologie Moléculaire, Université Libre de Bruxelles, B-1640 Rhode-Saint-Genèse, Belgium

Certain paroviruses have been reported to inhibit spontaneous[1] or virus-induced[2] tumorigenesis in rodents; the mechanisms of this antineoplastic activity is unknown. We have investigated the ability of the minute virus of mice (MVM), a non-defective parvovirus[3], to interfere with the *in vitro* transformation of mouse cells by simian virus 40 (SV40). We used variants of BALB/c 3T3 cells, denoted PVR, selected for their resistance to the lytic effect of MVM. We report here that inoculation of SV40-infected PVR cells with MVM reduced dramatically the yield of transformed clones. Moreover, stable SV40 transformants of PVR cells lost up to 85% of their ability to grow in soft agar after MVM infection. Our results indicate that the antineoplastic effect of parvoviruses can be simulated in cell cultures and may involve a direct and selective toxic effect of these viruses on malignant cells or their precursors.

In mature animals, parvoviruses interfere with the development of tumours but are, in general, innocuous for normal cells regardless of their mitotic activity[3]. It is unclear whether this selective inhibition of oncogenesis depends on complex events occurring in whole animals such as immunological, hormonal or interferon induction responses. We therefore investigated whether the antineoplastic activity of parvoviruses could be reproduced and analysed *in vitro* in the absence of these physiological processes. An inhibition of the oncogenesis of adenovirus[4]- or herpes simplex virus[5]-transformed cells was achieved by exposing *in vitro* cultures of these cells to adeno-associated virus (AAV), a defective parvovirus, before inoculation into animals. Adenovirus and herpes simplex virus are the only two viruses that can serve as helper for the replication of AAV. Thus, it is questionable whether the antineoplastic activity of AAV results from its relationship to the helper virus or from a direct interaction between the parvovirus and the transformed cell *per se*. We tested the latter possibility by investigating whether the non-defective parvovirus MVM interfered with *in vitro* cell transformation by SV40, a virus without discernible helper activity for parvoviruses.

The BALB/c 3T3 mouse cell line[6] was used as it is highly susceptible to SV40 transformation. These cells are normally sensitive to MVM lytic infection, as are other established cultures of mouse fibroblasts. To mimic the *in vivo* situation we isolated from BALB/c 3T3 cells a series of variant clones resistant to MVM infection. These clones were denoted PVR (parvovirus-resistant). Typical properties of PVR cells are illustrated in Table 1. The PVR cells resisted viral attack as shown by both high cell survival and low production of infectious progeny virus. In contrast, PVR cells did not differ significantly from the permissive parent cells with respect to MVM uptake (data not shown), suggesting that their resistance occurred at an intracellular step of MVM replication.

Table 2 (columns *a* and *b*) shows that the PVR strains tested were susceptible to transformation by the oncogenic virus SV40 as measured by the ability of SV40-infected cells to form colonies in soft agar. The transformation frequency of PVR cells inoculated with SV40 (100 plaque-forming units (PFU) per cell) ranged from 1 to 5% and was equivalent to that of parental BALB/c 3T3 cells. The selection of PVR cells therefore had no detectable effect on their susceptibility to *in vitro*

Table 1 Susceptibility of BALB/c 3T3 and PVR-1 cells to MVM infection

Multiplicity of infection (PFU per cell)	Surviving fraction relative to uninfected cells		Fraction of inoculated cells producing infectious centres	
	BALB/c 3T3	PVR-1	BALB/c 3T3	PVR-1
1	$<10^{-3}$	0.99	0.41	0.008
10	$<10^{-3}$	0.90	–	–
100	$<10^{-3}$	0.78	0.66	0.05

The PVR-1 strain was cloned from a population of BALB/c 3T3 cells[4] surviving two successive infections with 100 PFU of MVM per cell. Cells from the parental BALB/c 3T3 line and from the PVR-1 strain were inoculated with increasing amounts of MVM. After 1 h, the inoculum was removed and extracellular virus was inactivated by incubation for 3 h in medium containing rabbit anti-MVM serum[7] (given by P. Tattersall). Cultures were then collected and processed for cell survival and infectious centre assays. Cell survival was measured by colony formation on plates and is expressed relative to uninfected cells. The plating efficiencies of uninfected BALB/c 3T3 and PVR-1 cells were 0.35 and 0.27, respectively. The fraction of productively infected cells was measured by plaque formation after seeding of MVM-inoculated cells on to appropriate indicator cells[7]. The resistance of PVR cells to MVM attack was maintained during continuous subculturing for at least 1 yr.

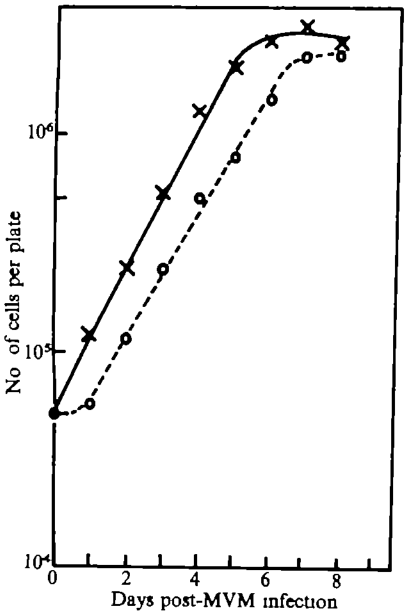

Fig. 1 Effect of MVM on the growth of monolayer cultures of SV40-transformed PVR-1 cells. SV40-transformed PVR-1 cells in 60-mm dishes were inoculated with MVM (100 PFU per cell; (O) or mock-infected(×). Cultures were further incubated in liquid medium containing rabbit anti-MVM serum[7] and collected at various intervals. Cells were counted with a haemocytometer.

transformation. Clearly, MVM reduced dramatically the yield of *in vitro* transformation of PVR cells previously infected by SV40 (Table 2, columns *c* and *d*). In order to identify which step of the transformation process is the target for MVM, we isolated stable SV40 transformants of PVR-1 cells and tested their sensitivity to MVM. Table 3 shows that MVM infection decreased markedly the viability of SV40-transformed PVR-1 cells as measured by their cloning efficiency on plastic plates. As SV40 transformation did not increase the plating efficiency of PVR-1 cells (see Tables 1 and 3), this effect can be accounted for, not by the reversion of the transformed phenotype, but rather by a cytotoxic action of MVM on transformed cells. Although 75% of the transformed PVR-1 cells were killed after inoculation with MVM at a multiplicity of 100 PFU per cell, only 16% of these cells supported a productive MVM infection (Table 3). However, the yield of infectious centres was 3–6 times greater for SV40-transformed (Table 3) than for normal (Table 1) cells. Thus, SV40 transformation was apparently associated with a greater sensitivity to the cytotoxic effect of MVM although only a very small fraction of transformed cells was fully permissive to this virus. The abortion of the productive infection in a fraction of the sensitive cells is a common, yet quantitatively variable, feature of parvovirus replication, as illustrated in Table 1 for BALB/c 3T3 cells. Table 3 also indicates that the cloning efficiency of stable SV40 transformants of PVR-1 cells in soft agar was reduced by 85% after infection with MVM at a multiplicity of 100 PFU per cell. As SV40-inoculated PVR-1 cells were prevented from forming clones in soft agar to a similar extent by MVM co-infection (Table 2), the data suggest that the presence of MVM during the establishment of the transformed phenotype is not essential for the inhibition of *in vitro* cell transformation.

Table 2 Effect of MVM on *in vitro* transformation of PVR cells by SV40

	Cloning efficiency in soft agar(%)			*d*, MVM inhibition of SV40 transformation
Cells	*a*, No virus	*b*, +SV40	*c*, +SV40 +MVM	(%)
PVR-1	$<5\times10^{-5}$	3.6	0.38	89.5
PVR-2	$<5\times10^{-5}$	2.4	0.37	84.2
PVR-3	$<5\times10^{-5}$	1.7	0.05	97.1

PVR-1, -2 and -3 strains were cloned from a population of BALB/c 3T3 cells surviving MVM infection and achieved similar levels of resistance to MVM (see Table 1). PVR strains were tested for their anchorage-independent growth ability, as measured by the formation of foci in soft agar[9]. *a*, Uninfected cells; *b*, cells inoculated with SV40 (100 PFU per cell) and propagated for six generations before suspension in agar-containing medium; *c*, same as *b*, except that cells were superinfected with MVM (100 PFU per cell) 24 h after SV40 inoculation. *a* and *b* series underwent mock infections. Intervals between SV40 and MVM infections ranging from 0 to 24 h were tested and gave essentially the same results (data not shown). Foci were counted 4 weeks after suspension in soft agar and were of similar size in all series. Incubation of MVM-treated cells for longer periods did not increase cloning efficiency.

The effect of MVM on the growth of monolayer cultures of SV40-transformed PVR-1 cells was studied in conditions that prevented secondary MVM infections. Figure 1 shows that MVM caused a delay in the proliferation of transformed PVR-1 cells. This lag was not detectable for non-transformed cells (data not shown) and probably reflects the killing of a fraction of the cells as a result of MVM infection (Table 3). SV40-transformed PVR-1 cells that survived MVM inoculation were not intrinsically resistant to MVM as they could be superinfected and showed the same growth delay as the parental culture (data not shown). Cell survivors contributing to the proliferation of the culture after the 1-day lag period did not differ markedly from uninfected cells with respect to their saturation density and growth rate (Fig. 1). It can be calculated from Fig. 1 that the generation time of MVM-infected cells was ~24 h, less than 1.5 h longer than for uninfected cells. Thus, the major restriction imposed by MVM on SV40-transformed cells seems to occur at the level of cell viability rather than growth properties. Recently, opposite conclusions were reached for the action of the defective parvovirus AAV on adenovirus-transformed cells. This discrepancy could be due to the fact that adenovirus is a helper for AAV replication. This interrelationship imposes specific restrictions on the expression of both viruses after AAV infection of adenovirus-transformed cells[4] and might account for the selective interference of AAV with the oncogenicity of its helper viruses[4,5]. Thus, the mechanisms underlying the inhibition of *in vitro* transformation might be at least partly different for defective AAV[4,8] and for autonomous MVM parvoviruses.

The results presented here indicate that one pathway of parvoviral surveillance against cancer might involve a direct and selective inactivation of transformed cells by these viruses. The privileged interaction of parvoviruses with transformed cells strongly suggests that transformation sensitizes cells that are normally resistant to virus infection, although a preferential transformation of pre-existing parvovirus-sensitive cells cannot be ruled out. It has been shown recently that the cellular permissivity to lytic parvovirus replication is controlled by developmentally regulated host factors[7]. The relevance of our

Table 3 Effects of MVM on SV40-transformed PVR-1 cells

			Colony formation in soft agar	
Multiplicity of infection (PFU per cell)	Cell surviving fraction	Fraction of productively infected cells	Cloning efficiency (%)	% Inhibition
0	1	0	7.8	0
0.1	—	—	5	36
1	0.52	0.05	4.1	48
10	0.32	—	2.1	74
100	0.25	0.16	1.2	85

A strain of transformed cells was derived from a clone of SV40-infected PVR-1 cells growing in soft agar (Table 2, column *b*). These cells expressed SV40 T antigen as measured by immunostaining (data not shown). SV40-transformed PVR-1 cells were inoculated with increasing amounts of MVM. Infected cells were then processed for cell survival and infectious centre assays (see Table 1 legend) or incubated for 5 h and suspended in soft agar for transformation assay (see Table 2). Viability and virus production were measured in the same experiment as for normal cells (Table 1). The plating efficiency of SV40-transformed PVR-1 cells was 0.12. The time of appearance and the size of foci in soft agar were not affected by MVM infection experimental system to the situation *in vivo* rests on the assumption that the expression of such a factor(s) is limiting in PVR cells as it is unknown why these selected cells fail to replicate MVM. Yet our data raise the possibility that changes in cellular gene expression triggered by neoplastic transformation might lift barriers to parvovirus replication, thereby making malignant cells a preferential target for the cytotoxic action of these viruses. Use of our *in vitro* system for the biochemical analysis of the MVM life cycle should elucidate these barriers. Such a system provides a means of studying the molecular mechanism of the parvoviral antineoplastic activity.

We thank Dr P. Tattersall for sharing unpublished information on MVM-resistant variants, Drs D. C. Ward and B. Hirt for stimulating discussions, Dr A. Schwers and Mr Lê Long for their collaboration, and Drs M. Errera and R. Thomas for their support. S. M. and J. R. are Chercheurs Qualifiés du Fonds National de la Recherche Scientifique de Belgique.

Oncogenes in solid human tumours

Simonetta Pulciani, Eugenio Santos,
Anne V. Lauver, Linda K. Long,

Laboratory of Cellular and Molecular Biology,
National Cancer Institute, Bethesda, Maryland 20205, USA

The identification and isolation of oncogenes capable of inducing malignant transformation on transfection into rodent cells from human tumour cells has opened the possibility of deciphering the processes involved in human carcinogenesis. With the exception of three human lymphomas[1], the human transforming genes so far identified have been detected in established tumour cell lines[1–8], raising the possibility that they might have been activated during *in vitro* manipulation of the cells. However, we report here that unmanipulated human solid tumours, including carcinomas of the colon (two), lung and pancreas and an embryonal rhabdomyosarcoma, also contain dominant transforming genes. The carcinomas of the lung and pancreas and the rhabdomyosarcoma possessed a common oncogene which, like that isolated from human LX-1 lung carcinoma cells[9], shares sequences with the *onc* gene of the Kirsten strain of murine sarcoma virus (MSV). We also show that several other human tumour cell lines, including those established from carcinomas of the colon (A2233), lung (A427 and A2182), gall bladder (A1604) and urinary bladder (A1698), possess the same oncogene. Thus a variety of human tumours, regardless of their clinical manifestations, contain a common transforming gene.

We have isolated high-molecular weight DNA from a variety of surgically removed solid human tumours, some of which have been stored at −70 °C for up to 5 yr. These human DNAs were used to transfect NIH 3T3 mouse cells by the calcium phosphate precipitation technique[10,11]. Foci of morphologically transformed NIH 3T3 cells were picked by the cloning cylinder technique and cloned as single cells in semi-solid media. The clonal cells were grown to mass culture and their DNAs analysed for the presence of human repetitive sequences[2] (Table 1). About 15% of the human solid tumours tested (5 out of 28) which included carcinomas of the colon (two), lung and pancreas and an embryonal rhabdomyosarcoma from a 1-yr-old patient, were found to contain dominant oncogenes capable of transforming NIH 3T3 cells. Transformation efficiencies (0.05–0.1 focus per μg of donor DNA per 2×10^5 NIH 3T3 cells) were about fivefold lower than those observed with T24 bladder carcinoma DNA, but comparable with those obtained with DNAs isolated from other human tumour cell lines[8]. Interestingly, DNA isolated from normal tissue of the patient, whose pancreatic carcinoma exhibited an oncogene, failed to induce transformation of NIH 3T3 cells in the same experimental conditions.

After three cycles of transfection, human DNA sequences encompassing the corresponding oncogenes present in each of the above solid human tumours were identified by Southern blot analysis using a probe specific for human repetitive sequences. Representative third-cycle transformants derived from a colon carcinoma of a 66-yr-old female, exhibited two common *Eco*RI-cleaved DNA fragments of about 10 and 7 kilobase pairs (kbp) (Fig. 1*A*). NIH 3T3 transformants derived from a second colon carcinoma obtained from the ascending portion of the colon of a 57-yr-old male patient also possessed two common *Eco*RI-cleaved human DNA fragments, although of different sizes (25 and 4 kbp; Fig. 1*B*). Southern blot analysis of these third-cycle transformants with other restriction endonucleases such as *Hin*dIII and *Bam*HI revealed different patterns of human DNA fragments (data not shown), suggesting that these two colon carcinomas contain different transforming genes.

When similar studies were performed with representative third-cycle transformants derived from the lung and pancreas carcinomas and from the rhabdomyosarcoma, a different picture emerged. All the transformants tested exhibited a common pattern of *Eco*RI-cleaved human DNA fragments of about 6.8, 6.7, 4.4, 4.0, 3.0 and 2.4 kbp (Fig. 1*C*). In analogous experiments, these transformants were found to possess three common *Hin*dIII-cleaved human DNA fragments of about 18.0, 12.2 and 3.4 kbp (data not shown). These results indicate that three different solid human tumours possess the same, or a highly related, oncogene.

We have also detected the presence of transforming genes in various human tumour cell lines including those established from carcinomas of the colon (A2233), lung (A427 and A2182), gall bladder (A1604) and urinary bladder (A1698 and T24) as well as from a fibrosarcoma (HT-1080). When the human DNA fragments carrying the corresponding oncogenes were characterized by submitting the DNAs of representative third-cycle NIH 3T3 transformants to Southern blot analysis, we observed that colon carcinoma A2233, lung carcinomas A427 and A2181, gall bladder carcinoma A1604 and urinary bladder carcinoma A1698 cells also contained the same pattern of human DNA fragments found in the oncogene present in the three solid human tumours described above (data not shown). Thus of the 12 human tumours (5 solid tumours and 7 established tumour cell lines) in which we have identified dominant transforming genes, 8 (67%) possess the same, or a highly related, oncogene.

Recently, Perucho *et al.* have reported that three human tumour cell lines established from lung and colon carcinomas contained the same transforming gene[6]. Moreover, this gene was indistinguishable from that previously identified by Murray *et al.* in SW480 colon carcinoma cells[5]. Close examination of the pattern of *Eco*RI-cleaved fragments of this lung/colon carcinoma oncogene and that depicted in Fig. 1*C* for the oncogene identified here in eight different tumours strongly suggests that they are the same oncogene.

It has been recently demonstrated that a human transforming gene isolated from T24 and EJ bladder carcinoma cells[8,12,13] is an activated form of the normal human homologue of the *onc* genes of the BALB and Harvey strains of murine sarcoma viruses (MSV)[9,14,15]. Furthermore, Der *et al.* have shown that the oncogene present in LX-1 human lung carcinoma cells contains a 3.0-kbp *Eco*RI fragment highly related to *kis*, the *onc* gene of the Kirsten strain of MSV[9]. Thus, we decided to

0028–0836/82/490539—04$01 00

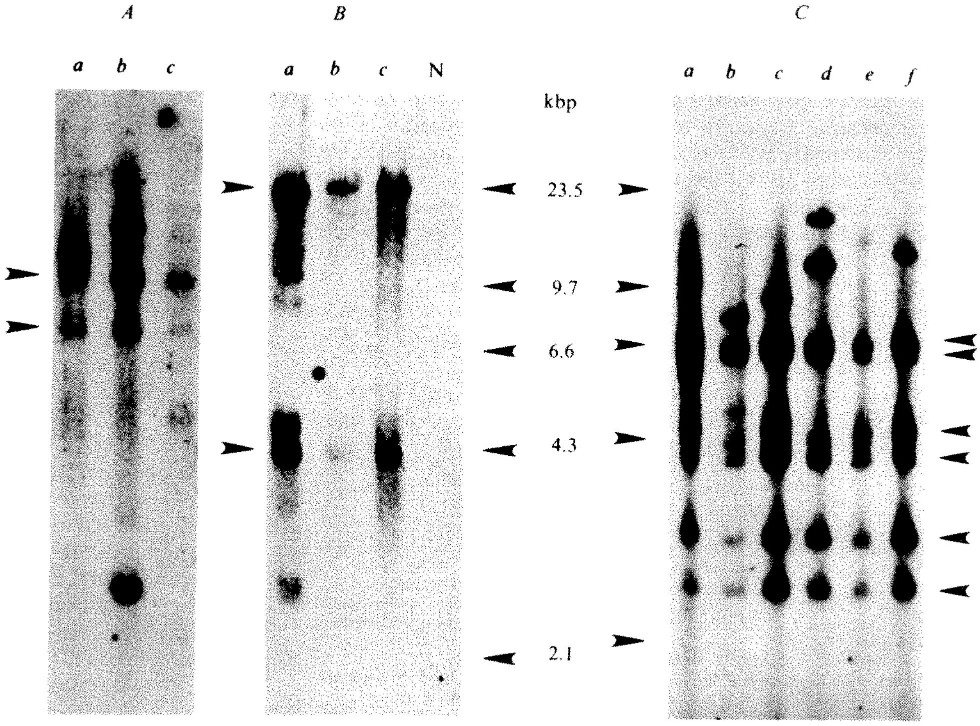

Fig. 1 Southern blot analysis of human repetitive sequences in third-cycle NIH 3T3 transformants derived from solid human tumours. 20 μg of high-molecular weight DNA isolated from: *A*, *a–c*, representative third-cycle transformants obtained by transfection with DNA isolated from colon carcinoma 1665; *B*, *a–c*, representative third-cycle transformants obtained by transfection with DNA isolated from colon carcinoma 2033; N, control NIH 3T3 mouse cells; *C*, representative third-cycle transformants obtained by transfection with DNA isolated from rhabdomyosarcoma 1085 (*a*, *b*), lung carcinoma 1615 (*c*, *d*) and pancreatic carcinoma 1189 (*e*, *f*) were digested with 20 U of *Eco*RI for 1 h at 37 °C, electrophoresed (18 h at 30 V) in horizontal agarose (0.7% w/v) gels and blotted to nitrocellulose filters as described by Southern[24]. Filters were hybridized in stringent conditions (50% formamide, 5 × SSC and 42 °C) for 44 h to 4×10^7 c.p.m. of nick-translated high-molecular weight human DNA. Hybridized blots were exposed to Kodak XR-5 film at −70 °C in the presence of intensifier screens for 2 days. Co-electrophoresed DNA fragments of *Hin*dIII-digested λ c1857 DNA served as size standards (labelled in kbp). Migration of *Eco*RI-cleaved human DNA fragments shared by third-cycle transformants derived from either *A*, colon carcinoma 1665; *B*, colon carcinoma 2033; or *C*, rhabdomyosarcoma 1085, lung carcinoma 1615 and pancreatic carcinoma 1189 are indicated by arrows.

investigate whether the oncogene present in the rhabdomyosarcoma, lung and pancreatic carcinomas, and in A2233 colon, A427 and A2182 lung, A1064 gall bladder and A1698 urinary bladder carcinoma cell lines also contained sequences related to retroviral transforming genes. DNAs isolated from representative third-cycle transformants derived from each of the above tumours were digested with *Eco*RI and submitted to Southern blot analysis for the presence of retroviral *onc* gene sequences. Radioactive probes included those specific for v-*abl* (Abelson murine leukaemia virus), v-*bas* (BALB-MSV), v-*fes*ST (Snyder–Theilen strain of feline sarcoma virus), v-*mos* (Moloney-MSV), v-*myb* (avian myeloblastosis virus), v-*myc* (avian MC29 virus), v-*kis* (Kirsten-MSV), v-*sis* (simian sarcoma virus) and v-*src* (Rous avian sarcoma virus)[15].

The *kis* probe specifically detected the presence of two *Eco*RI-cleaved DNA fragments of 6.8 and 3.0 kbp in the genomes of each of the NIH 3T3 transformants tested (Fig. 2). Neither of these DNA fragments was found in control NIH 3T3 cells, indicating that they were derived from c-*kis*, the human homologue of the *onc* gene of Kirsten-MSV[16]. None of the other retroviral probes used detected human DNA sequences present in these NIH 3T3 transformants, with the exception of v-*bas* which hybridized weakly to the 3.0-kbp *Eco*RI DNA fragment of human c-*kis*[16,17].

To determine whether the retrovirus-related sequences of this human oncogene were expressed, we analysed NIH 3T3 transformants for the presence of proteins antigenically related to p21, the gene product of Kirsten-MSV[18]. Radioactively

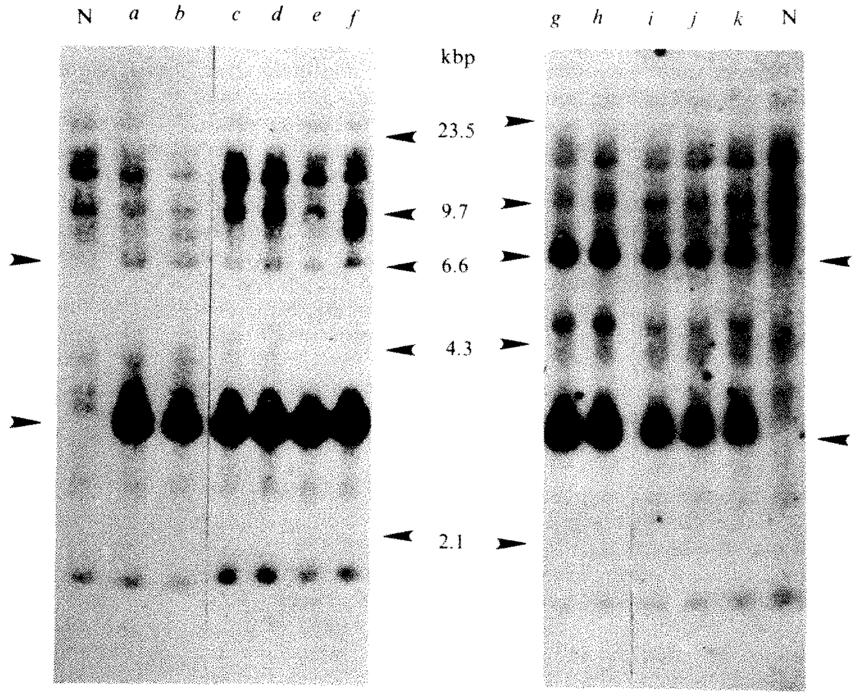

Fig. 2 Detection of sequences related to the *onc* gene of Kirsten-MSV in NIH 3T3 cells transformed by human tumour DNA. 20 μg of *Eco*RI-cleaved DNAs isolated from third-cycle transformants derived from rhabdomyosarcoma 1085 (*a*, *b*), lung carcinoma 1615 (*c*, *d*), pancreatic carcinoma 1189 (*e*, *f*), A2233 colon carcinoma cells (*g*), A427 lung carcinoma cells (*h*), A2182 lung carcinoma cells (*i*), A1604 gall bladder carcinoma cells (*j*) and A1698 bladder carcinoma cells (*k*) as well as from control NIH 3T3 cells (N), were blotted to nitrocellulose filters and hybridized to 4×10^7 c.p.m. of nick-translated Kirsten-MSV DNA clones 4E *Pvu*II (ref. 25) or pHiHi-3 (ref. 16) as described in Fig. 1 legend. Co-electrophoresed DNA size standards were those described in Fig. 1 legend. Migration of the 6.8- and 3.0-kbp *Eco*RI-cleaved DNA fragments of the human c-*kis* gene[16] is indicated by arrows.

labelled cell extracts of representative third-cycle transformants derived from each of the three human solid tumours and from several of the human tumour cell lines known to possess this gene (Table 2) were immunoprecipitated with antisera obtained from BALB-MSV-induced tumour-bearing rats. These antisera contain broadly reactive antibodies capable of recognizing not only the gene products of BALB-, Harvey- and Kirsten-MSVs, but also those coded for by the corresponding mouse and human homologue c-*onc* genes[15]. All the transformants tested exhibited elevated levels (about four- to eightfold higher than NIH 3T3 control cells as determined by densitometric analysis) of Kirsten-MSV p21-related proteins of molecular weights (MWs) 20,000–22,000 (Fig. 3). The different molecular weights exhibited by these proteins suggest the existence of some polymorphism in the human c-*kis* sequences. In one case (Fig. 3*G*), a third-cycle transformant derived from a pancreatic carcinoma exhibited an unusual Kirsten-MSV-related protein of MW 27,000. Because all other NIH 3T3 transformants derived from this tumour contained 21,000-MW proteins, it is possible that certain genetic alterations may occur during transfection. These results indicate that the observed Kirsten-MSV-related proteins represent the translational products of the transfected human oncogenes, thus providing further evidence that the c-*kis* sequences of this oncogene play a part in malignant transformation.

Previous studies have shown that a small percentage of human tumour cell lines contained oncogenes capable of inducing malignant transformation of NIH 3T3 mouse cells[1–8]. We have demonstrated here that similar results can be obtained using solid human tumours. About 15% of the tumour specimens whose DNAs were tested in transfection assays were shown to contain dominant transforming genes. The relatively high transformation efficiencies observed with these solid human tumour DNAs implies the presence of oncogenes in most of the cells present in these tumours. These results support the hypothesis that these oncogenes have played a part in the development of these neoplasias.

Molecular characterization of dominant transforming genes present in 12 different human tumours has revealed the frequent detection of an oncogene containing sequences related to the *onc* gene of Kirsten-MSV. In fact, this oncogene was detected in eight tumours, including a rhabdomyosarcoma and carcinomas of several organs such as colon, lung, gall bladder and urinary bladder. Other investigators have detected the same, or a closely related, oncogene in five additional lung and colon carcinoma cell lines[4,5,9]. These findings, together with the recent demonstration that the T24 and EJ bladder carcinoma oncogene is a transforming allele of the normal human c-*has*/*bas* gene[9,14,15], have posed the question of why most of the transforming genes present in human carcinomas are related to the c-*has*/*bas*/*kis* gene family. It could be argued that

Table 1 Summary of DNAs isolated from naturally occurring human tumours tested for transformation of NIH 3T3 mouse cells in transfection assays

Type of tumour	Total tested	Positive in transfection assays
Carcinomas		
Bladder	2	0
Breast	2	0
Colon	2	2
Kidney	3	0
Lung	5	1
Ovary	4	0
Pancreas	2	1
Sarcomas		
Fibrosarcoma	4	0
Osteosarcoma	2	0
Rhabdomyosarcoma	2	1

Human tumours were thawed and the necrotic tissues removed with a scalpel. Tumorous tissue was finely minced with the aid of razor-sharp scissors, disrupted in a loose-fitted Dounce, washed three times with phosphate-buffered saline and incubated for 16 h at 37 °C with 200 μg ml^{-1} of self-digested pronase in the presence of 0.2% SDS. High-molecular weight DNA was isolated by successive extractions with 1 vol of phenol, 1 vol of phenol/chloroform/isoamylalcohol (25 : 24 : 1) and chloroform/isoamylalcohol (24 : 1) followed by precipitation with 2 vols of ethanol. These DNAs (30 μg per plate, 16 plates in 4 different transfection experiments) were used to transfect NIH 3T3 cells by the calcium phosphate precipitation technique[10], as described previously[8,11].

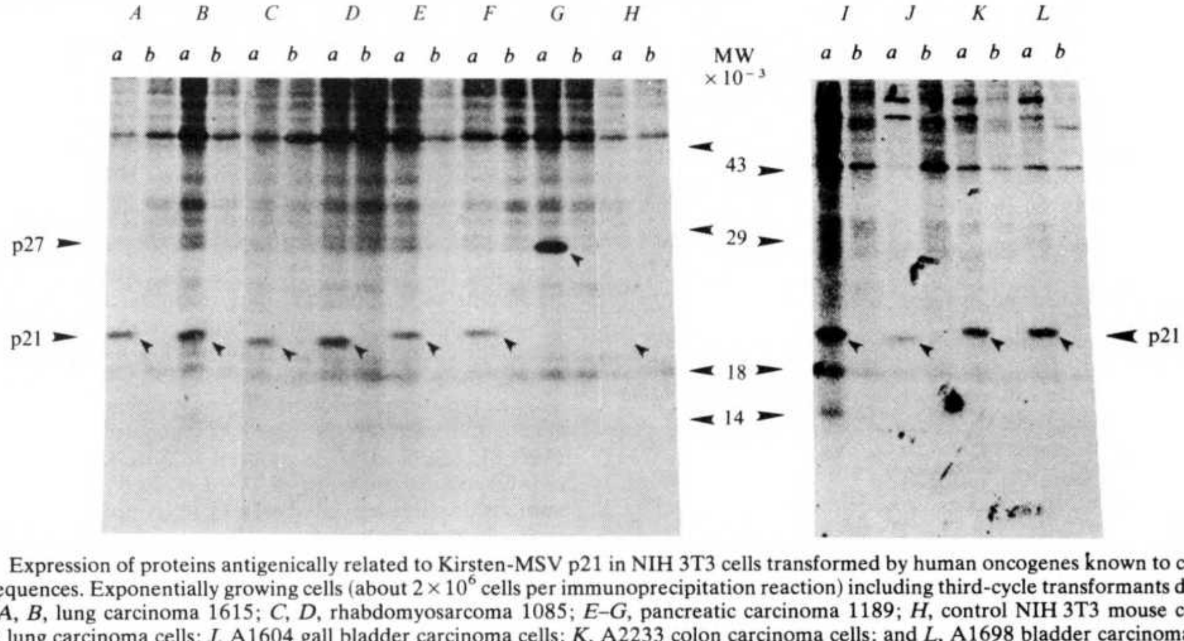

Fig. 3 Expression of proteins antigenically related to Kirsten-MSV p21 in NIH 3T3 cells transformed by human oncogenes known to contain c-*kis* sequences. Exponentially growing cells (about 2×10^6 cells per immunoprecipitation reaction) including third-cycle transformants derived from: *A*, *B*, lung carcinoma 1615; *C*, *D*, rhabdomyosarcoma 1085; *E–G*, pancreatic carcinoma 1189; *H*, control NIH 3T3 mouse cells; *I*, A2182 lung carcinoma cells; *J*, A1604 gall bladder carcinoma cells; *K*, A2233 colon carcinoma cells; and *L*, A1698 bladder carcinoma cells, were metabolically labelled with ^{35}S-methionine as previously described[26]. Post-microsomal fractions were incubated for 1 h at 4 °C with 0.01 ml of sera obtained from: *a*, BALB-MSV-induced tumour-bearing rats[15] or *b*, uninfected normal rats. Immunoprecipitates were collected with the aid of *Staphylococcus aureus* protein A bound to Sepharose 4B beads and disrupted in the presence of 1% SDS and 2% 2-mercaptoethanol by incubating them at 95 °C for 2 min. Denatured proteins were analysed by electrophoresis (18 h at 100 V) in SDS-polyacrylamide (14% w/v) gels. Electrophoresed gels were dried, fluorographed[27] and exposed to Kodak XR-5 films for 5 days at −70 °C. Co-electrophoresed molecular weight markers included ovalbumin (43,000), carbonic anhydrase (29,000), lactoglobulin (18,000) and lysozyme (14,000). Migration of proteins antigenically related to Kirsten-MSV p21 is indicated by arrows.

Table 2 Summary of human oncogenes detected in our laboratory

Type of tumour	Source of DNA	Ref	Oncogene	Relationship with retroviral *onc* genes
Carcinomas				
Bladder	T24 cells	21	*onc* A	*has, bas*
Bladder	A1698 cells		*onc* B	*kis*
Colon	Solid tumour 1665		*onc* C	—

Fibrosarcoma	HT-1080 cells	23	*onc* E	—
Rhabdomyosarcoma	Solid tumour 1085		*onc* B	*kis*

Human tumour cell lines A1604, A1698, A2182 and A2233 were established by S.A.A. Their human origin and independent identity have been determined by karyologic and isoenzyme (ADA, G-6-PD, LDH, PGD, PGM_1 and PGM_3) analysis. *onc* A, *onc* B and so on is an arbitrary designation used solely to indicate genetically distinct oncogenes. Retroviral *onc* genes tested· *abl, bas, fes, mos, myb, myc, kis, sis* and *src.*

transfection protocols favour the identification of a particular type of human oncogene that preferentially transforms NIH 3T3 mouse cells. However, Lane *et al.*, using the same assay cells, have shown that none of nine oncogenes present in lymphoid human tumours appeared to be a member of the *has/bas* gene family[9]. Moreover, these authors have identified different transforming genes in neoplasias representing different stages of lymphocyte differentiation[1]. Thus, it is possible that the c-*has/bas*-related oncogenes may be preferentially, although not specifically, activated in tumours of epithelial origin.

Shilo and Weinberg have recently shown that several 3-methylcholanthrene-transformed mouse cell lines may contain the same oncogene[19]. Interestingly, all oncogenes so far detected in carcinomas of the lung appeared to be the same (Table 2; refs 5, 6, 9). Although no definitive aetiology has been established for any form of human cancer, most lung carcinomas have been associated with smoking[20]. These observations are consistent with the hypothesis that neoplasms induced by certain carcinogens may be associated with the activation of a particular cellular oncogene.

We thank Drs N. Tsuchida and R. Ellis for providing Kirsten-MSV DNA clones.

Regulatory mutants of the maize *Adh1* gene caused by DNA insertions

Judith N. Strommer, Sarah Hake, Jeffrey Bennetzen*, William C. Taylor & Michael Freeling

Department of Genetics, University of California, Berkeley, California 94720, USA

Transposable elements in maize can induce changes in the timing of gene expression and the quantity of gene product[1,2]. The timing of expression of the *bronze* locus has been shown genetically to be affected by insertion of the transposable element *Ds* (dissociation)[3]. Molecular evidence has demonstrated that insertion of *Ds* at another locus, *shrunken-1*, disrupts the DNA sequence as expected of an insertion[4,5]. Here we report quantitative changes in gene expression resulting from the insertion of a 1.5-kilobase (kb) DNA element at an affected gene. The alcohol dehydrogenase-1 (*Adh1*) mutants described here, selected via allyl alcohol-resistant pollen grains[6], were recovered from a genetic background containing Robertson's mutator (*Mu*)[7]. We suggest that the *Mu* genetic background caused the DNA insertion at *Adh1*, and that the insertion assumed some regulatory function in the control of *Adh1* expression.

The *Adh1* alleles considered here, and their products, have been described elsewhere[8,9]. Their genealogies and characteristics are summarized in Fig. 1. *Adh1-S3034* (*S3034*) was induced in an *Adh1-S* (*S*) progenitor allele as a consequence of crossing an *S* line to a line carrying *Mu* and an electrophoretically distinct *Adh1* allele. The variant *Adh1* in the *Mu* line allowed unambiguous identification of *S* alleles among progeny, and recovery of marker genes from both parental lines ensured that *S3034* was not the product of pollen contamination.

S3034 is expressed in all organs normally exhibiting the *S* gene product, but at a level 40% that of the progenitor. It is 100-fold less stable than ethylmethane sulphonate (EMS)-induced mutants as judged from pollen samples stained for alcohol dehydrogenase (ADH) activity. Genetically unstable derivative alleles having even less ADH1 were selected from *S3034* lines as shown in Fig. 1: *S3034b* expresses 13% of the ADH1 activity seen in *S*, and *S3034a* expresses none.

ADH1 polypeptides are synthesized *de novo* by roots in response to anaerobic stress[10,11]. Gerlach *et al.*[12] have demonstrated, and we have confirmed in our lines (data not shown), that increased levels of ADH1 produced in anaerobic conditions are accompanied by increased levels of ADH1 RNA. Steady-state RNA levels are reached within 6 h.

We compared polyadenylated ADH RNA levels in roots from homozygotes of *S, S3034, S3034a* and *S3034b* after subjecting seedlings to 12 h of anaerobic stress. Figure 2 shows the results of a Northern blot in which equal amounts of polyadenylated RNA from the four homozygotes were hybridized to the cDNA probe pZmL84 (see Fig. 4 legend for descriptions of the probes). Results from RNA dot-blots of the same samples are shown below the corresponding gel tracks. 'Dots' were cut from filters for Cerenkov counting: ~40% normal levels of ADH1 RNA were seen in *S3034*, 15% in *S3034b* and essentially none in *S3034a* homozygotes. Thus, the amounts of polyadenylated ADH1 RNA produced by the progenitor and mutant alleles reflect relative enzymatic activities in the induced roots.

Decreased levels of ADH1 RNA in the mutants are not due to a general failure of anaerobic metabolism. Seedlings homozygous for either the mutant alleles described here or any of several *Adh1*-null alleles (which have no ADH1 polypeptides) continue to support protein synthesis for over 12 h. Indeed, several null mutants produce normal levels of ADH1 RNA for

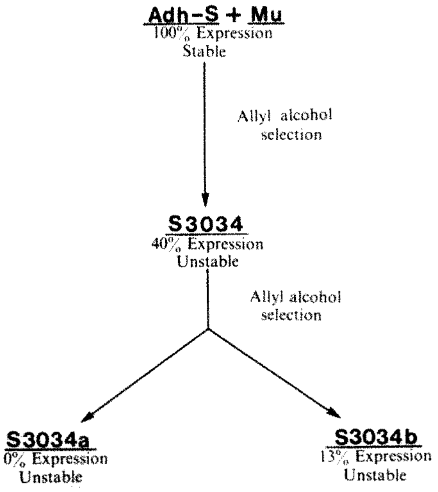

Fig. 1 The origin of our four *Adh1* alleles and a summary of their characteristics[9]. The *S* parent carried an electrophoretically identifiable EMS-induced mutant of *Adh2* which was recovered in *S3034* progeny, as was the somatic variegation phenotype characteristic of mutator lines. We have no lines capable of producing the *S3034* phenotype due to contamination. The *S* allele is defined as stable and 100% expressed. ADH1 activity was measured in mature scutella, in primary roots subjected to 24 h of anaerobic stress, and in pollen grains. Stable denotes (1) a phenotypic pollen revertant frequency similar to that of EMS-induced mutants at *Adh1-S*, that is, 2×10^{-6} ADH^+ pollen per total pollen[16]; and (2) a forward frequency of 2×10^{-7} ADH^- viable pollen per total viable pollen[17]. Reversion frequencies of mutant alleles are $1\text{–}2\times10^{-4}$ ADH^+ pollen per total pollen. Cytochemical staining of pollen or of germinating pollen *in situ* for ADH activity generated the data used to measure genetic stability.

that period (M. Sachs, personal communication and S.H., data not shown). Further, cDNA probes for other anaerobically induced RNA species detect the same levels of these other RNA species in all four genotypes (S.H., data not shown). We conclude that our four *Adh1* alleles differ in their quantitative expression because their ADH1 RNA levels differ, and that the observed changes are not merely secondary effects.

Figure 3 depicts Southern blots of genomic DNA probed with ADH1 cDNA from the plasmids pZmL84 and pKM1 (see Fig. 4 for descriptions of probes). Three conclusions can be drawn from the results. First, our hybridization conditions allow the cDNA to recognize a unique sequence of maize DNA. Second, in several cases *S3034* and its derivatives reside on fragments ~1.5 kb longer than fragments containing the progenitor allele. Third, despite the variations in ADH1 RNA levels, there are no detectable differences in endonuclease recognition sites around *S3034*, *S3034a* and *S3034b*.

A variety of single- and double-enzyme digests of genomic DNA allowed construction of the maps given in Fig. 4. Assignment of transcriptional polarity was simplified by the presence of a *Hin*dIII site in the *S* structural gene. Because the cDNA of pZmL84 has been sequenced[12] and correlated with peptide sequences (Inglis and Peacock, personal communication, and Kelly and M.F., unpublished data), there was no ambiguity in the assignment of polarity. The *Hin*dIII site in the recombinant clones allowed us to hybridize Southern blots of *Hin*dIII-digested DNA with 5′- and 3′-specific probes. Figure 4 insert illustrates the results of such an experiment. Clearly, the mutant *S3034* and its derivatives contain ~1.5 kb of additional DNA. This DNA element, containing a *Bst*EII recognition site, lies upstream from the ADH1-coding sequence represented in a probe which is 90% full-length (pKM1).

Although we have not proved that the *Mu* genetic background caused the DNA insertion at *Adh1*, evidence supports this hypothesis. Robertson's *Mu* background was crossed into the genotype from which the *S3034* pollen was selected. The pollen parent of *S3034* exhibited the behaviour characteristic of a *Mu* background[7], and the progeny exhibited the somatic variegation phenotype typical of *Mu* and heritable as a dominant non-mendelian trait (M.F. and J.N.S., to be published elsewhere). Furthermore, two additional *Mu*-induced mutants of *S* have been recovered, and they too contain 1.5 kb inserted DNA (R. Johns and J.N.S., unpublished data). Therefore, it seems most unlikely that the insertion of DNA at *S* occurred independently of *Mu*. However, we cannot conclude that the inserted sequences are Robertson's *Mu*. A molecular probe will be required to define *Mu* itself.

Evidence suggests that the quantitative regulation of *Adh1* by inserted DNA sequences occurs at the level of transcription or processing. The length of mature ADH1 RNA is unchanged, and the polypeptide produced by the mutants is unchanged in length, charge and specific activity[9]. We cannot exclude the possibility that less ADH1 RNA is seen in the mutants because it is more rapidly turned over, but our data are most compatible with altered transcription or processing.

The presence of inserted elements in *S3034a* and *S3034b* is not surprising, because these derivatives remain genetically unstable (Fig. 1). The lack of detectable differences between *S3034* and its derivatives was unexpected: transposition-associated events mapped at the DNA sequence level in other organisms involve conspicuous changes[13–15]. Although independent events occurring beyond the 20-kb window provided by our Southern blots might be responsible for decreases in expression of *S3034a* and *S3034b*, the distance required and the severity of the effect render this explanation unlikely. Alternatively, the unstable derivatives may differ from *S3034* by minor sequence changes that are below our threshold of detectability.

A possible interpretation of our results is that a *Mu* insertion has taken over some aspect of the regulation of *Adh1* expression. *Adh1-S* is expressed only in certain tissues; it is inducible by anaerobic stress and by the plant growth hormone, 2,4-dichlorophenoxyacetic acid[6]. Furthermore, we know that DNA acting in *cis* to *S* affects quantitative expression in an

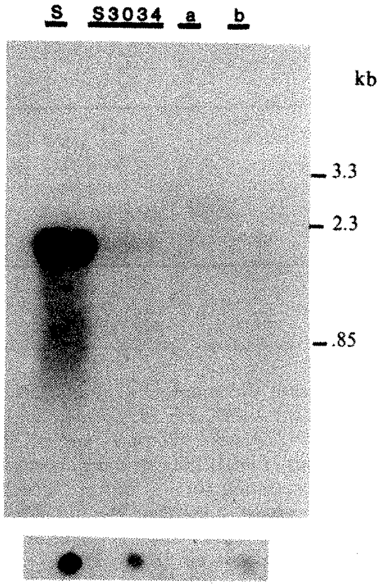

Fig. 2 Autoradiograms of Northern blots of polyadenylated RNA probed with the ADH1 cDNA plasmid pZmL84 (ref. 12) (see Fig. 4 legend for description of probes). Maize kernels of defined *Adh1* genotype were germinated and seedlings grown until primary roots were 5–10 cm long, at which time the seedlings were immersed in weakly buffered water for 12 h. Total RNA was isolated by the procedure of Lizardi and Engelberg[18]. We define polyadenylated RNA as that portion of total RNA recovered after selective binding to oligo(dT)-cellulose (T-2; Collaborative Research). The gel illustrated contained glyoxylated RNA (5 μg per track), separated on an agarose gel[19] and transferred to DPT paper by the unpublished procedure of B. Seed. Hybridizations were as described elsewhere[19] at 42 °C for 24 h with the addition of 100 $\mu g\ ml^{-1}$ polyadenosine; washes were as described by Gerlach *et al.*[12]. From left to right, polyadenylated RNA from *S*, *S3034*, *S3034a* (*a*) and *S3034b* (*b*) homozygotes.

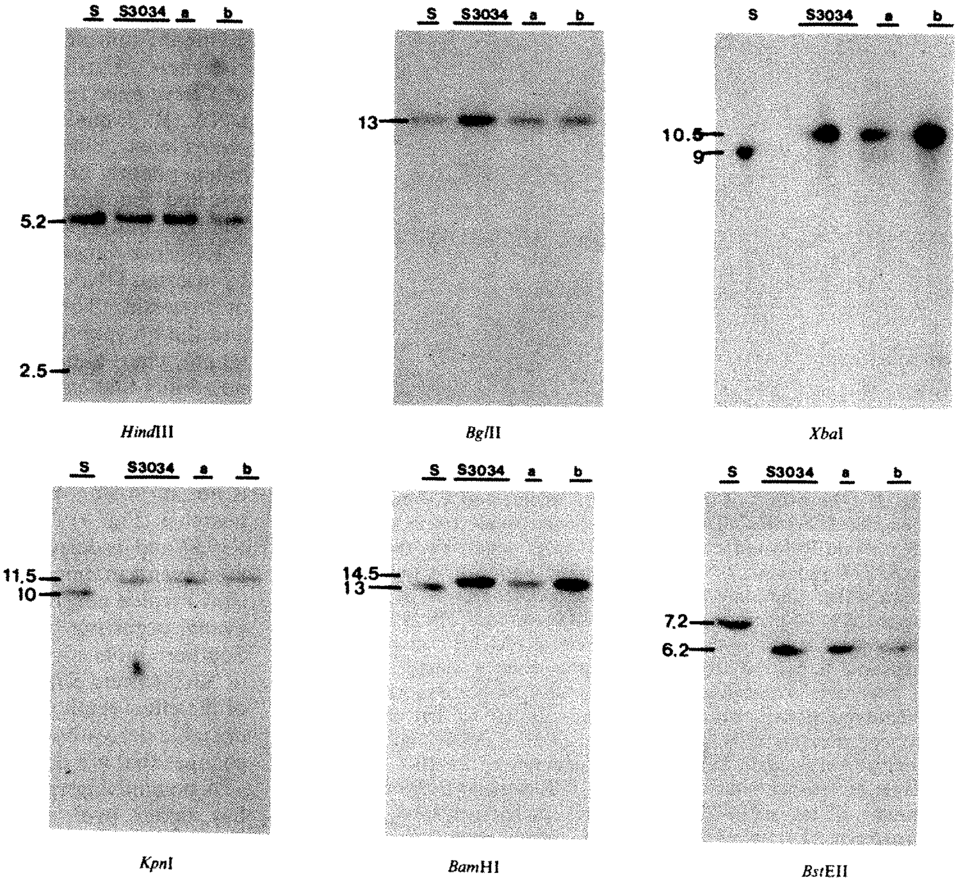

Fig. 3 Autoradiograms of probed Southern blots comparing the progenitor *S* allele with mutants *S3034*, *S3034a* and *S3034b*, and revealing the presence of ~1.5 kb additional DNA beyond the region of probe homology. Tracks are grouped by the endonuclease used to digest the genomic DNA before electrophoresis; *S*, *S3034a* and *S3034b* are displayed from left to right within each set. Genomic DNA was prepared by the method of Murray and Thompson[20], digested with restriction endonucleases as recommended by the supplier (BRL) and fractionated with 15 μg per track on 0.7% agarose (Seakem) gels in 90 mM Tris-base, 90 mM H_3BO_3, 3 mM EDTA, *p*H 8.3. Plasmid DNA was prepared by CsCl banding of cleared-lysate DNA[21] which had been precipitated with polyethylene glycol, and inserted cDNA sequences used as probes were isolated electrophoretically from plasmid endonuclease digests. Nick-translations, Southern blots and hybridizations were done using the procedure of Engel and Dodgson[22] with washing in 0.2×SSC, 0.1% SDS at 68 °C.

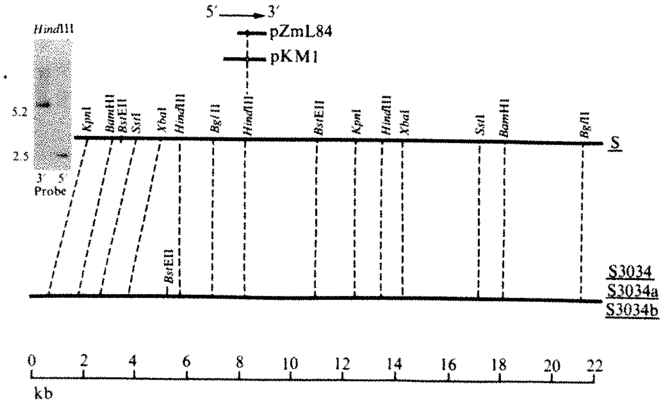

Fig. 4 Endonuclease site maps of genomic DNA containing *S* (top) and the mutant alleles *S3034*, *S3034a* and *S3034b* (bottom). The two cDNA probes, pZmL84 and pKM1, are aligned by their homologous *Hin*dIII sites, and the shortest possible transcriptional unit accounting for a 1,650-nucleotide transcript is represented by the arrow at the top. Plasmid pZmL84 was given by Gerlach *et al.*[12] and represents the 3′ half of ADH1 mRNA. Plasmid pKM1 was prepared from cDNA to anaerobically-induced mRNA, cloned in pBR322, detected as an anaerobically-stimulated sequence, and identified as ADH1 cDNA by hybridization to pZmL84; it contains ~1,500 base pairs (bp) of coding sequence. Localization of each endonuclease digestion site was confirmed with at least two sets of two-enzyme digests. Maps of *S3034*, *S3034a* and *S3034b* were generated independently. The inset illustrates the Southern blot of an *S Hin*dIII digest used to determine transcriptional orientation of the gene. The cDNA from pZmL84, with ~200 bp 5′ and 700 bp 3′ to the internal *Hin*dIII site, hybridized primarily to the large (5.2 kb) genomic fragment produced by *Hin*dIII digestion of *S*, while excised pKM1 sequences representing a region 5′ to the *Hin*dIII site recognized only the short (2.5 kb) genomic fragment. Note that the *Bst*EII site seen 5′ to the hybridizing sequences in *Adh1-S* is presumed present in *S3034* and its derivatives but cannot be detected due to the appearance of a new *Bst*EII site closer to the region of probe homology.

organ-specific way[9]. *S3034* and *S3034b* continue to exhibit all these aspects of normal regulation, producing 40% and 13%, respectively, of the level of ADH1 synthesized by *S*; organ specificity, developmental timing and inducibility remain unaltered. If *Mu* has assumed a regulatory function in the control of *Adh1-S* expression, it would seem to be a simple quantitative function that has been usurped.

We thank Wayne Gerlach, Tony Pryor, Liz Dennis, Rob Ferl, Marty Sachs and Jim Peacock of CSIRO, Australia, for sending us pZmL84 and unpublished data; Rick Johns for sharing preliminary data; and Mary Alleman, Lino Fragoso, Rick Johns and John Mottinger for critical reading of the manuscript. This research was supported by NIH grants GM28600 (to W.C.T. and M.F.) and GM21734 (to M.F.). J.N.S. and S.H. are NIH Postdoctoral Fellows supported by GM07981 and GM07931, respectively. J.B. was supported in part by a fellowship from the Monsanto Corporation.

Antibodies to Z-DNA interact with form V DNA

E. DiCapua

Institut für Zellbiologie, ETH Hönggerberg, CH-8093 Zürich, Switzerland

Annealing of single-stranded (ss) DNA rings of complementary base sequence gives rise to the so-called form V DNA which is characterized by a linking number of zero[1]. The similarity of the circular dichroism spectrum of form V DNA[1] with that of the 1:1 mixture of the low salt (B-type) and the high salt (Z-type) form of poly(dG-dC)·poly(dG-dC)[2,3] suggests that form V DNA might contain left-handed double-helical DNA of the Z-type. The discovery that the left-handed Z-form of poly(dG-dC)·poly(dG-dC) induces a strong immune response[4,5] has provided a novel means of searching for DNA of this particular conformation[6]. We therefore used antisera and monoclonal antibodies to Z-DNA to determine whether form V DNA contains stretches of left-handed double-helical conformation. We report here that form V DNA competes in the binding of antibodies to Z-form poly(dG-dC)·poly(dG-dC). The competition by form V DNA is similar to that of $(dG\text{-}dC)_5 \cdot (dG\text{-}dC)_5$. Thus, DNA of natural base sequence, when forced to adopt left-handed conformations by topological restrictions, is recognized by antibodies against Z-DNA.

Form V DNA, an 'unlinked' covalently closed, circular double-stranded (ds) molecule, is a form of DNA in which any right-handed double-helical structure has to be compensated by negative supercoils and left-handed duplex turns. It adopts a tightly folded structure, as revealed by sedimentation, electron microscopy and gel electrophoresis[1]. To date, it is the only form of DNA having a natural base sequence that displays a negative circular dichroism at 290 nm (Fig. 1). Such a negative circular dichroism band has been observed previously for poly(dG-dC)·poly(dG-dC) at high salt or ethanol concentration[2,3] and is characteristic of the left-handed double-helical conformation of Z-DNA[7].

Antisera against Z-DNA were obtained from a New Zealand White rabbit and BALB/c mice, respectively, after immunization with brominated poly(dG-dC)·poly(dG-dC), as described by Lafer *et al.*[4]. Such a mouse was used also for the selection of hybridomas producing monoclonal antibodies against Z-DNA (R.T., M. Leptin and F.M.P., in preparation). As the preparation of labelled form V DNA is very difficult, the interaction with antibodies was studied by the displacement of radioactively labelled poly(dG-dC)·poly(dG-dC); Fig. 2 summarizes the results of radioimmuno-competition assays in conditions in which poly(dG-dC)·poly(dG-dC) adopts the left-handed Z-form[2,7].

In the experimentally accessible range of concentrations, form V DNA of plasmid pBRβG2.17 competed with poly(dG-dC)·poly(dG-dC), whereas no competition was observed for open circular or covalently closed circular DNA with a natural superhelical density. No competition with circular ssDNA from phage M13 was found. This observation using rabbit antiserum has been substantiated with a purified monoclonal antibody against Z-DNA (Fig. 2*a*).

The concentration of form V DNA necessary for 50% inhibition of binding of the labelled polymer was about 400 times higher than obtained with unlabelled poly(dG-dC)·poly(dG-dC); this may be due either to much weaker binding of the antibodies to this DNA and/or to a low amount of Z-like DNA in form V. Figure 2*b* shows that the competition by oligo(dG-dC)·oligo(dG-dC) with a chain length of 10–14 base pairs (bp) is very similar to that of form V DNA. Poly d(I-5BrC)·poly d(I-5BrC), which also gives an inversion of the circular dichroism spectrum in high salt concentrations[8], competes even less and its effect is similar to that of $(dG\text{-}dC)_4 \cdot (dG\text{-}dC)_4$. The considerably stronger interaction with the polymeric antigen may be due to additional stabilization of the complex by the second binding site on the antibody compared with the short oligonucleotides, which apparently act as haptens.

To determine whether form V DNA interacts with antibodies at lower salt concentrations, the following more direct, qualitative approach was chosen (see Fig. 3): form V DNA was incubated with different amounts of antibodies to Z-DNA in 0.2 M NaCl, the reaction mixture applied to an agarose gel, and the DNA visualized by the fluorescence of bound ethidium bromide. The antibody–DNA complex does not enter the gel or is considerably retarded. Comparable results were obtained also with form V DNA prepared from phage PM2 (data not shown). The small amount of open circular DNA served as an internal standard, as it does not interact with the antiserum. For this type of assay, the final purification of form V DNA is unnecessary, as the antibodies discriminate between underwound closed circular DNA and the other forms of DNA.

The total amount of antibody necessary to retard 50% of the form V DNA could be estimated only very roughly and seems to be about half that necessary to precipitate the equivalent amount of poly(dG-dC)·poly(dG-dC) in 4 M NaCl. These results indicate that a considerable part of form V DNA interacts with antibodies to Z-DNA. The sequence of the plasmid pBRβG2.17 contains as alternating dG-dC stretches, one sequence of six base pairs and seven of five base pairs. If one considers also alternating purine–pyrimidine stretches, the lon-

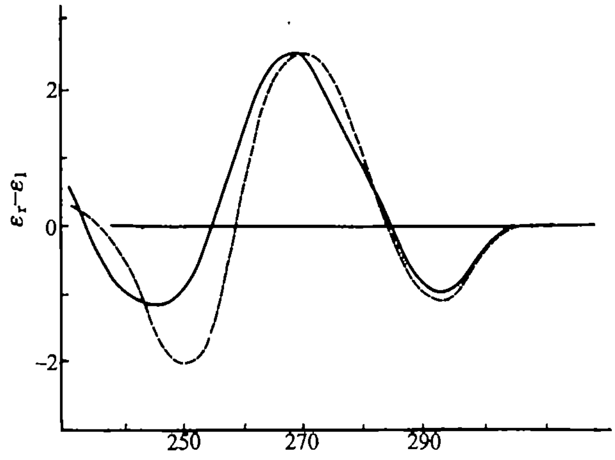

Fig. 1 Circular dichroism (CD) spectrum of form V DNA of pBRβG2.17 in 10 mM Tris-HCl *p*H 7.9, 1 mM EDTA (——) and a mixture of 50% low salt form (B-type) and 50% high salt form (Z-type) of poly(dG-dC)·poly(dG-dC) in 2.3 M NaCl, 10 mM Tris-HCl *p*H 7.9, 1 mM EDTA (– – –) as measured in a Cary 60 spectropolarimeter with CD attachment. The concentration of DNA was determined from the absorbance at 260 nm, using 6.8 $mM^{-1}\,cm^{-1}$ for form V DNA and 7.2 $mM^{-1}\,cm^{-1}$ for the low salt form of poly(dG-dC)·poly(dG-dC)[2]. Form V DNA was prepared by nicking closed circular DNA of the plasmid pBRβG2.17 with DNase I. Circular ssDNA was enriched by alkaline sucrose gradient centrifugation, brought to *p*H 9.0 and precipitated with ethanol. It was further purified by neutral sucrose gradient centrifugation as described by Stettler *et al.*[1]. We estimate that more than 95% of the DNA is form V, as judged in gel electrophoresis. Electron microscopy revealed highly folded molecules. Form V DNA could be cleaved with restriction endonuclease *Cfo*I and the fluorescence in 2.5 μM ethidium bromide *p*H 8.0 was almost the same before and after digestion, in contrast to naturally supercoiled form I DNA. $\varepsilon_r - \varepsilon_l$, difference of extinction coefficients for right and left circular polarized light ($M^{-1}\,cm^{-1}$).

0028-0836/82/490545—02$01 00

gest is 10 bp (Ph. Bucher, personal communication). Thus, it is tempting to conclude that a left-handed DNA conformation is not restricted to such a type of sequence as deduced from the X-ray structure determination of oligo(dC-dG)·oligo(dC-dG)[9,10]. This was the conclusion also of a study of the optical properties of form V DNA (S. Brahms *et al.*, in preparation).

Whether the apparently weaker interaction of our antisera with form V DNA than with the Z-form of poly(dG-dC)·poly(dG-dC) is due to subtle differences in the conformation of left-handed 'natural' DNA compared with that of poly(dG-dC)·poly(dG-dC), or to the lack of cooperation between the two binding sites on an antibody molecule, to structural perturbations at junctions between right- and left-handed segments[11], or to some other reason is unknown at present.

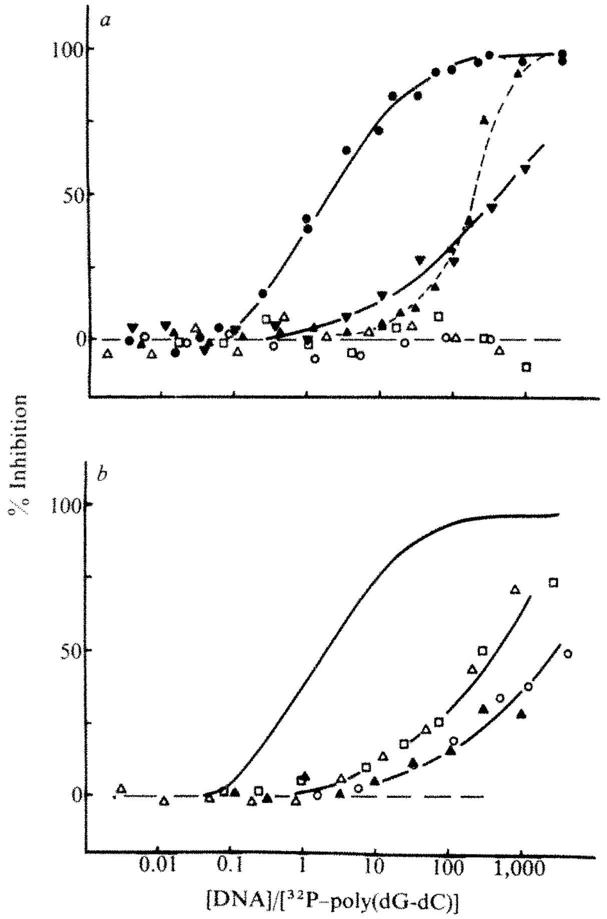

Fig. 2 Radioimmuno-competition assay with ^{32}P-labelled poly(dG-dC)·poly(dG-dC) in 4 M NaCl. *a*, Inhibition of the binding of radioactive poly(dG-dC)·poly(dG-dC) to rabbit antiserum by unlabelled poly(dG-dC)·poly(dG-dC) (●), and form V DNA (▲), prepared from the plasmid pBRβG2.17 (4,961 bp) according to Stettler *et al.*[1]. No inhibition is found with open circular (○) and superhelical, closed circular DNA (△) from the same plasmid, or with ssDNA prepared from phage M13 (□). ▼, A purified monoclonal antibody, Z-D11, and form V DNA were used in otherwise identical conditions. *b*, Inhibition by $(\text{dG-dC})_n \cdot (\text{dG-dC})_n$ of different chain lengths (○, 8; □, 10; △, 14 bp) prepared as described previously[12], and poly(dG-dC)·poly(dG-dC) (——) (see *a*); ▲, inhibition by poly d(I-5BrC)·poly d(I-5BrC) (PL Biochemicals). Poly(dG-dC)·poly(dG-dC) was synthesized as described previously[2] and the polymer was end-labelled with [α-^{32}P]dCTP (3,000 Ci mmol^{-1}) and DNA polymerase I from *Escherichia coli* to >5,000 c.p.m. ng^{-1}. Serum against Z-DNA was obtained from a rabbit immunized with brominated poly(dG-dC)·poly(dG-dC) according to Lafer *et al.*[4]. A given amount of DNA was incubated with 3.5–5 ng ^{32}P-labelled poly(dG-dC)·poly(dG-dC) and 0.05–0.07 µl rabbit antiserum or 14 ng purified monoclonal antibody in 100 µl solution (4 M NaCl, 60 mM sodium phosphate, 30 mM EDTA *p*H 8.0) for 1 h at room temperature. Goat antiserum to rabbit or mouse immunoglobulins was added, the mixture kept for another hour at room temperature, and then centrifuged. The radioactivity of the supernatant and washed pellet, respectively, was determined by Cherenkov counting. In the absence of competing DNA 30–60%, and using serum from a non-immunized rabbit, less than 0.5% of the radioactivity was found in the pellet.

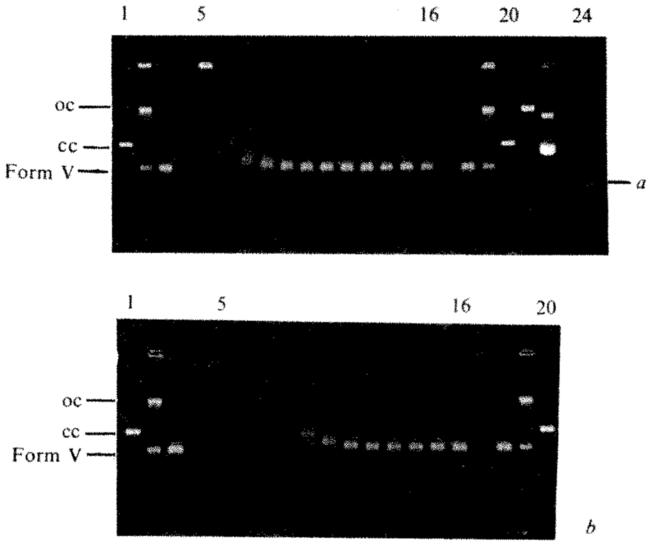

Fig. 3 Electrophoresis of form V DNA of plasmid pBRβG2.17 after reaction with different amounts of antibodies to Z-DNA in serial 1:2 dilution (lanes 5–16): starting with *a*, 1.3 µl rabbit antiserum; *b*, 2 µg monoclonal antibody Z-D11. Form V DNA (115 ng) was incubated for 1 h at room temperature with the indicated amount of antibody in a total volume of 10 µl (0.2 M NaCl, 60 mM sodium phosphate, 30 mM EDTA *p*H 8.0), 2.5 µl 50% glycerol added, and the solution loaded on to a 1% agarose gel. The electrophoresis buffer contained 36 mM Tris, 30 mM NaH_2PO_4, 1 mM EDTA, 1.25 µM ethidium bromide. Electrophoresis was at 5 V cm^{-1} for ~2 h and the gels were photographed under UV illumination. Control sera showed no effect and the following DNA samples were included as references: lanes 1,20, natural closed circular (cc) DNA; lanes 2,19, form V DNA before neutral sucrose gradient centrifugation with open circular (oc) and 'unlinked' closed circular DNA; lanes 3,18, form V DNA without antibody; 21, open circular DNA; 22, pBR322 DNA; 24, form V DNA denatured in 0.2 M NaOH.

We thank Professor Theo Koller for encouragement and helpful discussions, the Schweizer Nationalfonds zur Förderung der wissenschaftlichen Forschung (Professor Th. Koller), and the Deutsche Forschungsgemeinschaft (Po 155/6) for financial support.

Corrigendum

In the letter 'Redesigning enzyme structure by site-directed mutagenesis: tyrosyl tRNA synthetase and ATP binding' by G. Winter *et al.*, *Nature* **299,** 756–758 (1982), 'lower K_m' in the last line of the introductory paragraph should read 'poorer K_m'.

CHRISTMAS BOOKS SUPPLEMENT

Where do rainbows come from?

Peter Newmark looks at some of the science books for children recently published in Britain.*

WHAT an odd and lopsided view of science children would be left with from this selection of books. For the younger age groups the emphasis is on natural history and dinosaurs with a modicum of computers and a sprinkling of the four elements. For children approaching the end of their first decade the tables are turned: computers and other artefacts of high technology take first place from natural history and fossils, with some elementary physics thrown in. But, for whatever the age, of physiology, chemistry and genetics there is seldom a word. Even within the limited range of topics that seem to be considered palatable to the customer there are many missed opportunities for slipping in a scientific concept or two, surreptitiously if needs be.

Under-6s

It is a pity, for example, that Althea Braithwaite did not introduce the concept of photosynthesis — but not the word — in **Tree** (£2.95), one of Longman's *Life Cycle Books.* The tree in question, an oak, is said to obtain food and water through its roots, and to take back food from the leaves before they fall. When on the tree the role of dead leaves is, we are told, to protect new buds, and when off it to protect fallen acorns; but the living leaves are never given any function. Equally it would not have been impossible to have hinted at the concept of inheritance or of territory in **Foxes** (£2.95), another of the same series. That apart, both books are blessed with bright and uncluttered illustrations and — how nice to see them — delightful endplates.

Much more sophisticated illustrations adorn Vanessa Luff's **The River** (A&C Black, £3.95), 12 double-page spreads depicting the course of a river from its moorland source to the sea. Each spread is of a different habitat with representative fauna and flora, and carries only a nominal sentence or two of text. There is, however, an identification key to each picture at the back of the book. *The River* is for parent and child to "read" together with much adult pleasure to be had from the illustrations. There is rather less in the way of adult entertainment in either **Frogs** or **Butterflies** (Heinemann/Quixote Press, £2.95 each; to be published in the United States by Putnam at $6.95), two rather crudely illustrated Natural Pop-Ups. However the pop-up pictures and other paper mechanics work quite well and whisk one through the life-cycle of the beast concerned in all of five double pages. Your infant prodigy might notice that frogs mate before the female produces eggs whereas the female butterfly appears to go in for virgin birth.

6–8-year-olds

So, too, does — or rather did — the brontosaur, if I am not being misled by no less an authority than Beverly Halstead. My impression is gained from **A Brontosaur: The Life Story Unearthed** (Collins, £3.95), illustrated by Jenny Halstead and written by Beverly. In its 15 double-page spreads is recounted the 120-year life of a brontosaur named Ajax, whose mate lays eggs every spring as though that were the sole meaning of coming into season. The story is nicely illustrated and well told in about 100 words per page. Cleverly, there is also a boxed sentence or two per page which explains the evidence on which the depicted scene has been reconstructed.

Passing quickly over **Space Mission** and **Underwater Mission** by Terry Pastor (Methuen–Walker, £3.95 each), pop-up books that are more gimmick than value, brings me to four topic books from the same publishing stable: two of five in the *Animal Lives* series and the first two of *The Elements.* The animal lives are those of **The Spider** and **The Fox** (£3.95 each; published in the United States by Dial, $9.95 each). Both books are written by Margaret Lane, biographer of Beatrix Potter. Those whose sympathy is with the uneatable rather than the unspeakable in the fox hunt should be warned that Margaret Lane's views of the chase are that "It is not an easy sport, for the fox has his own methods of escape"; and anyone with a predisposition to arachnophobia had better be spared Barbara Firth's larger-than-life illustrations in *The Spider.* Both her illustrations and those by Kenneth Lilly for *The Fox* are stunning. David Lloyd's **Air** (£3.95) — one of *The Elements* books — is also well illustrated with a text that is informative but dull; in **Fire**, by John Satchwell (£3.95), the text outdoes the illustrations. All four books are well worth giving to the child who has started to investigate and write about particular topics at school — although sod's law being what it is, the chosen topic is bound never to coincide with the books available.

A much more unusual and altogether inspired book, the first in the *Tell Me About. . .* series, is **The Earth and the Sky** (Collins, £3.50) which has been translated from a French text by Pierre Avérous. It takes the form of about 75 questions and answers, three to the double page, on the weather, the Earth and the sky. Not only do they help the child to understand but also the adult to explain how, for example, night comes, where rainbows come from and why one cannot see that the Earth is round. Clever and inventive answers are given in both words and illustrations; the book is a Godsend for the harassed parent.

8–11-year-olds

There is also an inspired and out of the ordinary book for older children in Peter Ward's **The Adventures of Charles Darwin** (Cambridge University Press; £3.75, $7.95). George Carter, a cabin-boy on the *Beagle*, befriends Mr Darwin who proceeds to share his thoughts on such matters as slavery, the presence of sea shells on mountain tops, the variety of finches on the Galapagos Islands and much else besides. The educative role is never obtrusive, being carefully placed among adventures with South American gauchos and under Argentinian gunfire. Finely illustrated, and with chapter headings such as "Mr Darwin gets Ants in his Pants", this is writing for children at its best.

Dinosaurs by David Lambert (Kingfisher/Crown; £5.95, $6.95) is a much more conventional book but excellent in its own way. Its 90 large pages have vivid illustrations, graphics and photographs which provide a good counter-balance to the rather academic text. Complete with glossary and index, large-lizard-lovers will find this a nice book for browsing and better still for reference.

For reference sake, perhaps to coincide with a holiday, Penny Anderson's **The**

---

*Where possible, details of availability and price in the United States are given. All readers should check prices before ordering.

Wildlife of Mountains and Moorlands (Macdonald, £3.95) — one of a series of six *Nature in Focus* books — can also be recommended. Sixteen well-illustrated double-page spreads cover the designated habitat, its fauna and flora and its changes with the seasons. Useful for the purposes of identification, the scientific titbits are a welcome bonus. Almost at the other end of the scale is **Animals of the Mountains and Forests** (Burke; £4.95, $12.95) and its five companion volumes in the series *Animals and their Environment*. The choice of topics to occupy the 32 double pages appears to be far too arbitrary and the whole approach rather incoherent. Why, for instance, devote two whole pages to the seven-spot ladybird and include several species that are as typical of suburbia as of the habitat of the title? A redeeming feature of the books is their use of impressive colour photographs wherever possible.

Inanimate in subject but not in style is **Earthquakes and Volcanoes** by Sara Steel (A&C Black, £3.95), one of this publisher's Junior Reference Books. It starts with 10 pages on the causes of earthquakes and volcanoes and then devotes 50 more to descriptions of some of the most famous, from Santorini to Mount St Helens. Full of dramatic photographs and gory detail, this will be a sure-fire success as a topic book. It is more of a puzzle to know what to make of **Sam's System: A Guide to Computers** (Dent, £3.95), in which Rosemary Court adopts the anthropomorphic approach: ". . . it had two little feet dangling over the edge of the desk, two hands folded neatly under the screen . . . . I'm TAK the terminal. TAK's my pet name — but I have other names too. VDU and CRT, for instance". By chatting to TAK the terminal, Sid Software, Susie the Supermarket Stock Control Program and a host of others, Sam (of the title) becomes wise beyond his years. I could not stomach this book, but buy it if you are intent upon training a tiny technocrat.

Darwin agogo on Tierra del Fuego, together with George Carter the *Beagle's* cabin-boy. (From *The Adventures of Charles Darwin*, reviewed here.)
